***Abstract:***

A considerable number of international research groups as well as commercial entities work on the development of new bone grafting materials, carriers, growth factors and specifically tissue engineered constructs for bone regeneration. They are strongly interested in evaluating their concepts in highly reproducible large segmental defects in preclinical and large animal models. To allow comparison between different studies and their outcomes, it is essential that animal models, fixation devices, surgical procedures and methods of taking measurements are well standardized to produce reliable data pools and act as a base for further directions to orthopaedic and tissue engineering developments, specifically translation into the clinic. In this leading opinion paper, we aim to review and critically discuss the different large animal bone defect models reported in the literature. We conclude that most publications provide only rudimentary information on how to establish relevant preclinical segmental bone defects in large animals. Hence, we express our opinion on methodologies to establish preclinical critically-sized, segmental bone defect models used in past research with reference to surgical techniques, fixation methods and post-operative management focusing on tibial fracture and segmental defect models.

4 *1. Clinical Background*  
5

6 In general, bone possesses a good healing capacity and the vast majority of  
7 bone defects, when stimulated by well balanced biological and micro-environmental  
8 conditions, heal spontaneously. Refinements in surgical techniques, implant design  
9 and peri-operative management have significantly improved the treatment of complex  
10 fractures and other skeletal defects caused by high energy trauma, disease,  
11 developmental deformity, revision surgery, and tumour resection [1-6]. However, an  
12 unfavourable wound environment, sub-optimal surgical technique or biomechanical  
13 instability can lead to formation of large defects with limited intrinsic regeneration  
14 potential [7]. Such defects pose a major surgical, socio-economical and research  
15 challenge and can highly influence the patient's quality of life due to limb length  
16 discrepancy and prolonged, postoperative treatment courses [8, 9].  
17

26  
27  
28  
29  
30

31 Even though cancellous bone fractures of the proximal humerus, distal radius  
32 or the tibia plateau often lead to impaction of bone and consequently a defect after  
33 reduction [4], the tibia shaft represents the most common anatomic site for segmental  
34 bone defects. This is because it is devoid of muscle coverage on its anteromedial  
35 surface [8]. The poor soft tissue coverage both increases the risk of bone loss and  
36 complicates treatment [8]. Historically, limb amputation was the principal treatment  
37 option when facing segmental, non-healing defect sites [10].  
38  
39  
40  
41  
42  
43  
44  
45  
46

47 Over the years, bone grafts have advanced as the "gold standard" treatment to  
48 augment or accelerate bone regeneration [1, 2, 11-17]. However, significant  
49 drawbacks are associated with this approach. Additional anaesthetic time and  
50 personnel are needed for graft harvesting [13, 15, 18]. In many cases, insufficient  
51 grafts are obtained and the access to donor sites is limited [13, 14, 19, 20]. Donor site  
52 pain or haemorrhage can occur and the donor bone is predispositioned for failure [4,  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 13, 14, 21]. Moreover, the risk of infection is significantly increased. Graft failures  
5  
6 usually result from incomplete transplant integration, particularly in large defect sites  
7  
8 [15]. In addition, graft devitalisation and subsequent resorption processes can lead to  
9  
10 decreased mechanical stability [22]. Vascularised autografts are technically  
11  
12 demanding and allografts and xenografts carry the risk of immune-mediated rejection,  
13  
14 graft sequestration and transmission of infectious disease [9, 23-29]. The dense nature  
15  
16 of cortical bone allografts impedes revascularization and cellular invasion from the  
17  
18 host following implantation [19]. This limited ability to revascularize and remodel is  
19  
20 believed to be responsible for a failure rate of 25% and a 30-60% complication rate  
21  
22 associated with allografts [19, 30]. In addition, the maintenance of bone banks is  
23  
24 rather costly. A technique introduced to avoid graft integration-related difficulties is  
25  
26 commonly referred to as the “Ilizarov technique” which involves osteotomy and  
27  
28 distraction to stimulate bone formation. It is used as a treatment modality for large  
29  
30 bone defects, infected non-unions, and limb length discrepancy [31]. However, the  
31  
32 Ilizarov technique is a long-lasting procedure, highly inconvenient for the patient [32,  
33  
34 33] with recurrent pin track infections as a frequent complication [25, 34].  
35  
36  
37  
38  
39

40 In order to avoid the limitations associated with the current standard treatment  
41  
42 modalities for segmental bone deficiencies, there has been a continuous interest in the  
43  
44 use of naturally derived and synthetic bone graft substitutes during the past decades.  
45  
46

47 More recently, the concept of tissue engineering has emerged as an important  
48  
49 approach to bone regeneration research. Tissue engineering unites aspects of cellular  
50  
51 biology, biomechanical engineering, biomaterial sciences and trauma and orthopaedic  
52  
53 surgery. Its general principle involves the association of cells with a natural or  
54  
55 synthetic supporting scaffold to produce a three-dimensional, implantable construct.  
56  
57 To biomechanically simulate human *in vivo* conditions as closely as possible, and to  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 assess the effects of implanted bone grafts and tissue engineered constructs on  
5  
6 segmental long bone defect regeneration, a number of large animal models have been  
7  
8 developed. However, reviewing the current literature most of the preclinical models  
9  
10 reported in the literature are not well described, defined and standardized. This year,  
11  
12 the Journal of Bone and Joint Surgery published a number of review papers on  
13  
14 preclinical models in fracture healing and on non-unions [49]. However, these articles  
15  
16 provide only rudimentary information on how to establish relevant preclinical  
17  
18 segmental bone defects in a large animal model. Hence, the aim of this leading  
19  
20 opinion article is to provide both detailed information on the advantages and  
21  
22 disadvantages of the different animal models and to comprehensively share the  
23  
24 expertise and knowledge of three research groups that successfully established a  
25  
26 preclinical animal model for critically sized segmental bone defects.  
27  
28  
29  
30  
31  
32

33 *2. Definition of a Critical-Size Bone Defect*  
34

35 An experimental osseous injury inflicted to study bone repair mechanisms  
36  
37 should be of dimensions to preclude spontaneous healing [35]. Therefore, the non-  
38  
39 regenerative threshold of bone was determined in research animal models inducing  
40  
41 so-called critical-sized defects. Critical sized defects are defined as “the smallest size  
42  
43 intraosseous wound in a particular bone and species of animal that will not heal  
44  
45 spontaneously during the lifetime of the animal” [30, 36, 37] or as a defect which  
46  
47 shows less than 10 percent bony regeneration during the lifetime of the animal [37].  
48  
49  
50

51 Although the minimum size that renders a defect “critical” is not well  
52  
53 understood, it has been defined as a segmental bone deficiency of a length exceeding  
54  
55 2-2.5 times the diameter of the affected bone [25, 34]. Results of various animal  
56  
57 studies suggest that critical sized defects in sheep, however, could be approximately  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 three times the diameter of the corresponding diaphysis [34]. Nevertheless, a critical  
5  
6 defect in long bone cannot simply be defined by its size but may also be dependent on  
7  
8 the species phylogenetic scale, anatomic defect location, associated soft tissue and  
9  
10 biomechanical conditions in the affected limb as well as age, metabolic and systemic  
11  
12 conditions, and related morbidities affecting defect healing [25, 36].  
13  
14  
15  
16

### 17 *3. Large animal models in bone defect research*

18  
19  
20 Animal models in bone repair research include representations of normal  
21  
22 fracture-healing, segmental bone defects, and fracture non-unions in which regular  
23  
24 healing processes are compromised without presence of a critical-sized defect site  
25  
26 [38]. In critical-sized segmental defect models bridging of the respective defect does  
27  
28 not occur despite a sufficient biological microenvironment due to the removal of  
29  
30 critical amounts of bone substance. In contrast, in a true non-union deficient  
31  
32 signalling mechanisms, biomechanical stimuli or cellular responses may prevent  
33  
34 defect healing rather than the defect size.  
35  
36  
37

38  
39 When selecting a specific animal species as a model system, a number of factors  
40  
41 need to be considered. In comparison to humans, the chosen animal model should  
42  
43 clearly demonstrate both significant physiological and pathophysiological analogies in  
44  
45 respect to the scientific question under investigation prior to animal selection.  
46  
47 Moreover, it must be manageable to operate and observe a multiplicity of study  
48  
49 objects post surgery over a relatively short period of time [39-41]. Further selection  
50  
51 criteria include costs for acquisition and care, animal availability, acceptability to  
52  
53 society, tolerance to captivity and ease of housing [42].  
54  
55  
56

57  
58 Several publications over the last decades have described dogs as a suitable  
59  
60 model for research related to human orthopaedic conditions [43]. It was found that in  
61  
62  
63  
64  
65

1  
2  
3  
4 regard to bone weight, density and bone material constituents such as hydroxyproline,  
5  
6 extractable proteins, IGF-1, organic, inorganic and water fraction, dogs were the  
7  
8 closest to humans although clear differences in bone microstructure and remodelling  
9  
10 have been described [44, 45]. While the secondary structure of human bone is  
11  
12 predominantly organized in osteones, osteonal bone structure in dogs is limited to the  
13  
14 core of cortical bone, whereas in areas adjoining the periosteum and endosteum  
15  
16 mainly laminar bone is found. This is characteristic for large, fast-growing animals  
17  
18 [46]. It has been reported that higher rates of trabecular and cortical bone turnover can  
19  
20 be generally observed in dogs compared to humans [47] and differences in loads  
21  
22 acting on the bone as a result of the dog's quadrupedal gait must be taken into  
23  
24 consideration as well. A review article by Neyt states that between 1991 and 1995  
25  
26 11% of musculoskeletal research was undertaken in dogs. This is confirmed by  
27  
28 Martini et al. who find that between 1970 and 2001, 9% of orthopaedic and trauma  
29  
30 related research used dogs as animal models for orthopaedic and trauma-related  
31  
32 research [43, 48]. Recently, the use of dogs as experimental models has significantly  
33  
34 decreased mainly due to ethical issues, although between 1998 and 2008  
35  
36 approximately 9% of articles published in leading orthopaedic and musculoskeletal  
37  
38 journals described dogs as animal models for fracture healing research [49].  
39  
40  
41  
42  
43  
44

45 Mature sheep and goats possess a bodyweight comparable to adult humans and  
46  
47 long bone dimensions enabling the use of human implants [50]. The mechanical  
48  
49 loading environment occurring in sheep is well understood [51, 52]. The loading of  
50  
51 the hind limb bones, forces and moments, is roughly half of that determined for  
52  
53 humans during walking (Fig. 1). Since no major differences in mineral composition  
54  
55 [53] are evident and both metabolic and bone remodelling rates are akin to humans  
56  
57 [54], sheep are considered a valuable model for human bone turnover and remodelling  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 activity [55]. Bone histology however reveals some differences in bone structure  
5  
6 between sheep and humans. In sheep, bone consists principally of primary bone  
7  
8 structure [56] in comparison with the largely secondary, haversian bone composition  
9  
10 of humans [57]; furthermore the secondary, osteonal remodelling in sheep does not  
11  
12 take place until an average age of 7-9 years (Fig. 2)[50]. Although a significantly  
13  
14 higher trabecular bone density and greater bone strength was described for mature  
15  
16 sheep when compared to humans, the trabecular bone in immature sheep is weaker,  
17  
18 has a lower stiffness and density, a higher flexibility due to higher collagen content  
19  
20 [58], and shows comparable bone healing potential and tibial blood supply [59].  
21  
22

23  
24 In a variety of study designs, pigs are considered the animal of choice and were -  
25  
26 despite their denser trabecular network [60] - described as a highly representative  
27  
28 model of human bone regeneration processes in respect to anatomical and  
29  
30 morphological features, healing capacity and remodelling, bone mineral density and  
31  
32 concentration [44, 61]. However, pigs are often neglected in favour of sheep and goats  
33  
34 given that the handling of pigs has been described as rather intricate [50].  
35  
36 Furthermore, the length of the tibiae and femora in the pig is relatively small, which  
37  
38 causes the need for special implants, as one cannot use implants designed human use.  
39  
40  
41  
42  
43  
44

### 45 *3.1. Tibial fracture models*

46

47 Animal fracture models have been widely investigated to identify and further  
48  
49 characterize physiological and pathophysiological processes of fracture healing of  
50  
51 long bones. One of the most important elements in the study of fracture healing or  
52  
53 fixation is the establishment of standardized methods to create reproducible fractures.  
54  
55 Although a substantial number of articles on fracture models in animals and treatment  
56  
57 options have been described over the last decades, only few publications describe the  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 actual infliction of a fracture by trauma rather than the creation of a bony defect < 3  
5  
6 mm size by osteotomy, which is generally accepted as an alternative since it is less  
7  
8 problematic to standardize. In 1988, Macdonald et al. [62, 63] reported a device for  
9  
10 the reproducible creation of transverse fractures in canine tibiae utilizing a three-point  
11  
12 bending technique.  
13

14  
15 Similarly, to compare the effects of reamed versus unreamed locked intramedullary  
16  
17 nailing on cortical bone blood flow Schemitsch et al. created a standardized spiral  
18  
19 fracture by three-point bending with torsion in a fractured sheep tibia model [64, 65],  
20  
21 a method also described by Tepic [66] to establish a standardized oblique fracture in  
22  
23 sheep tibiae in order to compare healing in fractures stabilized with either a  
24  
25 conventional dynamic compression plate (DCP) or an internal point contact fixator  
26  
27 (PC-Fix). A minimally invasive approach to create a multifragmental fracture in the  
28  
29 sheep femur (classification by the Association for the Study of Internal Fixation, AO  
30  
31 type 32-C), in which the bone was weakened by two short, transverse anterior  
32  
33 osteotomies and bi-cortical drill holes created through small incisions, has recently  
34  
35 been described by Wullschleger et al. (unpublished data, Fig. 3). The insertion of two  
36  
37 chisels and one blade bar were then used to initiate cracks connecting both the  
38  
39 osteotomies and the drill holes, thereby creating a standardized multifragmental  
40  
41 fracture. This technique could easily be adopted when establishing standardized tibial  
42  
43 fractures as well.  
44  
45  
46  
47  
48

49  
50 Fracture models of osteotomized long bones have been well characterized over  
51  
52 the years in different large animal species. A number of publications have described  
53  
54 fracture models in dogs since the dog, beside pigs, is considered the most closely  
55  
56 related model for research of human orthopaedic conditions. The effect of bending  
57  
58 stiffness of external fixators on the early healing of transverse tibial osteotomies was  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 described in a canine model by Gilbert [67]. Tiedemann et al. assessed densitometric  
5  
6 approaches to measure fracture healing in 6-mm tibial segmental defects and single-  
7  
8 cut osteotomy defects in adult mongrel dogs [68]. Bilateral tibial transverse  
9  
10 osteotomies were performed with a 2-mm gap by Markel et al. to quantify local  
11  
12 material properties of fracture callus during gap healing [69]. To compare the dosage-  
13  
14 dependent efficacy of recombinant human bone morphogenetic protein-2 (rhBMP-2)  
15  
16 on tibial osteotomy healing, adult female dogs underwent right midshaft tibial  
17  
18 osteotomies with a 1-mm gap. The operated bones were stabilized using type I  
19  
20 external fixators [70]. In a similar study by Edwards, bilateral tibial osteotomies were  
21  
22 performed to evaluate the capacity of a single percutaneous injection of rhBMP-2  
23  
24 delivered in a rapidly resorbable calcium phosphate paste (alpha-BSM) to accelerate  
25  
26 bone-healing [71]. The effect of shock wave therapy on acute tibial fractures was  
27  
28 studied by Wang et al. in adult dogs after creation of bilateral tibial osteotomies with a  
29  
30 3-mm defined fracture gap [72]. Similar models were also described by Hupel to  
31  
32 compare the effects of unreamed and reamed nail insertion [73], Jain et al. [74] to  
33  
34 investigate whether or not the limited contact design of the low-contact dynamic  
35  
36 compression plate (LC-DCP) provides advantages over the dynamic compression  
37  
38 plate (DCP) in the context of cortical bone blood flow, biomechanical properties, and  
39  
40 remodelling of bone in segmental tibial fractures and Nakamura [75] to evaluate  
41  
42 effects of recombinant human basic fibroblast growth factor (bFGF) on fracture  
43  
44 healing in beagle dogs.  
45  
46  
47  
48  
49  
50

51  
52 As previously mentioned, mature sheep and goats possess a bodyweight  
53  
54 similar to adult humans, show no major differences in bone mineral composition with  
55  
56 similar metabolic and bone remodelling rates, and therefore are considered a valuable  
57  
58 model for human bone turnover and remodelling activity often used in fracture  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 research. In the period between 1990 and 2001, sheep as an animal model were used  
5  
6 in 9-12% of orthopaedic research, compared to only 5% between 1980 and 1989 [43].  
7  
8 Over the last ten years numbers of studies utilizing sheep and goats as animal models  
9  
10 have even increased to 11-15% [49].  
11

12  
13 The significance of postoperative mechanical stability for bony repair of a  
14  
15 comminuted fracture was investigated in a sheep study comparing four commonly  
16  
17 applied operative methods of stabilizing fractures. In this study, a triple-wedge  
18  
19 osteotomy of the right sheep tibia was used as a fracture model [76]. Using a standard  
20  
21 osteotomy of the ovine tibia stabilised by an external skeletal fixator, Goodship et al.  
22  
23 elucidated the influence of fixator frame stiffness on bone healing rates [77]. Wallace  
24  
25 et al. [78] used a similar model to investigate serum angiogenic factor levels after  
26  
27 tibial fracture. Likewise, transverse mid-diaphyseal osteotomies with an  
28  
29 interfragmentary gap of 3 mm, as an experimental fracture model in sheep, were used  
30  
31 to assess fracture repair processes [79-82]. To validate the principle of external  
32  
33 fixation dynamization in order to accelerate mineralized callus formation by *in vivo*  
34  
35 measurements of callus stiffness, transverse fractures with an interfragmentary gap of  
36  
37 3 mm width were created in the mid third of the tibial diaphysis [83]. Hantes et al.  
38  
39 investigated the effect of transosseous application of low-intensity ultrasound on  
40  
41 fracture-healing in a midshaft osteotomy sheep model [84]. Epari et al. were the first  
42  
43 authors to reported on the pressure, oxygen tension and temperature in the early phase  
44  
45 of callus tissue formation of six Merino-mix sheep that underwent a tibial osteotomy  
46  
47 to model fracture conditions [85]. In this study, the tibia was stabilized with a  
48  
49 standard mono-lateral external fixator. It was found that the maximum pressure during  
50  
51 gait increased from three to seven days. During the same interval, there was no  
52  
53 change in the peak ground reaction force or in the interfragmentary movement.  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 Oxygen tension in the haematoma was initially high post-op and decreased steadily  
5  
6 over the first five days. The temperature increased over the first four days before  
7  
8 reaching a plateau on day four.  
9

10  
11 Mechanical strain during callus distraction is known to stimulate osteogenesis  
12  
13 and it is so far unclear whether this stimulus can enhance the healing of a fracture  
14  
15 without affecting bone length. Just recently, Claes et al., reported for the first time that  
16  
17 a slow temporary distraction and compression of a diaphyseal osteotomy accelerates  
18  
19 fracture healing [86] in a mid-diaphyseal osteotomy fracture model of the right tibia in  
20  
21 sheep, stabilized by external fixation (Fig. 4).  
22  
23  
24  
25  
26

### 27 *3.2. Tibial segmental defect models*

28  
29 In order to ascertain whether newly developed bone graft substitutes or tissue  
30  
31 engineered constructs (TEC) comply with the requirements of biocompatibility,  
32  
33 mechanical stability and safety, the materials must be subject to rigorous testing both  
34  
35 *in vitro* and *in vivo*. To extrapolate results from *in vitro* studies to *in vivo* patient  
36  
37 situations however is often difficult. Therefore, the application and systematic  
38  
39 evaluation of new concepts in animal models is often an essential step in the process  
40  
41 of assessing newly developed bone grafts prior to clinical use in humans. To simulate  
42  
43 human *in vivo* conditions as closely as possible, a variety of large critical sized tibial  
44  
45 defect models - mainly in sheep - have been developed over the past decade in order  
46  
47 to investigate the influence of different types of bone grafts on bone repair and  
48  
49 regeneration. Critical sized segmental defects in long bones are usually defined by  
50  
51 multiplying the shaft diameter by 2.0-2.5 [25, 34]. Interestingly, the method of  
52  
53 producing the gap may influence the outcome of those studies. Kuttenger et al.  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 could show that by using a CO<sub>2</sub>-laser, the osteotomy ends were not as impaired in  
5  
6 structure as when using an oscillating saw [87].  
7

8  
9 To evaluate the effects of different bioceramics on bone regeneration during  
10 repair of segmental bone defects Gao et al. [88] implanted biocoral and tricalcium  
11 phosphate cylinders (TCP) in sheep tibial defects of 16 mm length. The defects were  
12 stabilized medially using two overlapping contoured auto-compression plates of 4 mm  
13 thickness (8 and 6 holes) and cortical screws. When compared to TCP, with the  
14 biocoral implants, a significant increase in external callus and density was seen after  
15 three weeks and an increase of torque capacity, maximal angle of deformation and  
16 energy absorption could be measured after 12 weeks while microscopically  
17 osseointegration appeared better. However, in his study, Gao used both male and  
18 female animals with a relatively large variation in body weight. Both factors, gender  
19 and body weight are known to have an influence on bone regeneration due to effects  
20 both on the biomechanical environment and hormonal feed-back control mechanisms.  
21 Hence, variations in sex and body weight should be avoided by all means. The defect  
22 fixation method used in this study can most likely be interpreted as a means to  
23 counteract bending forces on the implant after earlier failures. However, defect  
24 fixation by overlapping plates is not necessarily *lege artis* and has never been  
25 introduced and applied clinically to our knowledge. Therefore, a thicker and hence,  
26 stiffer plate should be chosen instead.  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47  
48

49 Den Boer et al. reported a new segmental bone defect model where a 30 mm  
50 segmental defect was inflicted on sheep tibiae and stabilized by an interlocking  
51 intramedullary nail (custom made AO unreamed humeral nail). X-ray absorptiometry  
52 was applied to quantify healing [55]. Groups of this pilot study included untreated  
53 controls and autograft. After 12 weeks, despite higher bone mineral density in the  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 autograft group, no significant difference in torsional strength and stiffness could be  
5  
6 revealed. Since 33% of the control animals showed sufficient bridging of the defect, it  
7  
8 needs to be questioned if the authors succeeded in establishing a reliable non-union  
9  
10 model. Removal of the periosteum or a larger defect site might have been beneficial.  
11  
12 In a subsequent study, the authors described the fabrication of biosynthetic bone grafts  
13  
14 and their application in the very same animal model [4]. The five treatment groups  
15  
16 included empty controls, autografts, hydroxyapatite alone, hydroxyapatite combined  
17  
18 with rhOP-1, and hydroxyapatite with autologous bone marrow. At 12 weeks, healing  
19  
20 of the defect was evaluated radiographically, biomechanically and histologically and  
21  
22 revealed that torsional strength and stiffness were two fold higher for animals treated  
23  
24 with autograft and hydroxyapatite plus rhOP-1 or bone marrow. Since healing was  
25  
26 only evaluated after 12 weeks, no conclusions could be drawn regarding the process  
27  
28 of healing. The mean values of both combination groups were comparable to those of  
29  
30 autografts. A higher number of defect unions was described when hydroxyapatite plus  
31  
32 rhOP-1 was applied rather than hydroxyapatite alone. Analysing this study, it has to  
33  
34 be taken into account that animals treated with hydroxyapatite and bone marrow were  
35  
36 of a different breed with a higher average body weight. Animals were held at a  
37  
38 different holding facility and accustomed to unequal forage all of which could  
39  
40 possibly influence study outcomes.  
41  
42  
43  
44  
45  
46

47 Bone healing in critical sized segmental diaphyseal defects in sheep tibiae was also  
48  
49 investigated by Gugala et al. [3, 37]. Defects were bridged with a single porous  
50  
51 tubular membrane or with anatomically shaped porous double tube-in-tube  
52  
53 membranes. Membranes with different pore structures were applied alone and/or in  
54  
55 combination with autologous bone graft. The diaphyseal defects were 40 mm in  
56  
57 length and stabilized with a bilateral AO external fixator. Operated animals were 6 to  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 7 years of age. Of the six treatment groups however, only in groups where the defect  
5  
6 was filled with autogenous cancellous bone graft and covered with a single perforated  
7  
8 membrane or where the bone graft was administered in a space between a perforated  
9  
10 internal and external membrane, could defect healing be observed. The authors partly  
11  
12 contribute the healing effect to their membrane system; however a control group,  
13  
14 where autologous bone graft is administered without any membrane was not  
15  
16 described. It could also be criticized that post surgery animals were suspended in  
17  
18 slings over the entire experimental period preventing the animals from sitting and  
19  
20 therefore getting up, thus not reflecting the normal physiological load bearing  
21  
22 conditions.  
23  
24

25  
26 Wefer et al. [89] conducted a study to develop and test a scoring system based  
27  
28 on real-time ultrasonography to predict the healing of a bone defect filled with a  
29  
30 porous hydroxyapatite bone graft substitute or cancellous bone graft from the iliac  
31  
32 crest and stabilized by anterolateral plate osteosynthesis. After sacrifice tibiae were  
33  
34 tested in torsion to failure. The results were correlated with radiographic and  
35  
36 ultrasound scores obtained. Sheep with ceramic implants that developed non-unions  
37  
38 showed a significantly lower score than sheep with sufficient implant integration. A  
39  
40 significant correlation between these scores and the biomechanical results was found.  
41  
42 However, although the authors describe their 20 mm defect as a critical sized model,  
43  
44 no control group was included for comparison. Hence, based on the clinical  
45  
46 experience in sheep the contributing authors from three different research groups have  
47  
48 gathered over the years, and the definition of a critical defect length requiring at least  
49  
50 2-2.5 times the diameter of the bone, the critical nature of the defect in this study can  
51  
52 be questioned.  
53  
54

65

1  
2  
3  
4 The effects of new resorbable calcium phosphate particles and paste forms,  
5  
6 which harden in situ after application, on bone healing were investigated by Bloemers  
7  
8 et al. [90]. They used a 30 mm segmental tibial defect fixed by a custom made AO  
9  
10 unreamed interlocking titanium tibial nail. Twelve weeks after defect reconstruction,  
11  
12 radiological, biomechanical, and histological examinations were performed.  
13  
14 Radiographically, the resorbable paste group performed better than all other groups.  
15  
16 Biomechanical tests revealed a significantly higher torsional stiffness for the  
17  
18 resorbable calcium-phosphate paste group in comparison with autologous bone. The  
19  
20 study indicated that new calcium phosphate based materials might be a potential  
21  
22 alternative for autologous bone grafts in humans. As with several other studies  
23  
24 critically reviewed in this article, animals of a minimum age of 2 years with a  
25  
26 significant variation in body weight were used in this study. As mentioned before, it  
27  
28 must be considered that secondary osteonal bone remodelling in sheep does not occur  
29  
30 until an age of 7-9 years. Therefore, it might be difficult to extrapolate results from  
31  
32 this study for applications in adult human patients as human bone primarily undergoes  
33  
34 secondary osteonal bone remodelling. Insulin-like growth factor I (IGF-1) exerts an  
35  
36 important role during skeletal growth and bone formation. Therefore, its localized  
37  
38 delivery appears attractive for the treatment of bone defects. To prolong IGF -1  
39  
40 delivery, Meinel et al. entrapped the protein into biodegradable poly(lactide-co-  
41  
42 glycolide) microspheres and evaluated the potential of this delivery system for new  
43  
44 bone formation in a non-critical 10 mm segmental tibia defect [91]. The defect was  
45  
46 stabilized using a 3.5 mm 11 hole DCP. Administration of 100 µg of IGF-1 in the  
47  
48 microspheres resulted in bridging of the segmental defect within 8 weeks. To avoid  
49  
50 excessive load on the operated limbs and fracturing of the freshly operated tibial  
51  
52 defects, the animals were accommodated in a suspension system for a period of 4  
53  
54  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 weeks postoperatively thus preventing physiologic-like biomechanical conditions.  
5  
6 When interpreting data published in this study, it must be taken into account that the  
7  
8 close position of the screws to the defect proximally and distally, and the obvious fact  
9  
10 that the screws at the defect site had not been inserted at a defined angle might have  
11  
12 influenced and biased the outcomes.  
13  
14

15 In a 48 mm tibial defect model in sheep ceramic implants of 100% synthetic calcium  
16  
17 phosphate multiphase biomaterial were evaluated [92]. The defect was stabilized with  
18  
19 a 4.5 mm neutralizing plate. Although not reported by the authors, one can observe  
20  
21 bent plates and axial deviations in presented x-ray and CT images, hence, from a  
22  
23 clinical point of view, it must be concluded that the chosen fixation in that model  
24  
25 seemed not to be sufficient (Fig. 5). The x-ray series of the 2 year animal suggests that  
26  
27 the internal fixation device had been explanted 12-14 weeks post surgery, a fact not  
28  
29 described and explained by the authors. Assuming recovery and bone regeneration  
30  
31 without any complications, in human patients, internal fixation devices would usually  
32  
33 not be removed until 12-18 months post implantation. Good integration between the  
34  
35 ceramic implants and the adjoining proximal and distal bone ends was observed. A  
36  
37 progressive increase in new bone formation was seen over time, along with  
38  
39 progressive resorption of the ceramic scaffold. Based on x-ray analysis, at the one-  
40  
41 year time-point, approximately 10% to 20% of the initial scaffold substance was still  
42  
43 present, and after two years it was almost completely resorbed. The authors state that  
44  
45 approximately 10-20% of the periosteum was deliberately left in situ as a source of  
46  
47 osteogenic cells. However, one might conclude that this procedure appears to be  
48  
49 rather difficult to standardize in order to develop a reproducible model.  
50  
51  
52  
53  
54  
55

56 Another study using an ovine segmental defect model investigated the  
57  
58 influence of rhTGF $\beta$ -3 on mechanical and radiological parameters of a healing bone  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 defect [93]. In 4-5 year old sheep, an 18 mm long osteoperiosteal defect in the tibia  
5  
6 fixed with a unilateral external fixator was treated by rhTGF $\beta$ -3 delivered by a  
7  
8 poly(L/DL-lactide) carrier, with the carrier only, with autologous cancellous bone  
9  
10 graft, or remained untreated. Weekly *in vivo* stiffness measurements and radiological  
11  
12 assessments were undertaken as well as quantitative computed tomographic  
13  
14 assessments of bone mineral density in 4 week intervals. The follow up of the  
15  
16 experiment was 12 weeks under partial weight bearing since animals were kept in a  
17  
18 support system to prevent critical loads on the fixator and its interface to bone thus not  
19  
20 reflecting physiological loading conditions. The 18 mm defect size described as  
21  
22 spontaneously non-healing, might not have been sufficient to establish a non-union  
23  
24 model in a fully weight bearing biomechanical environment. In the bone graft group, a  
25  
26 significantly higher increase in stiffness was observed than in the PLA/rhTGF $\beta$ -3  
27  
28 group and a significantly higher increase than in the PLA-only group. The  
29  
30 radiographic as well as the computer tomographic evaluation yielded significant  
31  
32 differences between the groups, indicating the bone graft treatment performed better  
33  
34 than the PLA/rhTGF $\beta$ -3 and the PLA-only treatment.  
35  
36  
37  
38  
39

40 Sarkar et al. assessed the effect of platelet rich plasma (PRP) on new bone  
41  
42 formation in a 25 mm diaphyseal tibial defect in sheep [94]. The defect was stabilized  
43  
44 with a custom-made intramedullary nail (stainless steel, diameter proximal 12 mm,  
45  
46 distal 10 mm) with two locking screws each proximal and distal. To reduce stress at  
47  
48 the screw/bone interface, a custom made stainless steel plate was additionally applied  
49  
50 medially representing an unconventional fixation method not found in the clinic.  
51  
52 However, no reasoning for the additional medial plating was provided in the  
53  
54 publication by the authors. Defects were treated with autogenous PRP in a collagen  
55  
56 carrier or with collagen alone. A control group to establish the critical nature of the  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 defect was not included and has therefore to be questioned. After 12 weeks, the  
5  
6 explanted bone specimens were quantitatively assessed by X-ray, computed  
7  
8 tomography (CT), biomechanical testing and histological evaluation. Bone volume,  
9  
10 mineral density, mechanical rigidity and histology of the newly formed bone in the  
11  
12 defect did not differ significantly between the PRP treated and the control group, and  
13  
14 no effect of PRP upon bone formation was observed.  
15

16  
17 In 2007 Tyllianakis [95] determined the size of a bone defect that can be  
18  
19 restored with one-stage lengthening over a reamed intramedullary nail in sheep tibiae.  
20  
21 Sixteen adult female sheep were divided into four main groups: a simple osteotomy  
22  
23 group (group I) and three segmental defect groups (10, 20, and 30 mm gaps, groups  
24  
25 II-IV). One intact left tibia from each group was also used as the non-osteotomized  
26  
27 intact control group (group V). In all cases, the osteotomy was fixed with an  
28  
29 interlocked Universal Humeral Nail (UHN-Protek-Synthes). Healing of the  
30  
31 osteotomies was evaluated after 16 weeks by biomechanical testing. The examined  
32  
33 parameters were torsional stiffness, shear stress, and angle of torsion at the time of  
34  
35 fracture. The regenerate bone obvious in x-rays in the groups with 10 and 20 mm gaps  
36  
37 had considerable mechanical properties. Torsional stiffness in these two groups was  
38  
39 nearly equal and its value was about 60% of the stiffness of the simple osteotomy  
40  
41 group. Gradually decreasing stiffness was observed as the osteotomy gap increased.  
42  
43 No significant differences were found among the angles of torsion at fracture for the  
44  
45 various osteotomies or the intact bone. These results showed that the group with the  
46  
47 10 cm gap had 65% of the shear stress at failure compared to the simple osteotomy  
48  
49 group.  
50  
51

52  
53 Teixeira et al. treated tibial segmental defects of 35 mm size in both male and  
54  
55 female sheep aged four to five months. Considering the age of the animals and the  
56  
57  
58  
59

61  
62  
63  
64  
65

1  
2  
3  
4 preservation of the periosteum, the critical size of this defect can be questioned and  
5  
6 results cannot necessarily be extrapolated to adult humans, as described correctly by  
7  
8 the authors. An empty control group was not included in the experiment. The bone  
9  
10 defects in the diaphysis of the right hind limb were stabilized with a titanium bone  
11  
12 plate (103 mm in length, 2 mm thickness, and 10 mm width) combined with a  
13  
14 titanium cage. As reported by the authors, plate bending occurred in 42% of the  
15  
16 animals and was partly attributed to the connection of the titanium cage to the plate.  
17  
18 However, it appears that the bending of the plate was rather a result of insufficient  
19  
20 thickness of the fixation device. The titanium cages were either filled with autologous  
21  
22 cortical bone graft or with a composite biomaterial consistent of inorganic bovine  
23  
24 bone, demineralised bovine bone, a pool of bovine bone morphogenetic proteins  
25  
26 bound to absorbable ultra-thin powdered hydroxyapatite and bone-derived  
27  
28 denaturated collagen. Bone defect healing was assessed clinically, radiographically  
29  
30 and histologically. Titanium cages might keep implanted scaffolds and biomaterials in  
31  
32 place initially and biomechanically support defect fixation, however, it must be taken  
33  
34 into consideration that – since titanium is not resorbable – the cages might hinder  
35  
36 complete bone remodelling in the long run.  
37  
38  
39  
40  
41

42 Radiographic examination showed initial formation of periosteal callus in both groups  
43  
44 at osteotomy sites, over the plate or cage 15 days postoperatively. At 60 and 90 days  
45  
46 callus remodelling occurred. Histological and morphometric analysis 90 days post  
47  
48 surgery showed that the quantity of implanted materials still present were similar for  
49  
50 both groups while the quantity of newly formed bone was less ( $p=0.0048$ ) in the  
51  
52 cortical bone graft group occupying  $51 \pm 3.46\%$  and  $62 \pm 6.26\%$  of the cage space,  
53  
54 respectively [96].

3  
4 Recently, Liu et al. reported on the use of highly porous beta-TCP scaffolds to  
5  
6 repair goat tibial defects [13]. In this study, fifteen goats were randomly assigned to  
7  
8 one of three groups, and a 26 mm-long defect at the middle part of the right tibia in  
9  
10 each goat was created and stabilized using a circular external fixator. In Group A, a  
11  
12 porous beta-TCP ceramic cylinder that had been loaded with osteogenically induced  
13  
14 autologous bone marrow stromal cells was implanted in the defect of each animal. In  
15  
16 Group B, the same beta-TCP ceramic cylinder without any cells was placed in the  
17  
18 defect. In Group C, the defect was left untreated. In Group A, bony union could be  
19  
20 observed by gross view, X-ray and micro-computed tomography ( $\mu$ CT) detection, and  
21  
22 histological observation at 32 weeks post-implantation. The implanted beta-TCP  
23  
24 scaffolds were almost completely replaced by host bone. Bone mineral density in the  
25  
26 repaired area of Group A was significantly higher than in Group B, in which scant  
27  
28 new bone was formed in each defect and the beta-TCP hadn't been completely  
29  
30 resorbed after 32 weeks. Moreover, the tissue-engineered bone of Group A had  
31  
32 similar biomechanical properties as the contralateral tibia in terms of bending strength  
33  
34 and Young's modulus. In Group C, little or no new bone was formed and non-union  
35  
36 occurred, demonstrating the critical nature of the defect.  
37  
38  
39  
40  
41  
42

43 To investigate the effect of chondroitine sulphate on bone remodelling and  
44  
45 regeneration, Schneiders et al. [97] created a 30 mm tibial mid-diaphyseal defect site  
46  
47 and reconstructed it using hydroxyapatite/collagen cement cylinders. Defect  
48  
49 stabilization was achieved by insertion of a universal tibial nail (UTN, Synthes,  
50  
51 Bochum). However, to place the scaffold into the defect, the authors had to use a  
52  
53 second operative aditus mid-diaphyseally. The published data suggest problems with  
54  
55 defect fixation not only due to reported implant failures but also to clearly evident  
56  
57 signs of locking bolt loosening, poor contact between bone and nail, and the proximal  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 nail end extending into the articular space (Fig. 6), facts not reported by the authors.  
5  
6 Moreover, it can be supposed that either the insertion of the nail or undesired  
7  
8 movement of the loosened nail has caused damage to the cylindrical biomaterials at  
9  
10 testing. When interpreting the acquired data, it also has to be taken into account that  
11  
12 obviously no fabrication method has been described to reliably reproduce implants of  
13  
14 corresponding geometrical shape.  
15

16  
17 The rapid progression of bone graft research and the great number of novel  
18  
19 developments must be supported by systematic assessment based on clinical  
20  
21 practicability and experience, the knowledge of basic biological principles, medical  
22  
23 necessity, and commercial practicality. From our literature review, it can be  
24  
25 concluded, that in a majority of the mentioned studies, follow up periods, which in  
26  
27 most cases don't exceed 6 months, are not suitable to evaluate long term effects of  
28  
29 bone substitutes and scaffolds on bone regeneration and remodelling, and to  
30  
31 determine in vivo resorption kinetics of the respective biomaterial. Variations in  
32  
33 defect sizes and methods of defect fixation as well as postoperative treatment and  
34  
35 management concepts make it difficult to compare studies and draw reliable  
36  
37 conclusions. The modifications of commercially available fixation devices and  
38  
39 supporting systems to prevent peak loads from acting on implants suggest the  
40  
41 occurrence of implant failures usually expected early after surgery. As a result, most  
42  
43 experimental settings do not reflect the actual clinical conditions faced and impede the  
44  
45 extrapolation of results.

4 *4. Conclusions and Opinions*  
5

6           The reconstruction of large bone segments remains a significant clinical  
7  
8 problem. Large bone defects occur mainly as a result of extensive bone loss due to  
9  
10 pathological events such as trauma, inflammation, and surgical treatment of tumours.  
11  
12 Present therapeutic approaches include the application of bone graft transplants  
13  
14 (autologous, allogenic, xenografts), as well as implants made of different synthetic  
15  
16 and natural biomaterials or segmental bone transport. However, no existing therapy  
17  
18 has been proven to be fully satisfactory. A large number of research groups  
19  
20 worldwide work on the development of new bone grafting materials, carriers, growth  
21  
22 factors, and tissue engineered constructs for bone regeneration and are therefore  
23  
24 interested to evaluate their concepts in reproducible large segmental defect models.  
25  
26 The optimization of cell-scaffold combinations and locally or systemically active  
27  
28 stimuli will remain a complex process characterized by a highly interdependent set of  
29  
30 variables with a large range of possible variations. Consequently, these developments  
31  
32 must be nurtured and evaluated by clinical experience, knowledge of basic biological  
33  
34 principles, medical necessity, and commercial practicality. The area of bone tissue  
35  
36 engineering which has its main focus on the development of bioactive materials  
37  
38 depends on the use of animal models to evaluate both experimental and clinical  
39  
40 hypotheses. To tackle major bone tissue engineering problems, researchers must rely  
41  
42 on the functional assessment of biological and biomechanical parameters of generated  
43  
44 constructs. However, to allow comparison between different studies and their  
45  
46 outcomes, it is essential that animal models, fixation devices, surgical procedures and  
47  
48 methods of taking measurements are standardized to achieve the accumulation of a  
49  
50 reliable data pool as a base for further directions to orthopaedic and tissue engineering  
51  
52 developments.

**Table captions**

*Table 1:* The table lists a selection of publications on segmental bone defect studies in sheep tibiae and summarizes animal age, selected defect size, defect fixation, animal housing as well as supportive devices. The majority must be considered short term studies where no complete bone remodelling can be expected during the experimental period. In many cases, authors fail to report important information concerning animal age, housing and supportive devices.

*Table 2:* Summary of advantages and disadvantages of common defect fixation methods

*Table 3:* Comparison of animal models for fracture and segmental bone defect research

*Table 4:* Summary of human and large animal bone properties

*Table 5:* Factors influencing the quality and quantity of bone healing in long bone critical-sized defects (CSD)

6

7 *Fig. 1:* The sheep has become a standard model for understanding the mechanical  
8 conditions that occur after injury and investigating surgical treatments such as  
9 segmental defect healing. However, limited work has been published on modelling  
10 this process. Hence, reconstruction of the musculoskeletal model of the sheep lower  
11 limb across the complete gait cycle was performed. The figure shows mechanical  
12 loading on mid-shaft level of the tibia (A). The bones are mainly compressed with  
13 minor shear forces. Compared to humans, the loading in sheep tibiae is in pattern  
14 similar but in magnitude roughly half of the one in humans (B) [52].

Table 1:

<i>Author</i>	<i>Animal age (years)</i>	<i>Defect size (mm)</i>	<i>Follow-up (months)</i>	<i>Fixation</i>	<i>Animal housing</i>	<i>Support</i>
<i>Gao et al., 1997</i>	a	16	4	Overlapping autocompression plates, 8 and 6 holes, 4 mm thickness	a	a
<i>DenBoer et al., 1999/03</i>	a	30	3	Custom-made AO unreamed nail (Synthes)	a	a
<i>Gugala et al. 1999/02</i>	6-7	40	4	AO bilateral external fixator	Single boxes	Suspending slings
<i>Wefer et al., 2000</i>	≥ 2	20	12	Anteeroilat. plate osteosynthesis (not specified)	a	a
<i>Bloemers et al., 2003</i>	≥ 2	30	3	AO unreamed tibial nail (Synthes)	6-8 animals in a 60 m <sup>2</sup> cage	a
<i>Meinel et al., 2003</i>	a	10	5	3.5 mmm DCP, 11 holes	a	a
<i>Mastrogiacomo et al, 2006</i>	2	48	12	4.5 mm plate (not specified), 10-12 holes	Single boxes	Fibre glass cast
<i>Maissen et al., 2006</i>	4-5	18	3	Unilateral external fixator	Single boxes	Custom-made support system
<i>Sarkar et al., 2006</i>	5.5-7	25	3	Custom-made intramedullary nail plus medial stainless steel plate	Single boxes	a
<i>Tyllianakis et al., 2007</i>	1-2	10,20,30	4	Universal Humeral Nail (UHN, Synthes)	Single boxes for 3 days post surgery	a
<i>Liu et al., 2007</i>	a	26	8	Circular external fixator	Single boxes	a

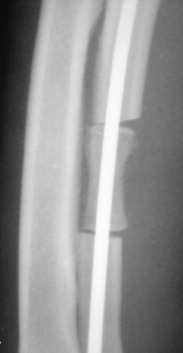

<sup>a</sup>information not provided by the authors

Table 2:

	<b>Advantages</b>	<b>Disadvantages</b>
<i>External fixator</i>	<ul style="list-style-type: none"> <li>- Versatility</li> <li>- Ease of application</li> <li>- Marginal effect on surrounding soft tissue</li> <li>- Minimal intraoperative trauma</li> <li>- Open space for implantation of biomedical construct</li> </ul>	<ul style="list-style-type: none"> <li>- Clinically only applied as temporary fixation device</li> <li>- Schantz screw loosening</li> <li>- Pin track infections</li> </ul>
<i>Intramedullary nail</i>	<ul style="list-style-type: none"> <li>- Standard treatment for diaphyseal fractures of lower extremity</li> <li>- Availability of UTN to avoid reaming related problems</li> <li>- Central load carrier</li> <li>- High tolerance of maximum applied forces</li> <li>- Low axial deviations</li> <li>- Reaming debris as possible source of multipotent stem cells</li> </ul>	<ul style="list-style-type: none"> <li>- Impairment of bone blood circulation by reaming</li> <li>- Thermal necrosis after reaming</li> <li>- Air or fat embolism</li> <li>- Failure of locking bolts</li> <li>- Limited application of load-bearing scaffolds</li> <li>- Prolonged healing period</li> </ul>
<i>Plate fixation</i>	<ul style="list-style-type: none"> <li>- Standard treatment for metaphyseal fractures</li> <li>- Optimal reduction</li> <li>- Minimal influence on defect (LC-LCP)</li> <li>- Open space for implantation of biomedical construct</li> </ul>	<ul style="list-style-type: none"> <li>- Eccentric load carrier</li> <li>- Impairment of periosteal blood flow (non LCP)</li> <li>- Bone loss through stress protection (non LCP)</li> <li>- Unclear role of plate fixation in tibial shaft fractures</li> <li>- Prone to axial deviations and implant failure</li> </ul>

8 *Intramedullary nailing*  
9

10 Intramedullary nailing was first introduced by Küntscher in 1953 [1] and once  
11 established, reaming soon advanced as a novel endorsement [2]. With the  
12 enhancement of intramedullary fixation devices and development of locked nailing,  
13 the indications for intramedullary stabilisation have been further expanded over the  
14 years making it a popular option in long bone fracture management. The treatment of  
15 diaphyseal fractures of the lower extremity has advanced as a commonly accepted  
16 standard treatment [3, 4]. Despite its wide-spread application, intramedullary nailing  
17 is associated with both positive and negative side aspects. It has been reported that the  
18 process of reaming leads to a considerable impairment of bone blood circulation by  
19 largely destroying both the intramedullary arterial and venous system [5,6]. The  
20 reaming procedure as well as the insertion of the nail causes a significant increase of  
21 intramedullary pressure. This increase in pressure can lead to both air or fat  
22 embolisms by intravasation of bone marrow or fat into the vascular system and the  
23 formation of microthrombi causing pulmonary microvascular damage [7, 8]. The  
24 process of reaming may also lead to a rise in temperature in the medullary canal.  
25 Rises in temperature of 50°C and more have been described [9, 10]. As a result,  
26 thermal necrosis of bone tissue with alteration of endosteal architecture and biological  
27 failure may be induced compromising fracture or defect healing [11]. In most cases  
28 however, the damage of local tissue is reversible and compensated for within 6-8  
29 weeks. Weak spot of various unreamed nailing systems prone to failure pose the  
30 interlocking screws and small dimension solid tibial nails do not always provide  
31 adequate stability in the proximal and/or distal defect site. The rate of failure however  
32

2  
3  
4 could be reduced over the years with advances in surgical techniques, optimization of  
5  
6 materials and with the use of e.g. angle stable locking bolts [12], and postoperative  
7  
8 treatment concepts. When discussing intramedullary stabilization in the context of  
9  
10 tissue engineering and the evaluation of biomaterials and constructs for bone graft  
11  
12 substitution, it must be considered, that, in a created defect area, an intramedullary  
13  
14 nail impedes the placement of a solid, one-piece load-bearing scaffold (Fig. 7).  
15  
16 However, since central load carriers are less susceptible for tilting in the frontal plane,  
17  
18 custom made intramedullary nailing systems have been widely applied for fixation of  
19  
20 large segmental bone defects in animal models [13-16].  
21  
22

23  
24 Reaming mobilizes cancellous bone within the medullary canal which is likely to  
25  
26 assemble in the area of the fracture gap. The effects of the collected material at the  
27  
28 gap are comparable to conventional bone graft from the iliac crest suggesting that  
29  
30 reaming debris represents a possible source of multipotent stem cells and growth  
31  
32 factors enhancing regeneration processes [17-19].  
33  
34  
35  
36  
37

### 38 *Internal plate fixation*

39  
40 While intramedullary stabilisation is the treatment of choice when reconstructing  
41  
42 closed diaphyseal shaft fractures, metaphyseal fractures are usually stabilised by  
43  
44 extramedullary implants, preferably angle-stable plates, pre-shaped in an anatomical  
45  
46 fashion where applicable [4]. Optimal reduction and good stability even in  
47  
48 complicated fractures can be achieved by plate and screw osteosynthesis [20, 21].  
49  
50 After conventional plate osteosynthesis however, in most cases histologically and  
51  
52 radiologically verifiable bone loss can be detected (principal of friction). This  
53  
54 phenomenon has been attributed to stress protection according to Wolff's law.  
55  
56  
57  
58  
59 Clinical observations and recent studies however have revealed the occurrence of  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 certain porosity within the cortical bone proximate to the plate during the early phase  
5  
6 following plate osteosynthesis. This porosity was found to be a result of impaired  
7  
8 perfusion underneath the plate [22]. The decrease in perfusion in proximity to the  
9  
10 plate results from high compression forces between plate on the one hand and  
11  
12 periosteum and bone on the other [23]. The contact pressure and the resulting  
13  
14 circulatory disturbance prolongate fracture healing and increase the risk of infection  
15  
16 and refracture after implant removal [24]. To overcome these drawbacks, a plate  
17  
18 system was developed where load and torque transmission can act through the screws  
19  
20 only. This was achieved by angle-stable, interlocking screws. As a result, to achieve a  
21  
22 stable fracture fixation, the plate-bone contact was not further necessary as the  
23  
24 stabilisation system acted rather like an internal fixator. The application of  
25  
26 monocortical screws can further minimize screw-related intramedullary circulatory  
27  
28 disturbances [25]. The development of such new biological techniques and implants  
29  
30 has revived the interest towards open reduction and plate fixation. Nevertheless, the  
31  
32 exact role of plate fixation in the treatment of tibial shaft fractures remains unclear, as  
33  
34 the literature is lacking randomised control trials comparing plate fixation with the  
35  
36 other established treatment concepts. In the area of tissue engineering and related  
37  
38 animal experiments, defect fixation with internal fixators offers the great advantage of  
39  
40 a minimal influence of the fixation device on the created defect site both concerning  
41  
42 space for scaffold implantation and biological factors. When compared to external  
43  
44 fixators or tibial nails, rates of infections (pin-track infection), infection related  
45  
46 complications and non-union rates (6-25%) are lower. However, higher numbers of  
47  
48 malalignment can be observed [26]. Especially in large animal models, defect fixation  
49  
50 with eccentrically placed devices seems to be challenging and was used only in few  
51  
52 studies [27-29] (Fig. 8). Since in most reports, complications, implant failures,

65

1  
2  
3  
4 postoperative treatment and animal care are not published and authors have described  
5  
6 unconventional methods of defect fixation such as the use of overlapping plates [30]  
7  
8 and the use of other supportive devices it can be assumed that implant modifications  
9  
10 and the use of supportive devices were a necessary protective measure to overcome  
11  
12 implant failures early after surgery resulting from critical loads/valgus stress  
13  
14 occurring during the act of the animal uprising with the relatively long tibia serving as  
15  
16 the lever arm of the force.  
17  
18  
19  
20  
21

### 22 *External fixator*

23  
24 In clinical settings, external fixation is often used as a temporary fixation  
25  
26 device in patients with severe open or contaminated fractures or in the case of  
27  
28 multiple traumas. Switch from external to internal fixation is best done as soon as the  
29  
30 soft tissue problems are resolved [31, 32]. In animal models, external fixators have  
31  
32 been widely used as they offer versatility and ease of application [33-35]. External  
33  
34 fixators affect the surrounding soft tissue only marginally due to minimal  
35  
36 intraoperative trauma. The most common complication when using external fixation  
37  
38 systems is loosening of Schanz screws and following pin track infections. When  
39  
40 compared to intramedullary nails, external fixators don't affect the defect site as  
41  
42 extensively not limiting space for the implantation of biomedical, tissue engineered  
43  
44 constructs. However, with external fixators healing periods are reported to be  
45  
46 significantly longer when compared to other fixation devices [36]. Moreover, external  
47  
48 fixators may be a burden for the animals as they represent an obstacle larger than the  
49  
50 physiological circumference of the animal limb.  
51  
52  
53  
54  
55

56 Mueller et al reported on a study designed to identify what levels of primary stability  
57  
58 could be achieved with different forms of osteosynthesis in the treatment of

diaphyseal fractures of the tibia. Treatment concepts included unreamed tibial nails (UTN), cannulated tibial nails (CTN), lateral tibial head buttress plates (LPO, Synthes), and 5-hole proximal lateral tibia less invasive stabilising systems (LISS), external fixators and hybrid fixators (Synthes) [37]. It was shown that the nailing systems as central load carriers tolerate higher maximum applied forces. The lowest axial deviations in varus and valgus direction were again described for the intramedullary nailing devices while the highest axial deviations were recorded for the plate fixations.
