EVALUATION OF THE LUNE FISHERY STOCK 1993

SUMMARY

The major findings from this project are as follows:-

- 1) The salmon stock in 1993 was dominated by two year old smolts. This varies from year to year.
- 2) Smolt age appears to have no effect on determining the fishes return as a grilse or MSW in any year sampled.
- 3) Weight breakdown indicates that grilse can be allocated to a <9.51 lbs class and MSW fish to >9.51 lbs size class in all data.
- 4) The weight/length relationship of salmon in 1993 indicates an overall growth rate = 2.65, with a coefficient of determination = 82.5%.
- 5) Sea trout smolt age is also dominated by two year old fish with 3 year old fish also being important. Some 4 year old smolts were recorded.
- 6) The sea trout population displays a normal population curve in terms of numbers of fish in each age and weight class. However, 0+ sea winter fish are under-represented due to capture methods. 4+ sea winter fish appear to have a smaller than expected year class strength.
- 6) Weight/length relationships in 1993 showed very consistent regression equations for all sub samples, with a coefficient of determination >90%.
- 7) For each age class <5+, a weight class can be allocated for sea trout. 4+ sea winter fish appear to have a higher weight class than 5+ fish. This may be due to a small year class leading to less competition for food resources.
- 8) Previous spawning data indicates that net caught fish are less likely than their trap caught counterparts to have spawned in any age class. However any fish over 3+ will have previously spawned.
- 9) The growth rate of salmon and sea trout is very similar even though salmon have the benefit of high sea feeding.

INTRODUCTION

During 1993, a comprehensive data set of scale readings, length and weight measurements was established for migratory salmonids on the River Lune. This information was collected using three methods of fish capture:-

1. The Lune estuary commercial nets.
2. River Lune Forge weir fish trap.
3. River Lune rod catch scale returns.

Additional information was contributed by the Kent, Leven and Duddon rod and commercial fisheries.

The aims of this project were to:-

- a. Identify the population structure of Salmon (Salmo salar) and Sea Trout (Salmo trutta)
- b. To assess the spawning history of the population.
- c. To establish if a weight/length relationship exists within the population and, if so, what implications this may have on future research.
- d. If a weight/length relationship is apparent, then is it possible to amplify this relationship to establish if a similar phenomenon exists between weight and age ?

For ease of data handling, Salmon and Sea Trout will be considered separately. Similarly each method of capture will be initially treated as an individual sample. Thus if any method is selective for a particular age class or size of fish this can be established before the data sets are combined.

METHODS

Data was obtained from nets, trap and rod sources. Each fish caught was weighed, its fork length measured and scales removed from the shoulder region.

Scales were read by three individuals without knowing the fish species or weight. A freshwater and sea age were assigned to each fish. All information was inputted on to a database. Several statistical and graphics packages were used to analysis the data.

SALMON STOCK OF THE RIVER LUNE

RESULTS

SALMON

Net Sample	472 fish
	375 x 1+ (grilse)
	97 x 2+ (MSW salmon)
Trap Sample	87 fish
	81 x 1+ (grilse)
	6 x 2+ (salmon)
Rod Sample	76 fish
	70 x 1+ (Grilse)
	6 x 2+ (MSW salmon)

An initial study of the age class of Lune fish was undertaken. Fig. 1 indicates that both grilse and multi- sea winter (MSW) fish caught by the nets and the weight abundance categories are depicted by a normal distribution curve. When analysed in more detail (Fig. 2 & 3) is apparent that 80% of grilse and 86% of MSW salmon smolt and migrate to sea in their second freshwater year. This is typical of a biologically productive river system. Some three year old smolts are present in grilse samples (12%) and MSW samples (10%) and is likely these will have originated from less productive areas of the system such as the Hindburn and the Roeburn which are of lower biological productivity. Conversely, a small proportion of one year old smolts were recorded, 8% in grilse and 4% in MSW salmon, these deriving potentially from a few nutrient rich areas of the catchment.

Historical data suggests this situation is varied with only 44% of salmon having spent two years in freshwater from 1988 Lune scale samples and 51% in 1987. In both 1987 and 1988 adult stock there was a higher proportion of 1 year old smolts.

There appears to be no significant difference in the freshwater age class distribution of grilse and MSW fish of adult returns in 1993. This infers that the reason for a salmon remaining at sea for one or more years is not determined by its age on entering the marine environment. Thus some genetic factor or environmental factor once at sea may be accountable for the different behaviour patterns of individual fish. A similar pattern was found in 1988 and 1987, although the numbers of younger smolts were higher.

The trap and rod catch fish exhibit a very similar age class distribution. However, whilst MSW fish represent approximately 20% of the net catch they only represent 7-8% of the trap and rod data. It is likely that this is partly because larger fish have a greater possibility of being caught by the nets for any given net mesh size and also, that the trap is thought to be selective for smaller fish as the trap entrance gates are narrow and may deter large fish from entering. Weight breakdowns of grilse and MSW salmon (Fig. 6, 7 & 8) clearly indicates this net exploitation of larger fish.

Historical rod caught scale data shows that the proportion of MSW fish compared to grilse caught also varies year to year with 16% of fish caught in 1987 in this category, whilst in 1988 the figure was 12%.

Fig.6 reveals an overlap in the weights of grilse and MSW salmon between 7-14 lbs. The mid-point of this band appears to be the weight class of 9-10 lbs. This is further supported by trap and rod data. This information can be used for fish counter analysis of the stock.

From net caught data, any fish assigned a weight of >9.51 lbs can be classed as a MSW fish with a 13% chance of error and any fish weighing <9.51 lbs has a 93% probability of being a grilse. The grilse weight breakdown appears to represent the expected normal distribution. However the MSW fish appear to have several peaks within the weight categories. Further analysis incorporating the spawning history of the MSW fish (Fig. 9-10) indicates that the majority of previous spawners are in the 7-11 lbs weight classes. However a maximum size of 15-16 lbs was obtained for a fish that had previously spawned. These findings suggest that the MSW distribution may be normal with the unusual peaks present being due to the limited sample size and the spawning history of the sample.

All the MSW fish recorded in the net catch sample that were <9.51lbs were previous spawners. These fish would have spent some 3-5months less at sea than their maiden MSW counterparts, hence their reduced size. It is not typical for 22% of MSW fish recorded in River Lune salmon stock to be previous spawners. Previous studies have shown 3% (1987) and 2% (1988) of River Lune MSW salmon to be previous spawners. Thus the accuracy of assessing MSW fish from weight alone may vary slightly depending upon kelt survival rates.

WEIGHT/LENGTH DISTRIBUTIONS FOR SALMON

Weight in pounds (lbs) was plotted versus length in centimetres (cm). This format was chosen as the data collection was mostly by anglers who are more familiar with imperial measurements, whereas the length was calculated in metric for use with the fish counter. As a large data set was available from the nets it was considered as a whole and split into monthly samples. (Fig. 11, 12, 13, & 14). The overall data set and July and August subsets exhibited very similar regression lines and growth rates. However, in June the regression equation indicates a slower growth rate and the

intercept is double that of the other net samples. This may be because the fish in the estuary in June are in peak condition having just returned to coastal waters. As the year progresses, a mixture of freshly arrived fish and fish held up will be present in the estuary. This will reflect in the weight/length relationship as will the increase in the proportion of grilse against MSW salmon found in the sample.

Both the Rivers Lune and Kent are known to have a very small spring run of fish, and also a run of summer salmon, consisting of MSW fish, in July and August. Some of these spring and summer fish will be present in the estuary in June and exploited by the nets prior to the arrival of the main grilse run, therefore affecting the regression during this month.

Comparing the annual net sample to the annual trap and rods samples (Fig. 15 & 16), the growth rates of trap and rod fish appear to be greater than those for the net. This may be due to the fact that the sampling period for the trap and rods continued until October, whereas the nets can only sample until the end of August. Heavier fish in both age classes may make up a larger component of the sample in September and October as they have had longer to feed at sea and thus the growth curve may be modified.

When all the data sets were combined it was found that for salmon and grilse:-

$$\text{Weight(lbs)} = (0.0001047) \text{ Length(cm)}^{2.65}$$

In all the data sets the coefficient of determination was >82.5% indicating that at least 82.5% of a fishes weight can be accounted for by its length. The overall equation would appear to be accurate enough to use for converting fish counter lengths to weights of fish for further stock assessment and age class determination.

SEA TROUT STOCK OF THE RIVER LUNE.

RESULTS

SEA AGE OF SEA TROUT

	Net Sample	Trap Sample	Rod Sample
	246 fish	262 fish	7 fish
0+	0	60	0
1+	15	102	3
2+	99	65	0
3+	67	26	2
4+	29	8	1
5+	23	0	1
>=6+	13	1	0

An initial break down of age and weight was carried out on the stock. (Fig.18-21)

Both net and trap sea age breakdowns exhibit an expected population curve apart from the absence of the 0+ age class in the net sample. This component of the population was not sampled as the fish would be too small to be retained in the nets. Similarly, a percentage of this size of fish could escape from the trap under the gates. This problem was reduced later in the trapping season by covering the base of the gates with wire mesh. If these fish had been sampled the bar chart curve would be heavily skewed to the left.

It should be also noted that there were slightly lower than expected numbers of 4+ sea winter fish in the net sample. By back calculation, these fish would be associated with the 1+ sea winter return of adults in 1990 and the 2+ sea winter sea trout return of 1991 both recorded as poor years for rod catches in these dominant age classes of fish.

Freshwater age distribution was similar to that found in salmon, with a slightly lower representation of 1 year old smolts at only 3%. Just under 82% of sea trout sampled smolted as 2 year old fish, whilst 15% remained in freshwater for a third year and left as three year old smolts. Two fish were recorded as 4 year old smolts, but these appear from the sample size to be the exception.

WEIGHT/LENGTH DISTRIBUTION FOR SEA TROUT

Weight breakdown shows a similar distribution to age class, showing that the nets do not exploit any fish under a weight of 1 lb.

Weight was regressed against length for net and trap data whilst rod data was combined with all data as the sample was very small (Fig. 23, 24 & 25)

In all cases the regression equations were very similar with a growth rate of approximately 2.73 and a coefficient of determination of >90%. This may indicate that when sea trout return to freshwater to spawn, (and as generally they are thought to stop feeding) they must neither gain weight nor grow in length. Otherwise long lean fish would exist in the population and the coefficient of determination would be lower.

This coefficient was higher than that of salmon, although the two species growth rates were very comparable despite salmon having the added food resources of high sea feeding.

The similarity of the regression equations for each sample of sea trout compared to the variation in the salmon samples may be an effect of trap and rod caught sea trout being taken between June and August which is the same period as the net sample. Most of the salmon from the trap were captured after the nets season had ended.

WEIGHT/AGE CLASS OF SEA TROUT

As such a high coefficient of determination was found for weight to length relationships, the analysis was further extrapolated in an attempt to relate fish weight to age. (Fig 26-28)

From the net's sample it was found that 0+ and 1+ sea winter fish were poorly or not represented.

For the other age classes the following may be derived;

Sea age	Av. weight(lbs)	% of fish in avg age class	Max. weight(lbs)
2+	2-3	58%	6-7
3+	3-4	31%	9-10
4+	5-6	32%	6-7
5+	4-5	34%	9-10

The above ages had the average weights as shown, with a variation that tailed off to the maximum weight recorded. The 6+ to 8+ age classes were represented by a small sample set which displayed a broad distribution of weight classes. This is probably due to the vast number of different life strategies the fish could have adopted by this point in its life.

Relating this information to the trap data set (Fig 27-28) where younger, smaller fish were sampled

Sea age	Av. weight(lbs)	% of fish in avg age class	Max. weight(lbs)
0+	0-1	90%	<2
1+	1-2	64%	3-4

2+ to 4+ sea winter fish were represented by the same average weight classes as the net sample.

These results indicate that many 4+ fish are heavier than the 5+ fish. This may again relate to the poorer run of fish in 1990 and 1991, leaving those 4+ year class fish that did exist with less competition for resources than the older year classes and thus the potential for gaining more weight. The largest overlap of weight class and age is within the older fish. A definite average weight which represents at least one third of the stock can be assigned to younger year classes (>4+ sea age). This data should be helpful for fish counter age class studies.

PREVIOUS SPAWNING HISTORY

Spawning mark reading information was used to assess the population's spawning history. (Fig 29-33)

The following table summarizes this information:-

Sea age	% previously spawned	
	Net	Trap
1+		23.5
2+	33.3	55.0
3+	75.0	84.6
4+	100	100

This information suggests that net sampled fish of less than 4 sea winters are less likely to have spawned than those fish of the same age class caught in the trap.

This variation may be due to where the fish were caught. In the trap sample the fish are committed to spawning as they have entered freshwater. The net sampled fish may have a considerable number of individuals in the sample which had no intention of entering the river to spawn this year, but are part of the overall stock. Such fish would not be represented in the trap sample this year and in subsequent years would have one less spawning mark than their counterparts who were caught in the trap this year.

In both the net and trap sampled data, all fish over 3+ had previously spawned. When a fish returns to spawn, i.e. as a 1+ or a 2+, does not seem to be dependent on weight as there is a large variety of weights of maiden spawning fish.

ACKNOWLEDGEMENTS

The authors would like to thank Bailiff A. Clarke for his assistance in collecting scale samples; the commercial fishermen of the Lune estuary for their co-operation in sample collection; the Fisheries science team at Warrington for their assistance in operating the fish trap at Forge; and Fisheries Assistant Ben Bayliss for his considerable efforts in scale reading.
