This circular was prepared by D. W. Graffis, Associate Professor of Forage Crops Extension, G. L. Ross, Assistant Agronomist, and J. E. Dillon, Associate Agronomist. Data processing was done by the Statistical Laboratory of the Agronomy Department. R. D. Seif, Professor of Biometry, and S. G. Carmer, Associate Professor of Biometry, supervised the analysis and preparation of the data.

Urbana, Illinois

January, 1971

Issued in furtherance of Cooperative Extension Work, Acts of May 8 and June 30, 1914, in cooperation with the U.S. Department of Agriculture. JOHN B. CLAAR, Director, Cooperative Extension Service, University of Illinois at Urbana-Champaign.

PERFORMANCE OF CORN HYBRIDS IN ILLINOIS, 1970

CORN YIELDS IN ILLINOIS in 1970 are estimated to average 75 bushels per acre, or 23 bushels less than the 1969 average production. A wet, cool spring delayed planting throughout the state. Some corn was planted as much as six to eight weeks later than normal and the prospects for record yields were "washed out" early in the growing season. Flooding, saturated soils, inability to apply herbicides at the right time, and side-dress nitrogen that was not applied preplant all hampered the growth and survival of the corn crop. A severe drouth during July and August in many areas of the state further reduced the yields while a wet October slowed harvest.

An already potentially poor corn year received the "crowning blow" when a new race of southern corn leaf blight (*Helminthosporium maydis* T.) appeared. The disease was detected in some fields in late June and spread over the entire state during July, August, and September. The disease caused severe damage to nearly all hybrids produced by the male sterile system.

Essentially all of the male sterility in corn hybrids marketed in 1970 was controlled by a particular cytoplasm that was discovered several years ago by geneticists in Texas and was named the Texas cytoplasm. This cytoplasm was very successful in transmitting male sterility to the next generation. The system was so effective in controlling fertile or sterile pollen that about 90 percent of all hybrids available in 1970 were produced by the male sterile system using the Texas source of male sterile cytoplasm.

Unfortunately, a new race of southern corn leaf blight appeared through mutation or by some other unknown means. The new race was able to infect and grow rapidly on hybrids produced by the male sterile system using the Texas source of male sterile cytoplasm. The old race of southern corn leaf blight could infect these same hybrids but made little growth because of genetic resistance.

A new disease, a large acreage of susceptible crop, and suitable climatic conditions for growth and spread of the disease resulted in one of the poorest corn years in recent history.

Fortunately, it is known that corn hybrids produced without using the Texas cytoplasm for male sterility are resistant to southern corn leaf blight race T. These hybrids have the ear parent rows detasseled by hand to remove their fertile pollen to prevent inbreeding. The pol-

len-bearing rows are present as in all seed production fields, providing pollen for the detasseled rows.

Also, some of the hybrids produced with Texas male sterile cytoplasm have some resistance to southern corn leaf blight race T. The degree of resistance varies considerably among hybrids, but rarely are hybrids from male sterile parentage as resistant as hybrids from nonmale sterile (normal cytoplasm) parentage.

The tables in this circular list southern corn leaf blight rate T ratings for each hybrid entry. Use the leaf blight rating in conjunction with the yield of the hybrid in 1970 for a relative estimate of the leaf blight resistance. Notice that not all locations were equally severely infected. *Do not compare yields or leaf blight ratings of a hybrid at one location with another hybrid at another location. Make all comparisons within a test location.*

The leaf blight ratings were made in late August but some advance in leaf area damage occurred after this date. Thus the ratings should not be interpreted as the extent of the damage for the entire season.

Yields for 1968-1969 and for 1970 are presented separately to provide an indication of relative performance of hybrids both in the absence and the presence of southern corn leaf blight race T.

Because the type of cytoplasm largely determines the resistance of hybrids to southern corn leaf blight race T, participating seed companies were asked to supply information on the type of cytoplasm in their entries in the tests reported in this circular. Hybrids using Texas male sterile cytoplasm are referred to as Tms cytoplasm. Hybrids without the Tms cytoplasm are referred to as normal cytoplasm, designated "N." Hybrids composed of a mixture of seeds, some from Tms and some from N cytoplasm, as referred to as a blend, designated "B." The cytoplasm source in the University of Illinois tests may have been different than that offered for sale to farmers in 1970 and may be different in 1971. Information on the cytoplasm sources for 1970 and on plans for 1971 is given in Table 3. Use this information when evaluating the leaf blight ratings and yields obtained in 1970. If the cytoplasm source is unknown (unsure), the designation "U" is used.

PLAN OF THE TESTS

Selection of entries. Each year all producers of hybrid seed corn in Illinois and surrounding states are invited to enter hybrids in the Illinois performance trials. To finance this testing program, a fee is charged for each hybrid entered by seed companies. Most of these

hybrids are commercially available, but seed companies occasionally enter experimental hybrids for testing.

Number and location of tests. In 1970, 18 major tests were carried on at 11 locations in the state (see map on page 7). These sites were chosen to represent major soil and climatic areas of the state.

Hybrids. This year over 360 hybrids were tested, including entries from 46 companies. The seed companies supplied seed of their entries.

Field-plot design. Each test was set up in either randomized complete block or lattice designs. These arrangements are practical and efficient and give each hybrid an equal chance to show its merits.

Planting methods. All trials were planted by machine except those at Woodstock and Augusta, which were planted by hand to obtain an earlier planting. All test fields except those at DeKalb, Urbana, Brownstown, and Carbondale were part of larger corn fields and were surrounded by market corn. Plots were kept small to avoid differences due to soil variation. Each individual plot was three rows, 26 feet long. The center row of each plot was harvested to check performance. All plots were overplanted 30 percent and later thinned to desired stand.

Fertilization. In general, all test fields were at a high level of fertility. Additional fertilizer was plowed down or side-dressed as needed to assure top yields.

Method of harvest. All plots were harvested mechanically with a self-propelled corn-head combine. Shelled corn from each plot was collected, weighed, and tested for moisture percentage. No allowance was made for shelled corn that might have been lost in harvest.

MEASURING PERFORMANCE

It sometimes happens that hybrids too late in maturity for a given area are entered in the tests. While such hybrids often are high in yield, their high moisture content might make them unsafe choices for use unless proper drying or storage facilities are available. Therefore, the hybrids in the 1968-1969 average are listed in the order of their kernel moisture with lowest moisture listed first.

Yield of grain. Shelled-corn weight and moisture percentage were measured for each plot of a hybrid and converted to yields of No. 2 shelled corn (15.5 percent moisture). An electronic moisture tester was used for all moisture readings.

Table 1.—General Information: Illinois Hybrid Corn Tests, 1970

Erect plants. The number of erect plants in each plot of a hybrid was counted at harvest time. Any plant leaning at an angle of more than 45 degrees or broken below the ear was considered lodged. Plants broken above the ear were considered erect.

Stand. In late June, plants in all plots on all fields were counted and the percent of stand was computed by comparing this number with the number of kernels planted. Plots with over 100 percent stand were thinned at this time. Stand differences may be caused by failure to germinate or by disease, insect injury, or cultivation damage.

Plants per acre. Plants per acre was calculated for each plot by using the percent stand obtained from plant counts. Differences in plants per acre are caused by the same factors that cause differences in percent stand.

Blight infection. The observations were noted during the last week of August. A reading of zero indicates no blight visible. A reading of 5 to 10 indicates blight visible but little or no growth. Higher readings indicate sensitivity to blight and the amount of infection on the plants. A number of hybrids were observed as being blends of N and Tms cytoplasm and were averaged. Drought caused premature dying of corn at the Elwood field and prevented reliable leaf blight ratings.

Comparing hybrids. In any test of plant material, it is impossible to measure performance exactly. Samples may vary, soils may not be uniform, and many other conditions may produce variability. Results of repeated tests, like those reported in this circular, are more reliable than those of a single year or a single strip test. In general, a yield difference of a few bushels per acre is not significant in these tests. When one hybrid consistently outyields another at several test locations and over several years of testing, the chances are good that this difference is *real* and should be a consideration in choosing a hybrid. But yield alone is not enough. Consider also the grain moisture content, percentage of erect plants, percent stand, or plants per acre in comparing hybrids.

As an aid to comparing hybrids, certain statistical tests have been devised. D. B. Duncan¹ has outlined an approach to the problem of multiple comparisons when only two means are compared among a set of hybrid means. Certain factors not accounted for in previous tests of this type are included in Bayes L.S.D. This test is applied in the same manner as previous statistical tests used in these circulars. When two hybrids in a trial are compared, and the difference between them is greater than the tabulated L.S.D. value, then the hybrids are said to be "significantly different."

GROWING CONDITIONS ON 1970 TEST FIELDS

Extreme Northern Illinois: Woodstock. This test field represents the cool, humid area in northeastern Illinois. The test plot is on land operated by the Hughes Farms and Seed Co. The soil type is Proctor silt loam, a fertile, deep, well-drained, dark prairie soil. This plot was in a field of third-year corn.

Northern Illinois: DeKalb. This test is on the University's Northern Illinois Research Center near Shabbona in DeKalb County. R. E. Bell is field manager of the research center. The soil type is Flanagan silt loam, a dark-brown, adequately drained soil of high fertility. The rotation used is a corn-corn-oats-clover rotation. The high planting rate test was in first-year corn. The low planting rate was in second-year corn. The field was wet and cold at planting time and high-population stands were reduced on some of the hybrids.

West North-Central Illinois: Galesburg. This test is located on the Hawkinson Farms, operated by Harold and Dave Hawkinson. The test field represents the highly fertile, heavy-textured, Sable silty clay loam of the area. The plot was in a field of third-year corn. Cold,

Table 2.—Growing Season Rainfall

Field	May	June	July	August
<i>inches</i>				
Woodstock.....	5.5	5.5	.6	.6
DeKalb.....	5.2	7.0	6.4	.2
Galesburg.....	6.1	7.5	3.6	4.6
Elwood.....	4.8	6.3	.7	2.4
Augusta.....	5.6	6.1	2.4	7.8
Stanford.....	4.8	2.8	1.9	3.6
Urbana.....	1.6	3.2	4.5	3.1
Greenfield.....	3.5	6.5	2.6	1.8
Brownstown.....	4.8	9.0	2.6	1.4
Carbondale.....	3.3	4.7	1.7	2.9
Dixon Springs.....	6.6	5.4	.5	.9

wet weather in early May reduced some of the high-population stands. The field was damaged in mid-August by hail.

East North-Central Illinois: Elwood. This plot was moved from the Ashkum area to the Elwood Research Center in 1969. The Elwood field is in Will County and Dale Harshbarger is the field manager. The soil is a Drummer silty clay loam. The field suffered from a severe midsummer drought.

West-Central Illinois: Augusta. This test is located on the William Finney farm, west of Augusta in Hancock County. The soil is Harrison silt loam, a moderately well-drained, dark grayish-brown prairie soil. The area was wet all spring causing a delay in planting. Adequate rainfall throughout the growing season resulted in good corn yields in spite of the late May planting.

Central Illinois: Stanford. During the past four years, this field has been located on a farm operated by Howard Logsdon in the western part of McLean County. The soil is a deep, well-drained, fertile Muscatine silt loam. The area was wet in the spring and most of the planting was done two weeks later than the year before.

East-Central Illinois: Urbana. This test is located on the Agronomy South Farm of the University of Illinois at Urbana-Champaign in Champaign County. M. G. Oldham is the farm manager. Fields on which the test plots were grown are level, heavy-textured Drummer silty clay loam. The conventional 40-inch trial and 30-inch trial were in the second year of corn of a corn-corn-oats-alfalfa rotation.

West South-Central Illinois: Greenfield. This test represents the moderately poorly drained, level soils of western south-central Illinois. The soil type is Herrick silt loam. It is located on the C. H. Ross, Jr. farm northeast of Greenfield in Macoupin County.

Southern Illinois: Brownstown. This test is located on the University's Brownstown Experiment Field in Fayette County. The soil is Cisne silt loam, a poorly drained, gray prairie soil with a well-developed claypan. Natural fertility of the soil is not high. Arden Christensen is the area agronomist in charge of the field.

Extreme Southern Illinois Bottomland: Dixon Springs. This test was located at the Dixon Springs Agricultural Center in Pope County. The test plot is on an area of Sharon silt loam, which is a light-colored moderately well-drained to well-drained, medium-textured bottomland soil. Fertility of this field is high. G. E. McKibben is the area agronomist in charge of this field. The field had a severe infection of leaf blight early in August.

Extreme Southern Illinois Upland: Carbondale. The test at Carbondale represents a typical upland area in southern Illinois. This test was carried on at the Southern Illinois University and University of Illinois Agronomy Research Center, where Roy Browning is superintendent. The soil types are classified as Weir and Stoy silt loams, which are rather shallow, silty soils over claypan. The growing season started normally and in early July it appeared that there would be an ideal crop. However, by August 1 the summer drouth had already done its damage. Many varieties that did not set seed were noted and the leaf blight was active.

Location of 1970 test fields.
