ABSTRACT

Hydrogenetic ferromanganese crusts are iron-manganese oxide chemical precipitates on the seafloor that grow over periods of tens of millions of years. Their secular records of chemical, mineralogical, and textural variations are archives of deep-sea environmental changes. However, environmental reconstruction requires reliable high-resolution age dating. Earlier chronological methods using radiochemical and stable isotopes provided age models for ferromanganese crusts, but have limitations on the millimeter scale. For example, the reliability of $^{10}Be/^9Be$ chronometry, commonly considered the most reliable technique, depends on the assumption that the production and preservation of ^{10}Be are constant, and requires accurate knowledge of the ^{10}Be half-life. To overcome these limitations, we applied an alternative chronometric technique,

23   magnetostratigraphy, to a 50-mm-thick hydrogenetic ferromanganese crust (D96-m4)

24   from the northwest Pacific. Submillimeter-scale magnetic stripes originating from

25   approximately oppositely magnetized regions oriented parallel to bedding were clearly

26   recognized on thin sections of the crust using a high-resolution magnetometry technique

27   called scanning SQUID (superconducting quantum interference device) microscopy. By

28   correlating the boundaries of the magnetic stripes with known geomagnetic reversals, we

29   determined an average growth rate of 5.1 ± 0.2 mm/m.y., which is within 16% of that

30   deduced from $^{10}Be/^9Be$ method (6.0 ± 0.2 mm/m.y.). This is the finest-scale

31   magnetostratigraphic study of a geologic sample to date. Ultrafine-scale

32   magnetostratigraphy using SQUID microscopy is a powerful new chronological tool for

33   estimating ages and growth rates for hydrogenetic ferromanganese crusts. It provides

34   chronological constraints with the accuracy promised by the astronomically calibrated

35   magnetostratigraphic time scale (1–40 k.y.).

36   **INTRODUCTION**

37   Hydrogenetic ferromanganese crusts are typically formed through accumulation

38   of colloidal precipitates of iron-manganese oxide on seamounts away from terrigenous

39   sources, where sedimentation is scarce. Due to their continuous slow growth rate (1–10

40   mm/m.y.), hydrogenetic ferromanganese crusts record long-term environmental

41   variations, including bottom-water circulation patterns (van de Flierdt et al., 2004) and

42   supply of dust and sediments from continents (Banakar et al., 2003). The crusts also

43   record extraterrestrial events such as meteoroid impacts (Prasad, 1994).

44   In order to reconstruct geological and oceanographic signatures from

45   ferromanganese crusts, it is crucial to provide a reliable fine-scale age model for each

2

46   crust. A first-order age model was established by dividing the thickness of the crust by

47   the age of the substrate assuming constant growth (e.g., Barnes and Dymond, 1967).

48   Subsequently, absolute dating techniques were attempted using radioactive tracers, such

49   as U-Th series (younger than 750 ka; Ku, 1976) and ^{10}Be/^{9}Be (younger than 10 Ma;

50   Graham et al., 2004) dating.

51   For ferromanganese crusts older than 10 Ma, chronologies were established based

52   on empirical formulae on the Co flux into the ferromanganese crusts (e.g., Puteanus and

53   Halbach, 1988). However, these empirical formulae have not been well documented

54   theoretically, and Frank et al. (1999) found disagreement between the Co chronometer

55   and ^{10}Be/^{9}Be dating. Alternatively, ^{187}Os/^{188}Os chronology was successfully applied on a

56   ferromanganese crust by comparing its ^{187}Os/^{188}Os isotopic curve with the evolution of

57   ^{187}Os/^{188}Os in seawater established from sediments (Klemm et al., 2005). Although this

58   method has an advantage of covering long-term ranges back to 80 Ma, its low resolution

59   leads to considerable errors, to several million years.

60   Magnetostratigraphy could provide an alternative, independent dating technique

61   for ferromanganese crusts. Given the rate of geomagnetic reversals in the Cenozoic, a

62   successful magnetostratigraphy should provide more than one chronological control point

63   per million years. Once a magnetostratigraphic correlation is established, the accuracy of

64   the age model is secured by the astronomically calibrated magnetostratigraphic time scale

65   (1–40 k.y.; Lourens et al., 2004), which is not possible with the other geochemical

66   methods alone. Crecelius et al. (1973) pioneered the investigation of natural remanent

67   magnetization (NRM) in ferromanganese nodules and found evidence of geomagnetic

68   reversals. Paleomagnetic studies of thin (1–4 mm thick) slices of ferromanganese crusts

69 were performed by Chan et al. (1985) and Linkova and Ivanov (1993), but

70 magnetostratigraphic correlations were not successful due to poor resolution of the

71 paleomagnetic chrons.

72   The first apparently successful identification of paleomagnetic chrons in

73 ferromanganese crusts was reported by Joshima and Usui (1998). They reported

74 magnetostratigraphic correlations at 2.5 mm intervals from three ferromanganese crusts

75 consistent with Co-based growth rates and radiochemical ages of substrate rocks.

76 However, they found that the magnetostratigraphy-based growth rate for crust sample

77 D96-m4 (16–17 mm/m.y.) was approximately three times higher than that based on

78 $^{10}Be/^9Be$ ages (6 mm/m.y.; Usui et al., 2007), indicating that paleomagnetic chrons and/or

79 subchrons were mismatched due to poor spatial resolution.

80   A spatial resolution finer than 1 mm is crucial to enable successful

81 magnetostratigraphic correlations for slowly growing (1–10 mm/m.y.) ferromanganese

82 crusts. However, preparation of specimens thinner than 1 mm from fragile crusts is not

83 realistic. Thus, we developed an alternative method to construct age models for the crusts

84 using a new high-resolution paleomagnetic method known as room-temperature scanning

85 superconducting quantum interference device (SQUID) microscopy. Here we describe

86 the results on thin sections of ferromanganese crust.

87 **SAMPLE AND PREPARATION**

88   Ferromanganese crust D96-m4 was selected from one of the three crust samples

89 used by Joshima and Usui (1998). It was collected as an unoriented sample by dredging

90 the Shotoku seamount (30°48.7′N, 138°19.14′E, water depth 1940 m) in the northwest

91 Pacific Ocean during the R/V *Moana Wave* cruise MW9507 in June 1996. The seamount

4

92   is part of a currently inactive volcanic arc of Nishi-Shichito Ridge (Tamaki, 1985). A

93   basalt sampled from close to the location of D96-m4 has an ^{40}Ar/^{39}Ar plateau age of 9.0 ±

94   0.4 Ma (Ishizuka et al., 2003). The crust is 50 mm thick, is brownish-black, and in cross

95   section shows densely packed, weakly laminated growth patterns. The matrix consists of

96   vernadite as the major iron-manganese mineral, and minor quartz, plagioclase, smectite,

97   and apatite. The Mn/Fe ratio ranges from 0.78 to 1.01, and it contains <0.2% Cu, Ni, and

98   Co (Joshima and Usui, 1998).

99   A block of ferromanganese crust (Fig. 1A; left) was taken next to that studied by

100   Joshima and Usui (1998). Two slabs (length 35 mm, width 5 mm) were cut perpendicular

101   to the growth layers and perpendicular to each other, and polished thin sections of 0.2

102   mm thickness were made for scanning SQUID microscopy (MA1 and MB1 in Fig. 1A).

103   Next to these slabs, a columnar block was cut (15 mm × 20 mm; MC in Fig. 1A) and

104   sliced parallel to the growth lamination at 1.5 mm intervals using a 0.3-mm-thick

105   diamond-wire saw. The NRM and anhysteretic remanent magnetization (ARM) of the

106   slices were measured with a SQUID moment magnetometer.

107   **SQUID AND ELECTRON MICROSCOPY**

108   Scanning SQUID microscopy is a new tool for high-resolution mapping of

109   remanent magnetization in samples (Weiss et al., 2007). The instrument uses a

110   monolithic directly coupled niobium-based planar SQUID with a field sensitivity of

111   ~0.01 nT at a frequency of ~0.01 Hz (Baudenbacher et al., 2003; Fong et al., 2005; Weiss

112   et al., 2007). It measures the vertical component of the magnetic field above thin sections.

113   Measurements of the two thin sections MA1 and MB1 with the SQUID microscope were

114   taken inside a magnetic shield in planar grids with 85 µm spacing at a sensor-to-sample

115   distance (and approximate horizontal spatial resolution) of ~170 μm. Measurements were

116   conducted for NRM before and after alternating field (AF) demagnetization at steps of

117   10, 20, 30, and 40 mT, and after giving the sample an ARM (direct current, DC field =

118   100 μT, alternating current field = 100 mT).

119   After SQUID microscopy, backscattered electron images (BEI) were obtained

120   with an electron probe microanalyzer (EPMA, JEOL JXA-8900) at electron acceleration,

121   probe current, and pixel sizes of 15 kV, 12 nA, and 2 μm, respectively. Compositional

122   images (Si, Al, Ti, Mn, Fe, K, Mg, Ca, and P) were obtained by using the EPMA with a

123   pixel size of 20 μm. On selected spots, major elements were examined with an electron

124   probe diameter of 4 μm.

125   **RESULTS**

126   The NRMs of the slices (MC in Fig. 1A) are stable both for normal (Fig. 1B) and

127   reversed (Fig. 1C) polarity intervals. An overprinting magnetization (probably viscous in

128   origin) was removed after AF demagnetization at 10 mT. Declination and inclination

129   (Figs. 1D and 1E; solid circles) are similar to those measured previously on the same

130   crust (Joshima and Usui, 1998; gray circles in Figs. 1D and 1E). Although the polarity

131   boundary observed at 5 mm depth can be recognized as the last geomagnetic reversal

132   (0.78 Ma), earlier reversals are difficult to identify. The NRM intensity is lower for the

133   older part of the crust (Fig. 1F); this is considered to be caused by multiple polarity

134   transitions within each specimen, because ARM in the older part is higher than that of the

135   younger part (Fig. 1G).

136   Figure 2 shows the results of the NRM magnetic field over thin-section MB1

137   imaged with the SQUID microscope together with BEI. Using an intensity scale of ±5

6

138   nT, magnetic stripes with downward (blue) and upward (red) orientation can be observed.

139   The magnetic stripes are almost parallel to the growth pattern on the BEI (Fig. 2A). With

140   an intensity scale of ±100 nT, intense positive and negative isolated spots can be

141   observed. Some of these spots appear as pairs, indicating the presence of dipole magnetic

142   sources. Opaque mineral grains in the center of some of the dipoles were identified by

143   optical microscopy and their chemical composition determined with EPMA (see the

144   following).

145   From the 24 thin slices used for magnetization measurements, 4 normal and 10

146   reversed-polarity stable magnetization directions were determined. Using these 14

147   directions, a mean direction was determined after inverting the reversed polarity

148   directions of declination 233.7° and inclination 46.7° (with a 95% confidence circle of

149   radius 6.5°). The positive inclination indicates that the ferromanganese crust was growing

150   upward on the upper surface of the rock forming the seamount, although the crust was not

151   oriented due to the sampling by a dredger.

152   After AF demagnetization, ARM was imparted upward perpendicularly to the

153   surface of each thin section. Figure 2F shows that the magnetic field produced by ARM is

154   dominantly upward with some intensity variation. The pattern does not directly

155   correspond to the pattern of magnetic stripes observed for NRM. In Figure 2G (stretched

156   intensity scale), there are tiny regions where a negative field (blue to light blue) is

157   observed, indicating weakly ferromagnetic material. Strong negative fields (blue) in

158   Figures 2E and 2F can be interpreted as magnetic dipoles originating from multidomain

159   magnetic minerals not aligned to the DC bias field direction. Support for this

160   interpretation is provided by the observation that the orientations of many of these

161   dipoles changed by tens of degrees or more between the NRM image and the AF 20 mT

162   image. This instability indicates a low-coercivity source, which will be susceptible to

163   ARM noise, as expected for multidomain grains.

164   The other weakly negative field (light blue) might represent the regions where

165   magnetization is weak and the positive magnetization surrounding the region is

166   producing the downward magnetic field. However, these regions are very small and most

167   of the rest of the thin section is associated with a positive field. This confirms that the

168   magnetic stripes are produced by upward and downward magnetization, and rules out the

169   possibility that these are produced by the unidirectionally magnetized layers with

170   magnetization intensity contrasts.

171   **MAGNETIC MINERALS**

172   Observations with the scanning electron microscope–EPMA revealed that the

173   sources of strong NRM dipole fields before (Fig. 2C) and after (Fig. 2E) demagnetization

174   consist of Fe oxides with sizes of a few tens of microns containing ~7% Ti with minor

175   amounts of Al, Mn, and Mg (arrows in Fig. 2). Preliminary analysis of electron

176   backscatter diffraction data indicates the presence of titanomagnetite of several microns,

177   implying the presence of single domain (SD) and pseudo-single domain (PSD) grains. A

178   thermomagnetic analysis on a magnetic extract revealed that Curie temperature is ~550

179   °C, which is consistent with titanomagnetite ($Fe_{3-z}Ti_zO_4$) with $z = 7\%$ (Dunlop and

180   Özdemir, 1997), expected from EMPA analyses. These data collectively indicate that the

181   major ferromagnetic mineral in our ferromanganese crust sample is titanomagnetite. The

182   SEM-EPMA analyses indicate that the abundance of titanomagnetite is $\ll 1\%$. In fact,

183   magnetite and titanomagnetite are known accessory minerals in hydrogenetic

184   ferromanganese crusts (Bogdanova et al., 2008). The chemical composition of the

185   titanomagnetite indicates a volcanogenic origin, implying that the NRM is predominantly

186   a detrital remanent magnetization, although the possibility of a chemical origin cannot be

187   ruled out.

188   **ABSOLUTE AGE AND GROWTH RATE ESTIMATED BY**

189   **MAGNETOSTRATIGRAPHY**

190   We have chosen the magnetic image of NRM before demagnetization to identify

191   the magnetic polarity boundaries because of the NRM's generally single component

192   nature (as indicated by measurements of slices; Figs. 1B and 1C), and because further

193   demagnetization did not enhance the magnetic stripes due to contamination of magnetic

194   dipoles (Figs. 2C and 2F). We attempted to enhance the visibility of normal and reversed

195   stripes with further data processing. First, we applied upward continuation (Blakely,

196   1996) of 200 μm (370 μm from surface of thin sections) on the original magnetic image

197   to reduce the effect of magnetic dipoles, which have lower spatial resolution than the

198   magnetic stripes.

199   Second, the following data processing was conducted to recognize the polarity

200   boundaries for magnetostratigraphic correlation. Several tens of characteristic growth

201   layer boundaries with significant contrast on BEIs were traced and registered as reference

202   lines for the datum planes of simultaneous precipitation to be straightened. Mapping was

203   conducted on the magnetic image parallel to the long axis with the previously registered

204   reference lines (Figs. 3A and 3E). The lower boundary lines of the thin sections were

205   used as base lines. From the straightened magnetic images, magnetic field values of −10

206   to +10 nT were extracted and summed perpendicularly to the growth axis within the

9

207   ferromanganese crust. Magnetic field values >10 nT were neglected because these are

208   considered as noise mostly originating from randomly oriented dipole sources. Finally,

209   the zero crossings were extracted as magnetostratigraphic boundaries and correlated with

210   the standard magnetostratigraphic time scale of Lourens et al. (2004). The angle of the

211   growth layers and the lines perpendicular to the baseline changes from 0° to 38°,

212   implying a maximum distortion of the time scale by no more than 27%.

213   Figure 3 illustrates the results of data processing on MA1 and MB1 and their

214   magnetostratigraphic correlations. Both MA1 (Fig. 3A) and MB1 (Fig. 3E) show

215   magnetic stripes parallel to the surface of the ferromanganese crust after the above

216   corrections. Most of the zero crossings (Figs. 3B and 3D) were correlated with the

217   standard magnetostratigraphic time scale (Lourens et al. 2004; Fig. 3C). Correlations

218   were primarily made based on the long polarity chrons, including Brunhes normal and

219   Matuyama reversed chrons. The extracted polarity boundary depths were plotted versus

220   ages (Fig. 3F). Growth rates are estimated to be 4.99 ± 0.43 and 4.90 ± 0.32 mm/m.y.

221   (errors are in 2σ) for the upper (0–3.596 Ma; blue solid line) and lower (4.631–7.212 Ma;

222   blue broken line) parts of MA1. Between 3.596 and 4.641 Ma, the growth rate is

223   apparently slower (3.20 ± 2.84 mm/m.y.); this can be interpreted as a result of change in

224   the tilt angle observed on the BEI. We calculated the average growth rate for MA1 to be

225   4.95 ± 0.27 mm/m.y. The growth rate for MB1 can be calculated as 5.25 ± 0.37 mm/m.y.

226   (red line). The growth rate for D96-m4 based on magnetostratigraphy can be calculated

227   as 5.10 ± 0.23 mm/m.y. by averaging MA1 and MB1.

228   Usui et al. (2007) obtained a growth rate of ~6 mm/m.y. for the ferromanganese

229   crust D96-m4 by $^{10}Be/^{9}Be$ using a ^{10}Be half-life of 1.5 m.y. Recently, a sequence of

230   carefully designed laboratory experiments led to the best estimate for the ^{10}Be half-life of

231   1.387 ± 0.012 m.y. (Chmeleff et al., 2010). Applying this new half-life to the data of Usui

232   et al. (2007) and excluding the oldest points, we obtain a growth rate of 6.04 ± 0.18

233   mm/m.y. The ^{10}Be/^{9}Be initial value ($1.29 \pm 0.05 \times 10^{-7}$) is consistent with a modern

234   ^{10}Be/^{9}Be ratio for the studied area ($1.36 \pm 0.05 \times 10^{-7}$; Usui et al., 2007), which suggests

235   that the youngest paleomagnetic chron is the Brunhes normal polarity chron. The growth

236   rate from magnetostratigraphy is ~16% lower than that from ^{10}Be/^{9}Be dating.

237   Considering the meandering growth structure (change in tilt of layers along sampling

238   baseline), the errors due to half-life, violation of the constancy of production and

239   preservation of ^{10}Be, thickness (a few millimeters) of ^{10}Be analysis, and identification of

240   polarity boundaries, the new dating method with the SQUID microscope shows great

241   promise for absolute chronological control.

242   **CONCLUSIONS**

243   　　　We have shown that ultrafine-scale magnetostratigraphy using state of the art

244   SQUID microscopy is a promising chronological tool for determining absolute ages and

245   growth rates for the ferromanganese crusts. Approximately oppositely magnetized stripes

246   oriented parallel to bedding were clearly observed on thin sections of a crust and could be

247   correlated with the standard magnetostratigraphic time scale. The average growth rate

248   obtained by magnetostratigraphy (5.1 ± 0.2 mm/m.y.) is within 16% of that

249   independently estimated by ^{10}Be/^{9}Be (6.0 ± 0.2 mm/m.y.). SQUID

250   micromagnetostratigraphy in combination with other chronometric techniques is thus a

251   potentially powerful technique for high-resolution absolute chronology of

252   ferromanganese crusts. In ideal cases, the method may provide an alternative quick dating

253 tool for the ferromanganese crust without laborious chemical separation and mass

254 spectroscopy, once the routine analysis is established. The method can also serve as a

255 valuable tool for calibrating other chronological data and can be used to test the accuracy

256 of experimentally derived half-lives of radioactive isotopes such as ^{10}Be in

257 ferromanganese crusts.

343   **FIGURE CAPTIONS**

344 Figure 1. A: Backscattered electron images of thin sections (MA1 and MB1) and photo of

345 columnar block (MC) used for bulk measurements from block of crust D96-m4 (left).

346 MA1 and MB1 were taken with parallel growth pictures on their surface and

347 perpendicular to each other; MA1 (MB1) with surface facing +X (+Y) axis. Marks on

348 scale of columnar block (MC) are specimen boundaries. Typical vector end-point

349 diagrams of bulk paleomagnetic measurements on thin sliced specimens are plotted. B:

350 Normal (depth = 1.5 mm) polarity intervals. NRM—natural remanent magnetization. C:

351 Reversed (depth = 8.3 mm) polarity intervals. Solid circles (open circles) denote

352 magnetization vector at each demagnetization steps projected onto horizontal (vertical)

353 plane. Numbers denote demagnetization steps (in mT). D: Declination after alternating

354 field (AF) demagnetization at 20 mT. E: Inclination after AF demagnetization at 20 mT.

355 F: Intensity of NRM before demagnetization. G: Intensity of anhysteretic remanent

356 (ARM) magnetization plotted versus corrected depth (solid circles). Thin sliced

357 specimens were cut parallel to growth layer. Corrected depth is depth collected for dip

358 angle (32°) of MC. Declination and inclination (in D, E; measured by Joshima and Usui,

359 1998) after 10 mT alternating field demagnetization are also plotted as gray circles and

360 lines. [[SU: what is "Div." in Figs. B, C? Need space around mult ×, = signs]]

361

362 Figure 2. Analysis of thin-section MB1. A: Backscattered electron image (BEI). B:

363 Natural remanent magnetization (NRM) before demagnetization with scale of ±5 nT. C:

364 With scale of ±100 nT. D: NRM after 20 mT alternating field demagnetization with scale

365 of ±5 nT. E: With scale of ±100 nT. F: Anhysteretic remanent magnetization (ARM) with

366 scale of ±100 nT. G: With scale of ±5 nT. Thin black lines in B–G indicate outer rim of

367   crust. Arrows indicate spots where titanomagnetite grains were observed with electron

368   probe microanalyzer. **[[SU: on right axis, need space before mT]]**

369

370   Figure 3. Magnetostratigraphic correlations using SQUID (see text) microscope maps of

371   undemagnetized natural remanent magnetization for thin-sections MA1 and MB1.

372   Magnetic images were straightened using backscattered electron image growth pattern.

373   A, E: After upward continuation of 200 μm for MA1 and MB1, respectively. B, D:

374   Stacked for MA1 and MB1, respectively. C: Stacks were correlated with standard

375   magnetostratigraphic time scale (Lourens et al., 2004). F: Depths were plotted versus age

376   for MA1 (blue circles) and MB1 (red circles). Black circles are ^{10}Be/^{9}Be data (Usui et al.,

377   2007). Growth rates estimated for each method are shown as inset (see text for details).
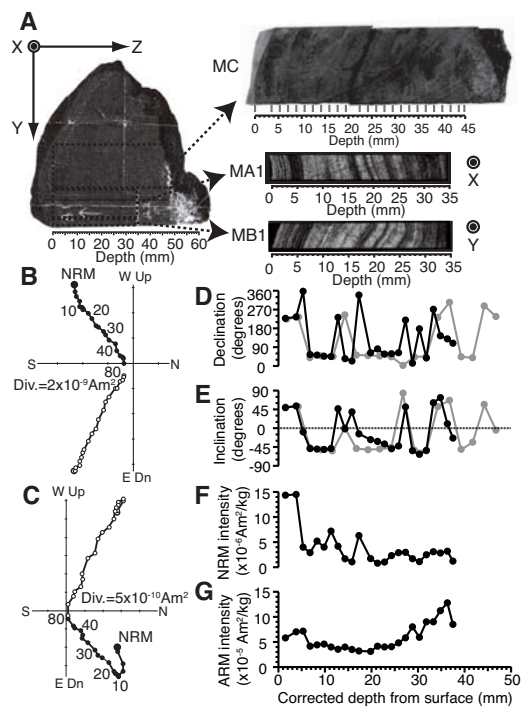

378   **[[SU: don't see any "inset" in figure?]]**
