Washability of Trace Elements in Product (Marketed) Coals from Illinois Mines

Ilham Demir, Rodney R. Ruch, John D. Steele, and Saleem Khan

CONTENTS

ABSTRACT

In the past, washability data on trace elements in Illinois coals were generated mostly using float-sink methods, which cannot be used to estimate the performance of froth flotation or column flotation circuits. There is a particular lack of washability data on product (as-shipped) coals from modern preparation plants. The goal of this study was to provide the needed froth flotation washability data on trace elements in as-shipped Illinois coals.

Thirty-four coals, as shipped by Illinois mines, were ground to -100, -200, and -400 mesh sizes. Each ground sample was cleaned using a froth flotation/release analysis (FF/RA) test procedure. Concentrate and tailing fractions from the FF/RA tests were analyzed for ash and moisture; some samples were also tested for sulfur (S), heating value (Btu), and trace and minor elements. A composite sample having 80% of the total combustibles of the feed coal was prepared for each FF/RA test by combining the concentrates from that test in proportion to their ash contents. The composite samples were analyzed for trace and minor elements. The analytical data were used to evaluate the removal of ash, S, and trace elements from the as-shipped coals. The data indicate that, at 80%-combustibles recovery, as much as 69%, 76%, and 83% reductions in ash content can be achieved for the -100, -200, and -400 mesh sizes, respectively. The average reductions for trace elements were generally less than those for ash. However, reductions for some elements in individual samples approached or exceeded reductions for ash.

One of the as-shipped coals was subjected to FF/RA tests at -100 and -400 mesh sizes to investigate mass balances for ash, S, and for some trace and minor elements. Analytical results on concentrates and tailings from these FF/RA tests indicate mass balances within experimental errors.

OBJECTIVE

The objective of this study was to evaluate the beneficiation potential for trace elements in 34 coals, as shipped by Illinois mines, by applying a surface-based, fine-coal cleaning process. The term washability, which conventionally refers to float-sink data, is used in this report to describe data on the reduction of ash yield, S, and trace and minor elements in coal through the use of a special froth flotation procedure known as "release analysis." The data will be helpful in evaluating environmental requirements for noxious emissions at power-generating plants. The availability of trace element washability data will also permit matching specific coals with prospective markets (e.g., in advanced gasification processes and in the production of synthetic organic chemicals). To meet our objective, we conducted the following specific tasks.

1. Quality assurance/quality control (QA/QC): an existing Illinois State Geological Survey (ISGS) QA/QC plan was modified and applied during all phases of this study.
2. Sample preparation: samples collected during 1992-1993 and stored under nitrogen gas were used. Representative splits of the samples were ground to three different sizes (-100 mesh, -200 mesh, and -400 mesh) for the washability tests.
3. Washability (release analysis) tests: trace element cleanability of coal at fine to ultrafine particle sizes was evaluated using a special froth flotation process called release analysis.
4. Chemical analysis: the products from the release analysis tests were analyzed for moisture, ash, S, heating value, and trace and minor elements.

INTRODUCTION

The availability of trace element washability data could help encourage the use of Illinois coal products given the advent of new and improved technologies and expanding opportunities for exporting to foreign markets, as well as the requirements of recent environmental legislation.

The efficiency of cleanability from traditional density or float-sink separation of fine coal in the laboratory may not be achievable with large-scale cleaning processes used in industry. It is important, therefore, to develop a washability database that has industrial application. The washability testing process we used has the potential for economical and commercial applications. The process uses multi-stage flotation in a standard sub-aeration flotation cell to

1

generate special washability (release analysis) data. The release analysis data have been demonstrated to correlate well with optimum performance of standard fine-coal cleaning procedures, namely froth flotation and column flotation (Forrest 1990, Honaker and Paul 1994).

BACKGROUND

Trace and Minor Elements in Coal and Coal Combustion

A study by the U.S. National Committee for Geochemistry (National Research Council [NRC] 1980) discussed the potential health hazards of various trace elements that might be encountered during the development and utilization of coal. Three categories of elements of environmental concern were identified with respect to coal.

- Of greatest concern: As, B, Cd, Pb, Hg, Mo, and Se.
- Of moderate concern: V, Cr, Ni, Cu, Zn, and F.
- Of minor concern: Li, Na, Sr, Ba, Mn, Co, Ge, Cl, Br, and radioactive elements Ra, Po, Rn, Th, and U.

These judgments were made on the basis of known toxicity, levels of occurrence of each element in coal, and anticipated mobility upon coal combustion or disposal of coal ash. These Eventual emission standards should be based on valid biological data.

The Clean Air Act (CAA) Amendments of 1990 (Public Law 101-549, 1990) includes 16 elements that occur in coal in a list of 189 "Hazardous Air Pollutants" (HAPs): As, Be, Cd, Cl, Cr, Co, F, Hg, Mn, Ni, P, Pb, Sb, Se, Th, and U. Radioactive isotopes derived from U and Th, such as Po, Ra, and Rn, are also implicated as HAPs. A parallel regulation to classify certain elements in coal as HAPs has also been considered in Illinois (Illinois Pollution Control Board 1990).

The HAP elements are present in all coals, not only those from Illinois, but their concentrations can vary considerably between coals (Gluskoter et al. 1977, Swanson et al. 1976, Zubovic et al. 1979, 1980, Cahill et al. 1982, Harvey et al. 1983). Electrical utilities are not currently required to meet any standards for HAPs emissions. This may change, however, after the U.S. Environmental Protection Agency (U.S. EPA) completes its risk assessment studies and establishes emission standards. Coal-burning utilities may eventually be required to monitor the amount of each HAP element emitted to the atmosphere from their power plants.

Klein et al. (1975) conducted mass balance studies on the Allen cyclone boiler power plant at Memphis, Tennessee, using coals from Illinois and western Kentucky. These studies indicate that most coal-derived Hg, some Se, and probably most Cl and Br are released as gases to the atmosphere. The elements As, Cd, Cu, Ga, Mo, Pb, Sb, Se, and Zn were concentrated in the fly ash and partially released to the atmosphere attached to small fly ash particles. The electrostatic precipitator removed about 96.5% to 99.5% of the fly ash. Kaakinen et al. (1975) measured the concentrations of 17 elements in a mass balance study of a power plant fueled with a western coal. The elements Pb, Cu, Zn, As, Mo, Hg, and Se were found to be partially volatilized. Natusch et al. (1974) observed that certain elements, especially As, Sb, Cd, Pb, Se, and Tl, were more concentrated on smaller, respirable-sized fly ash particles.

Swaine (1989) reviewed the environmental aspects of trace elements in coal. Modern electrostatic precipitators can trap as much as 99% of the fly ash. Trace elements emitted into the atmosphere during combustion are thus either attached to ultrafine fly ash particles or in a gaseous state. Swaine concluded that, in general, no trace element posed a significant environmental problem. This conclusion was made assuming the use of state-of-the-art electrostatic precipitators and the use of coals with no exceptionally high concentrations of those noxious elements that would be emitted in a gas phase or attached to small fly ash particles that can pass through electrostatic precipitators.

Removal of Trace Elements from Coal

Reviews summarizing progress in the removal of trace elements via coal cleaning include Jacobsen et al. (1992), Norton et al. (1985, 1986, 1992), Kaiser Engineers (1989), Norton and Markuszewski (1989), Streeter (1986), Wheelock and Markuszewski (1981, 1984), National Research Council (1979, 1980), and Mezey (1977).

Several studies have evaluated the removal of trace elements from coal through various cleaning methods. Deep physical cleaning of coal was reported to significantly reduce the level of most trace elements (Gluskoter et al. 1977, Cavallaro et al. 1978, Harvey et al. 1983) as shown by float-sink testing. There is, however, a lack of data on the trace element washability of product coals from modern preparation plants. In general, physical cleaning becomes efficient (70%-90% removal) if a high degree of comminution is used to free mineral matter from the coal macerals. Those trace elements associated with the macerals, however, are not removed. Their concentrations are actually increased in the cleaned coal. Studies tracking trace element removal using chemical means indicate better removal; however, costs would be quite high.

Float-sink separation studies have shown that significant reduction can be achieved for some trace elements through conventional coal cleaning; however, the coarse particles (approx. > 3/8 in.) generally limit the amount of minerals liberated. Extensive ISGS float-sink studies (Gluskoter et al. 1977, Fiene et al. 1979, Harvey et al. 1983) on Illinois coals indicate that many elements (As, Ba, Ca, Cd, Fe, Mn, Mo, Pb, Tl, and Zn) have strong inorganic association and can be removed to a significant degree (50% or greater). Other elements (B, Be, Ge, Ni, Sb, U, and V) are strongly associated with organic matter and are generally not removed by physical cleaning. Some 32 other elements showed indications of mixed association. However, even the organically associated elements may actually occur in disseminated minerals that are not removed by float-sink separation at coarse particle sizes. Kuhn et al. (1980) found differences in trace element/mineral association and possible cleaning potential for an eastern seam (Pittsburgh 8) and a western seam (Rosebud). For example, in the Rosebud coal, Sb was classified to be associated with the organic fraction; in the Pittsburg Coal, it largely shows inorganic association. Cavallaro et al. (1978) reported on the float-sink behavior of eight elements (Cd, Cs, Cu, F, Hg, Mn, Ni, and Pb) in ten coals from various producing areas of the United States. Although the concentration of individual trace elements in the feed coal varied within and between regions, the removal of the heavier fraction (>1.6 S.G.) resulted in significant reductions in the 14-mesh clean coal product for all tested coals. Depending upon the geographical region, 64% to 88% of the composite trace element concentrations were in the 1.6-S.G. sink fraction.

Akers and Dospoy (1992) reported washability data on the Upper Freeport coal for As and Ni at several size fractions; they observed better removal at the smaller sizes. They also presented data on reductions for ten trace elements for four coal seams at several combustible recoveries using conventional gravity separations.

Ford et al. (1976) demonstrated that cleaning at a top size of 30 mesh via a concentrating table was effective in partially removing Hg, Pb, As, Mn, and Se from eight diverse coal types. Removal ranges were reported for Hg (3%–68%), Pb (8%–63%), As (11%–67%), Mn (9%–6%), and Se (2%–61%). Ford and Price (1980) reported results of conventional and non-conventional cleaning of 20 run-of-mine coals. The elements As, Cd, Cr, Co, Cu, F, Pb, Mn, V, and Zn, as well as most major ash elements, were significantly removed. Ford and Price (1982) reported on trace element removal via heavy media cyclone cleaning. Average percentages of the original amount of trace elements that remained in the clean fractions for four Appalachian and two midwestern coals were as follows: As, 53%; B, 98%; Be, 75%; Cd, 54%; Co, 63%; Cr, 60%; Cu, 60%; F, 49%; Hg, 89%; Mn, 37%; Ni, 62%; Pb, 32%; Sb, 91%; Se, 67%; V, 76%; and Zn, 51%. Conzemius et al. (1988) determined the effect of cleaning with a heavy media cyclone on 75 elements. Although most elements followed the ash, cleaned coal was enriched in Be, Mo, U, I, Co, and Sb.

Kulinenko and Barma (1990) used a combination of screening, density separation, jigging, flotation, centrifugation, and vacuum filtration, and they monitored 29 trace elements in the various streams. Arsenic and Hg were most abundant in jigging refuse. In density separation refuse, F and Ga were most abundant; Hg, Be, and Ge were least abundant. Cesium was least abundant in flotation refuse.

3

Capes et al. (1974) reported that levels of As, Cs, Pb, Mn, Mo, Ni, and V were reduced by 50% to 80% during separation by oil agglomeration. Knott et al. (1985) reported on trace element reduction comparisons obtained by oil agglomeration, froth flotation, and float-sink processes on Australian coals. The OTISCA process, an oil agglomeration approach using a fluorocarbon liquid (freon), indicated more than 90% removal of As, Cd, and Pb from coal (Jacobsen et al. 1992).

A combination process of froth flotation and oil agglomeration known as aggregate flotation was able to remove greater than 50% of Cd, Co, Cr, Li, Mn, Na, Sb, Sr, Th, and V from Illinois coals (Buckentin et al. 1985). A combination of heavy media cyclone or table separation and advanced froth flotation approach utilizing microbubble processing (Bechtel National Inc. 1988) removed 80% to 90% of As, Be, Co, F, Ni, Pb, Sb, Th, U, Cr, and Sc from Illinois coal.

The LICADO process (Jacobsen et al. 1992), based on surface-separation using liquid CO_2, indicated only moderate separation for As, Ni, and Pb.

Limited data for Battelle hydrothermal and TRW/Molten caustic leachings (Jacobsen et al. 1992) show high removal of Pb but only mixed reduction for Cd, Ni, Se, and As. Data on the Battelle Alkaline desulfurization process for three Ohio coals indicate high (>70%) removal for Li, Ba, Be, B, K, P, Mo, V, As, and Ba (Mezey 1977, Stambaugh et al. 1979).

In the Jet Propulsion Laboratory chlorinolysis process, chlorine gas is passed through a slurry of finely ground coal, organic solvent, and water at 50° to 100° C (Jacobsen et al. 1992, DuFresne and Kalvinskas 1980). Removals were high for Pb, medium for As, and low for Cd, Hg, and Se.

The Meyers process (Mezey 1977, Hamersma et al. 1974) uses and regenerates $Fe_2(SO_4)_3$ and is said to remove pyrite effectively. In a study of some western, eastern interior, and Appalachian coals, As, Zn, Cd, Pb, Ni, Mn, Cr, and other elements normally known to be associated with pyrite and other minerals were significantly reduced. The results for B, Be, Cu, F, Hg, Li, and V were somewhat mixed.

Norton et al. (1986) reported on the comparative treatment of the Herrin (Illinois No. 6) coal using molten NaOH/KOH or 1.0 M Na_2CO_3 addition under elevated temperature/pressure conditions followed by acid wash. Levels of Mn, Pb, Rb, Sr, and Zn were lowered by 75% or more, while those of Ba, Cd, Cr, Ni, and Se were lowered by 30% to 60%. They also reported results, obtained by the TRW Gravimelt process, where levels of As, Be, Cd, Hg, Pb, Se, and Sr were reduced by 75% or more. Kuhn et al. (1980) reported on some 52 trace and minor elements in eastern and western coals that were subjected to float-sink separation and extensive extractions with dilute HNO_3 and HF, followed by washing with water. This approach indicates the amount of trace elements that would remain in the coal after an exhaustive physical and chemical cleaning.

In a previous study, Demir et al. (1994) generated data on trace elements in 34 product (as-shipped) coals from operating Illinois mines and compiled existing ISGS data on channel and other samples. These coal data permit prediction of maximum possible emission levels for individual trace elements that would result from burning Illinois coals. The present study characterizes froth-flotation washability of trace elements in the same 34 product coals. The terms product coal, as-shipped coal, marketed coal, and washed coal are used interchangeably for the 34 samples investigated in this study. Because of the proprietary nature of the data, individual mine results are reported only by sample numbers and by multi-county regions.

EXPERIMENTAL PROCEDURES
Quality Assurance/Quality Control (QA/QC)
The ISGS's Quality Assurance/Quality Control plan was implemented for this study. The QA/QC plan includes the standard operating procedures for each analytical task and for sample preparation. Blank, blind, and replicate samples were analyzed to ensure data reliability. Detailed sample description, requests for analysis forms, unique sample identification numbers, and sample handling procedures were used. Further details of the QA/QC plan are available upon request.

Samples and Sample Preparation
Thirty-four samples of as-shipped coals collected from one mine and 33 coal preparation plants that were in operation in Illinois during 1992-1993 were used in this study. Details of the collection, preparation, and storage of the as-shipped coal samples are described in Demir et al. (1994).

-100 mesh samples Representative samples of the 34 as-shipped coals were passed through a jaw crusher and then a roll crusher to reduce the particle size of the coal to <3/8 in. and -4 mesh, respectively. A split of each -4 mesh size coal was then dry-ground in a hammer mill in conjunction with a -60 mesh screen. The ground samples were analyzed for particle size distribution on a Microtrac particle size analyzer. The particle size data indicated that about 90% of the ground material was -100 mesh size.

-200 mesh samples About 700 g of each -4 mesh coal (see preparation of -100 mesh samples above) was mixed with 700 mL of tap water and ground in a rod mill for 30 minutes. The coal slurry was filtered, split in half, and saved for froth flotation/release analysis (FF/RA) tests. A split of the filter cake was tested for particle size distribution. In general, the samples tested in the range of 90% -200 to -270 mesh. Several samples tested in the range of 90% -325 mesh and 80% -500 mesh. In those cases, grinding was repeated for less than 30 minutes to achieve a particle size distribution of about 90% -200 mesh.

-400 mesh samples About 700 g of each -4 mesh coal was mixed with 700 mL of tap water and ground in a rod mill for about 60 minutes. The coal slurry was filtered, split in half, and saved for the FF/RA tests. Data on particle size analysis indicated a particle size distribution of 85% to 90% -400 mesh.

Froth Flotation Washability Procedure
The ground as-shipped samples were cleaned through froth flotation using the release analysis technique (Dell 1964, Forrest 1990). Figure 1 shows the systematic series of sequential flotations performed to obtain five concentrates and four tailings (the tailings are eventually combined for analysis) having different ash yield and concentrations of trace elements.

For the -100 mesh samples, a representative split (300 g, dry basis) was slurried with about 3.5 L of tap water in a conventional Denver froth flotation cell, conditioned with 0.4 mL of kerosene. Then 0.4 mL of frother (2-ethylhexanol) was added, and approximately 7 L of air per minute passed through the cell with the rotor set at 1,200 rpm. The resulting float (concentrate) fraction was again mixed with water and floated three times (adding 0.1 mL additional frother), and the corresponding tailings were collected. The resulting concentrate from the third flotation was again mixed with water, refloated, and then the float was collected at 20-second intervals (C1, C2, C3, C4, C5) and at varying air flow rates (2-8 L). This procedure generates the cleanest sample (C1) and progressively less clean samples (C2, C3, C4, C5) in addition to the lower grade tailings (T1, T2, T3, T4).

The same FF/RA procedure illustrated in figure 1, with a few changes in reagent concentrations, was applied to the -200 and -400 mesh samples. Filtered cakes were subjected to the FF/RA on the same day they were ground. Generally, 0.7 and 1.0 mL kerosene were used for the -200 and -400 mesh samples, respectively, in the first flotation. In some cases additional kerosene had to be added to condition the coal and prevent excess amounts of tailings. For both -200 and -400 mesh samples, 0.5 mL frother was added in the first flotation.

Chemical Analyses of Samples
All concentrates and tailings from the FF/RA tests were analyzed for moisture and ash, and some were tested for total S and heating value (Btu). A good empirical relationship was found between heating value and combustibles for all samples (fig. 2). Concentrates and tailings from two of the FF/RA tests were also analyzed for forms of S, Cl, and trace and minor elements. A composite

sample containing 80% of the total combustibles of the feed coal was prepared for each of the FF/RA tests by combining the concentrates from that test in proportion to their ash contents. The composite samples were analyzed for ash, moisture, and trace and minor elements. All the analyses were carried out in accordance with strict ISGS QA/QC procedures. Methods of chemical analyses used and levels of their precision and accuracy are shown in table 1.

RESULTS AND DISCUSSION

Froth Flotation Washability

Release analysis curves for ash and sulfur Data are available to construct froth flotation washability (release) curves that show ash yield and S content of clean coal products at various values of combustibles recovery. As an example, two sets of curves from each of the four regions of the Illinois coal field (fig. 3; see Demir et al. [1994] for more information) are included in this report (figs. 4 and 5). Ash yield and S content of the FF/RA products vary depending on the type of coal, particle size used, and desired combustibles recovery. In general, production of low ash (2%–5%) and lower S (1.2%–2.4%) coals is possible in some cases. Data on ash yield and S for individual FF/RA fractions of all samples are available upon request.

Trace elements in 80%-combustibles recovery composites Data on ash yield, heating value (Btu/lb), and concentrations of HAP elements in as-shipped coals and in their 80%-combustibles recovery products from the FF/RA tests are given in table 2. All of the elements classified as HAPs in the CAA Amendments of 1990, except Cl, are included in table 2. Results on other trace elements, as well as minor elements, are available upon request. The heating values of the 80%-combustibles recovery composites were calculated using the empirical relationship given in figure 2, and the calculated values were then converted to a dry basis. Reductions in ash yield and HAP elements were calculated using the data from table 2:

$$\%reduction = ((C_{feed} - C_{clean})/C_{feed}) \times 100$$

where C_{feed} and C_{clean} are the ash yield or a trace element content in feed and clean coals, respectively. The reduction results for the −100 mesh FF/RA tests are given in table 3; those for the −200 and −400 mesh FF/RA tests are given in table 4.

The data in tables 3 and 4 indicate significant reductions for most of the samples considering that the FF/RA tests were performed on as-shipped coals, which themselves are already cleaned products from conventional coal preparation plants. Average reduction values generally increased as the particle size of the feed decreased from −100 mesh through −200 mesh to −400 mesh. The average reductions for most HAP elements were less than those for ash yield, as illustrated by four examples shown in figure 6. However, reductions for some elements in individual samples can approach or exceed reductions for ash yield.

8
Figure 5 Sulfur release curves for flotation of three as-shipped Illinois coals (–100 mesh size).

Reductions for Mn and P approached or exceeded reductions for ash yield for the majority of the samples. A substantial portion of Mn is expected to occur in solid solution in calcite, and P is associated, perhaps primarily, with apatite in coal. Most of the calcite and some of the apatite occur as cleat fillings, nodules, and/or partings (Rao and Gluskoter 1973, Harvey et al. 1983); cleat, parting, and nodule minerals are more easily removed during coal cleaning than finely disseminated minerals. Those HAP elements that have lower reductions than ash yield are apparently enriched in finely disseminated mineral matter or in clay minerals that are generally trapped in the concentrates from the FF/RA tests.

Data on average concentrations of trace elements in as-shipped Illinois coals and in their FF/RA beneficiated products indicate that both as-shipped samples and the FF/RA products contain significantly less HAP elements than channel samples (fig. 7). In the –200 mesh FF/RA products, for example, average concentrations of As, Hg, and Se were reduced by 73%, 75%, and 46%, respectively, relative to their average concentrations in channel samples. These reductions are important because As, Hg, and Se are highly volatile during combustion and may become targets of air quality legislation.

Comparing results for a set of five as-shipped coals subjected to FF/RA at –100, –200, and –400 mesh indicates that, in general, additional beneficiation achieved by grinding the coal finer than –200 mesh is relatively small for the majority of HAP elements (fig. 8). This is likely a result of trapping of fine ash material in the concentrates for the majority of samples. Beneficiated coals, however, have higher heating value than feed coals. The reductions shown in figures 7 and 8 would, therefore, be greater if the concentrations were compared on a mg/MMBtu basis.

9
Figure 6 Rejections of ash and HAP elements versus combustibles recovery for four coals ground to –200 mesh and cleaned using the FF/RA process.

Mass Balance Study

Results from FF/RA of one of the as-shipped samples (sample C32796) at –100 and –400 mesh sizes were used to determine mass balances for the test procedures used. This sample was selected because of its high ash yield, high Cl content, and favorable distribution of weights in the FF/RA fractions. All of the various solid concentrate and tailing fractions, representative samples of the water used for grinding and FF/RA tests, and representative sample of the feed coal were analyzed for moisture, ash, total sulfur, forms of sulfur, chlorine, and trace and minor elements. Mass balances achieved (table 5) are generally within analytical and experimental errors, except for sulfatic S.

Excess sulfatic S was generated during grinding and FF/RA. More sulfatic S was generated during the latter than during the former, apparently due to accelerated oxidation of pyrite caused by the introduction of the air bubbles. Most of the sulfatic S was, however, washed away by the process water. The total amount of sulfatic S recovered from the concentrates and tailings was 20% of the original sulfatic S concentration in the feed coal. A considerable portion of Cl was also washed away by the process water because Cl in Illinois coals occurs as dissolved salt and exchangeable anion (Demir et al. 1990, Chou 1991). The total amount of Cl recovered from the concentrates and tailings was 66% and 42% of the original amount for the –100 mesh and –400 mesh FF/RA tests, respectively. Mercury, Mn, and Pb have somewhat higher percent mass

10
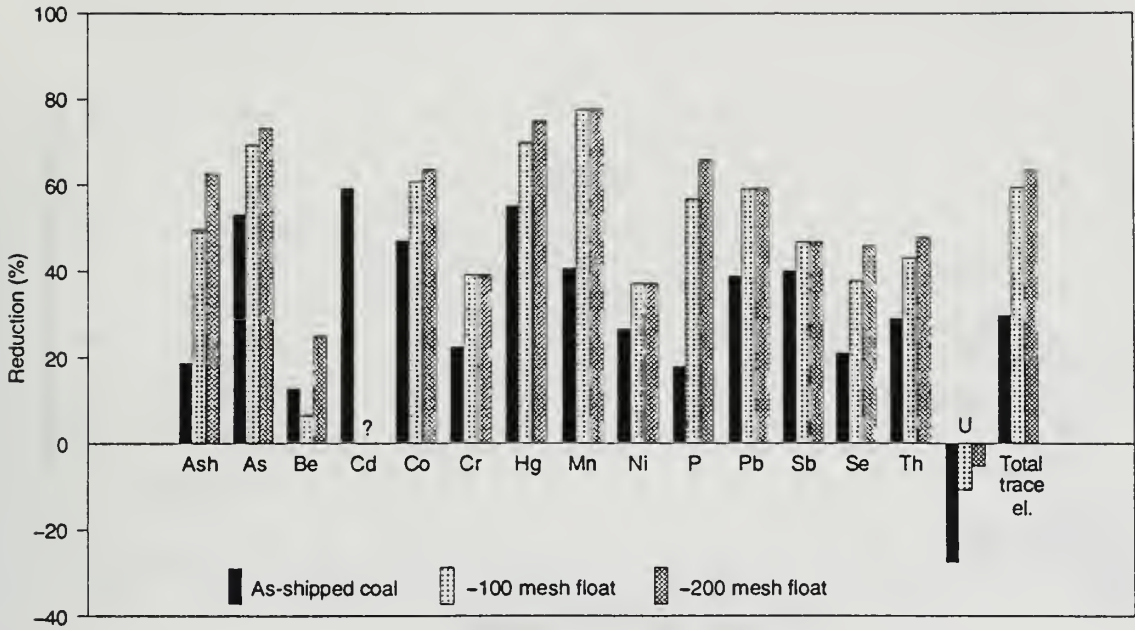

Figure 7 Reductions in average concentrations relative to those in channel samples. −100 mesh and −200 mesh floats represent composites of 80%-combustibles recovery from the FF/RA tests.
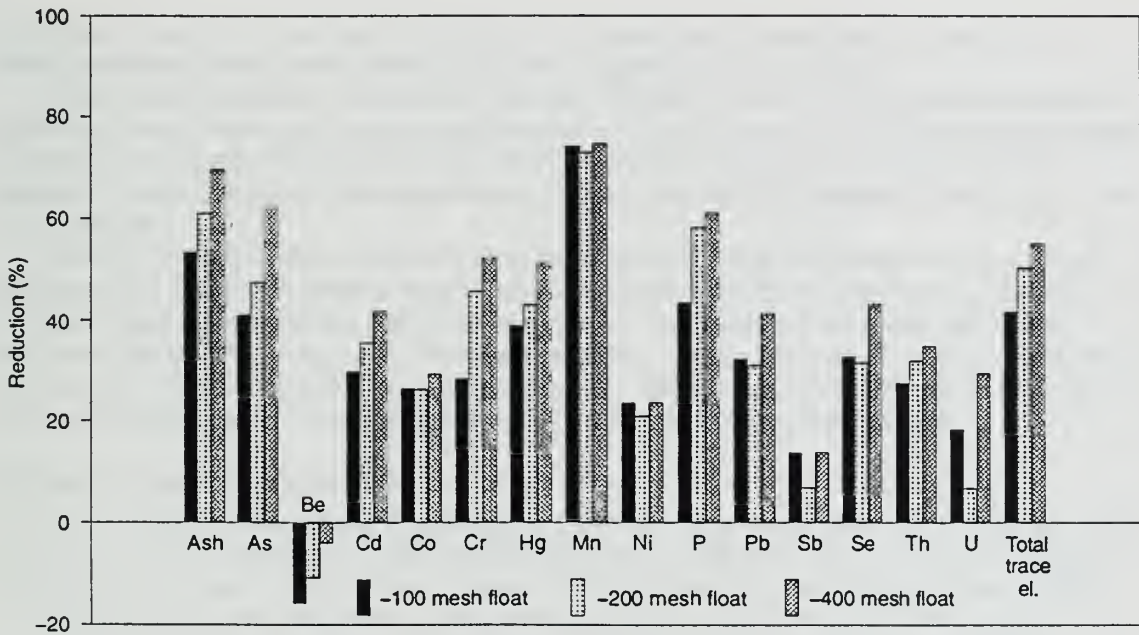

Figure 8 Reductions of average concentrations of ash and HAP elements in FF/RA products relative to those in washed (feed) coals for samples C32774, C32777, C32798, C32801, and C32793. The data for Be and U are averages of four and three samples, respectively.
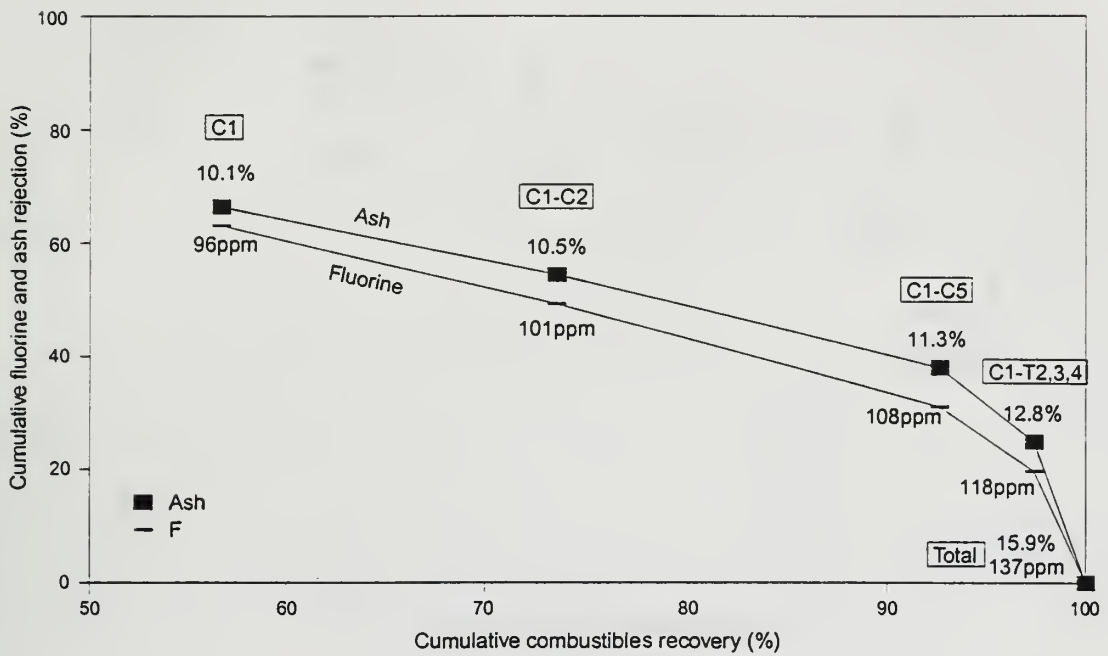

Figure 9 Release analysis curves indicating ash and F rejections versus combustibles recovery for the as-shipped sample C32796 ground to –100 mesh and cleaned through FF/RA. Numbers on the plot are actual ash (in %) and F (in ppm) values of the indicated cumulative concentrate (C1, C2, etc.) and tailing (T1, T2, etc.) fractions.

balances for the –400 mesh test than for the –100 mesh test. Present data cannot confirm whether this suggests a minor contamination during grinding in the rod mill.

Mass balance data can be plotted to generate release curves that indicate the beneficiation obtained in the progressive clean concentrates (C1-C5) and tailings (T1-T4). Examples of release curves are displayed in figures 9 and 10, which show that F removal follows ash removal. Achieving mass balances within experimental errors indicates a high degree of reliability for the data obtained.

Sample C32796, which was used for the mass balance study, is perhaps the most difficult one of the 34 as-shipped coals to clean. Most of the mineral matter in this coal may be in the form of disseminated clay minerals, a large portion of which could easily have remained in clean fractions during FF/RA separation. There is a possibility that for this type of sample, FF/RA may not be as efficient as a modern static tube column for reducing ash yield. Therefore, running column flotation tests on sample C32796 and similar coals should be considered.

SUMMARY AND CONCLUSIONS

Thirty-four washed (as-shipped) coal products collected from Illinois mines were tested at –100, –200, and –400 mesh sizes for froth flotation cleanability of ash and trace and minor elements; some were also tested for froth flotation cleanability of S and Cl. Composite samples of 80%-combustibles recovery were prepared by combining concentrates from the FF/RA tests in proportion to their ash contents. The composite samples as well as concentrate and tailing fractions from the FF/RA tests were chemically analyzed. Conclusions reached are as follows.

• Significant reduction for ash yield and most of the HAP elements is possible when deep cleaning is applied to the washed coals. At 80%-combustibles recovery, as much as 69%, 76%, and 83% reductions in ash yield were observed for the –100, –200, and –400 mesh FF/RA tests, respectively.
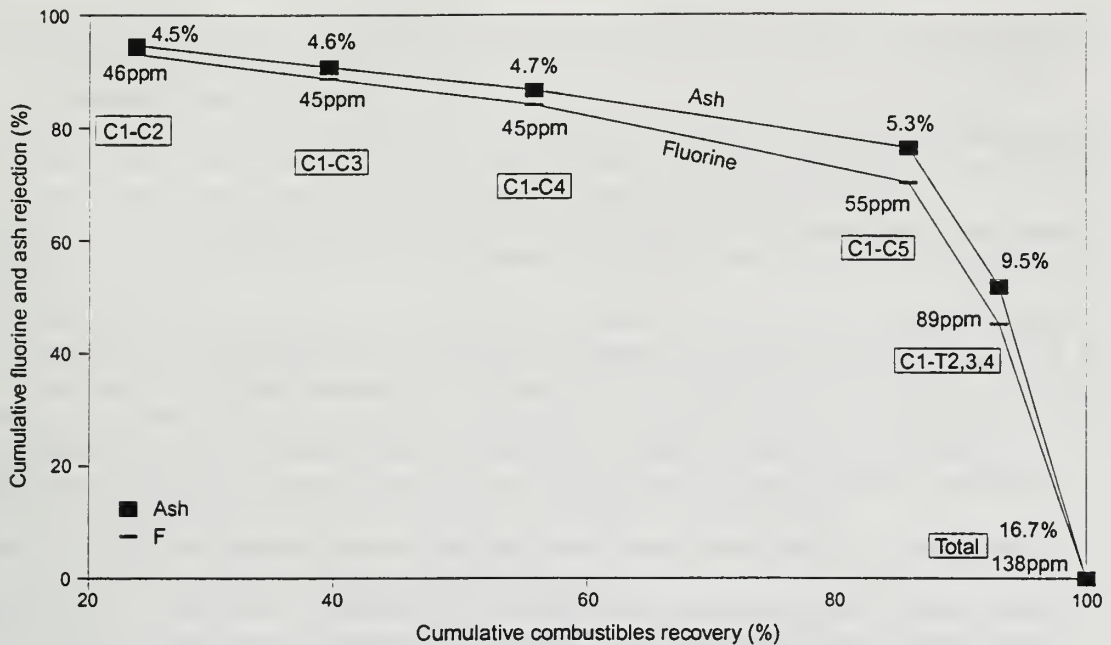

Figure 10 Release curves indicating ash and F rejections versus combustibles recovery for the as-shipped sample C32796 ground to –400 mesh and cleaned through FF/RA. Numbers on the plot are actual ash (in %) and F (in ppm) values of the indicated cumulative concentrate (C1, C2, etc.) and tailing (T1, T2, etc.) fractions.

• The average reductions for most HAP elements were less than those for ash yield. However, reductions for some elements in individual samples approached or exceeded reductions for ash yield. The elements with lower reductions than ash yield apparently are generally concentrated in finely disseminated minerals trapped in the FF/RA concentrates.

• Both the washed coals and their FF/RA products contain significantly less HAP elements than channel samples. In the –200 mesh FF/RA products with 80%-combustibles recovery, for example, average concentrations of As, Hg, and Se were reduced by 73%, 75%, and 46%, respectively, relative to their average concentrations in channel samples.

• Additional FF/RA beneficiation achieved by grinding as-shipped coals finer than –200 mesh is generally small. This is probably a result of trapping of fine ash-forming material in the FF/RA concentrates.

• Mass balances for ash yield, forms of S, Cl, and trace and minor elements were computed for FF/RA tests on one of the coals at –100 and –400 mesh sizes. Mass balances achieved were within analytical and experimental errors, except for sulfatic S; a significant amount of sulfatic S was generated during wet-grinding and FF/RA tests. However, a large portion of sulfatic S, as well as Cl, was washed away by the process water.

• It is possible that for samples with high contents of finely disseminated mineral matter, especially clays, FF/RA may not be as efficient as a modern static tube column in reducing ash yield. Therefore, tests on cleaning such samples with column flotation should be considered in the future.
