17

18 **Abstract**

19 *Brachyspira pilosicoli* is an anaerobic intestinal spirochaete that colonizes the large  
20 intestine of various host species, in which it may induce diarrhoea, poor growth rates  
21 and a localized colitis known as intestinal (or colonic) spirochaetosis. The spirochaete  
22 is considered to be potentially zoonotic. The purpose of the current study was to  
23 develop a multiple-locus variable number tandem repeat analysis (MLVA) method as  
24 a simple and rapid tool to investigate the molecular epidemiology of *B. pilosicoli*. The  
25 genomic sequence of *B. pilosicoli* strain 95/1000 was analysed for potential tandem  
26 repeats using the default parameters of the Tandem Repeat Finder program. A total of  
27 22 repeat loci were identified and tested for their presence and variability on a set of  
28 10 *B. pilosicoli* isolates. Five loci that were present in most isolates and that showed  
29 evidence of allelic variation were selected and used with a collection of 119 isolates  
30 from different host species and geographical locations. Not all the isolates amplified  
31 at all loci, but using the available data a total of 103 VNTR profiles were generated.  
32 The discriminatory power of this method was 0.976. A phylogenetic tree constructed  
33 from the allelic profiles confirmed the diversity of *B. pilosicoli*, and the general lack  
34 of clustering of strains based on species of origin or geographic origin. Some isolates  
35 with known epidemiological links were found to be identical or highly similar. The  
36 MLVA method was simple and easy to use, and could readily differentiate between  
37 strains of *B. pilosicoli*. MLVA should prove to be a useful tool for rapid identification  
38 of relationships between *B. pilosicoli* isolates in epidemiological investigations.

39 **Keywords:** Spirochaete; *Brachyspira pilosicoli*; MLVA; molecular epidemiology;  
40 zoonosis.

41

## 42 1. Introduction

43 The genus *Brachyspira* includes species of anaerobic spirochaetes that colonize the  
44 large intestine of animals and birds (Stanton, 2006). The two most important  
45 pathogenic species are *Brachyspira hyodysenteriae*, the agent of swine dysentery, and  
46 *Brachyspira pilosicoli*, the agent of intestinal spirochaetosis (Hampson, 2012). *B.*  
47 *pilosicoli* has a broader host range than *B. hyodysenteriae*, colonizing various species  
48 of animals and birds, as well as human beings (Hampson et al., 2006). Colonized  
49 individuals may develop focal colitis, with chronic diarrhoea. Infections with *B.*  
50 *pilosicoli* are particularly common in intensively housed pigs and chickens, in which  
51 rates of growth and production may be depressed. Colonization also is common  
52 amongst humans living in crowded and unhygienic conditions (Trott et al., 1997a;  
53 Nelson et al., 2009). Spirochaetemia with *B. pilosicoli* has been recorded in  
54 immunocompromised or debilitated human beings (Trott et al., 1997b), but not yet in  
55 animals. Transmission may be by direct exposure to infected faeces, or by indirect  
56 routes; for example, carcasses of spent hens in supermarkets may be contaminated  
57 with *B. pilosicoli* (Verlinden et al., 2012), while accessing drinking water from wells  
58 has been linked to transmission in humans (Margawani et al., 2004).

59  
60 To help answer questions about transmission routes of *B. pilosicoli*, a simple, rapid  
61 and discriminating typing system that gives information about genetic relatedness of  
62 isolates is needed. Pulsed field gel electrophoresis has been used for this purpose  
63 (Atyeo et al., 1996), but it is quite time consuming and requires large quantities of  
64 pure DNA. Multiple-locus variable number tandem repeat analysis (MLVA) is a  
65 method that uses non-coding regions of genomic DNA, consisting of direct repeats of  
66 the same sequence of bases, referred to as tandem repeats. The number of repeats in

67 the sequence is determined genetically and can vary between different strains. These  
68 regions are known as variable number tandem repeats (VNTR) loci. Recently, an  
69 MLVA scheme had been developed and used for *B. hyodysenteriae* (Hidago et al.,  
70 2010). The purpose of the current study was to develop an MLVA scheme for *B.*  
71 *pilosicoli*, and to use it as an epidemiological tool to compare isolates from different  
72 sources.

73

## 74 **2. Materials and Methods**

75

### 76 *2.1. Spirochaete isolates*

77

78 A total of 119 *B. pilosicoli* isolates and strains recovered from different host  
79 species and geographical areas were obtained from the culture collection at the  
80 Reference Centre for Intestinal Spirochaetes at Murdoch University (Table 1). These  
81 consisted of 45 isolates from pigs, 42 from human beings, 25 from chickens, five  
82 from dogs, and two from horses. They originated from Australia (n=66), Papua New  
83 Guinea (n=29), the USA (n=8), Canada (n=5), Italy (n=5), the UK (n=3) and New  
84 Zealand (n=1). The isolates had been identified as *B. pilosicoli* on the basis of their  
85 phenotypic properties and amplification in a species-specific PCR, as previously  
86 described (La et al., 2003).

87

### 88 *2.2. Spirochaete culture and DNA extraction*

89

90 The spirochaetes were thawed from frozen stock and subcultured at 37°C in  
91 Kunkle's pre-reduced anaerobic broth containing 2 % (vol/vol) foetal bovine serum

92 and a 1 % (vol/vol) ethanolic cholesterol solution (Kunkle et al., 1986). Cells were  
93 harvested from mid-log phase culture by centrifuging at 10,000 x g, and counted in a  
94 haemocytometer chamber under a phase contrast microscope. For each isolate, 10ml  
95 of Trypticase Soy broth containing  $\sim 10^8$  cells/ml of *B. pilosicoli* was centrifuged at  
96 5000g. The supernatant was discarded and the pellet resuspended in an equal volume  
97 of phosphate buffered saline (37 mM NaCl, 2.7 mM KCl, 4.3 mM Na<sub>2</sub>HPO<sub>4</sub>, 1.47  
98 mM KH<sub>2</sub>PO<sub>4</sub>, pH 7.4) and heat killed at 95°C for 15 min to release the DNA, before  
99 being stored frozen at -20°C. The solution containing the extracted DNA was used as  
100 the template for the PCR reactions.

101

## 102 2.2. Selection and PCR amplification of potential VNTR loci

103

104 The complete genome sequence of *B. pilosicoli* strain 95/1000 (Wanchanathuek  
105 et al., 2010), isolated from a pig, was obtained from GenBank (accession number  
106 CP002025; Project ID: 48097) and investigated for potential tandem repeats using the  
107 default parameters of the Tandem Repeat Finder program (Benson, 1999), which is  
108 available as a Web service (<http://tandem.bu.edu/trf/trf.html>). The selected tandem-  
109 repeat loci were ranked by consensus length, and those between 40 and 300 base pairs  
110 were used to design primers, using the flanking regions. These 22 loci were named  
111 BPilo, followed by the repeat length ranking number (from 1 to 22), separated by an  
112 underscore. The primer sequences are shown in Table 2.

113

114 PCR and electrophoresis was carried out on DNA from the *B. pilosicoli* strains.

115 PCR was performed using 0.2µl *Taq* DNA polymerase, 5µl of 10x PCR buffers, 3µl

116 of 25mM MgCl<sub>2</sub>, 5µl of 8mM dNTP, 5µl of the forward and reverse primers, 12µl of

117 cresol red solution and 2µl of template, with the reaction mix topped up with PCR-  
118 grade water to a final 50µl volume. The PCR conditions were 95°C for 2 min,  
119 followed by 33 cycles at 95°C for 30 s, 50°C for 15 s, 72°C for 1 min for every 1kbp  
120 of product, and a final extension period of 5 min at 72°C before holding at 14°C. The  
121 products were visualized using gel electrophoresis and staining by immersion in 1%  
122 ethidium bromide for 30 min. A molecular mass marker (1Kbp Ladder; Axygen  
123 Biosciences, California, USA) was placed in a well at each end of the gel. Images of  
124 the gel were captured using a Biorad Chem Doc XRS Universal Hood and were used  
125 for analysis. On the gel image, lines were drawn from bands of the ladder on one side  
126 of the gel, connecting the bands of the same size on the ladder at the other end. The  
127 size of each VNTR was estimated using the lines as reference points.

128

129 Initially all 22 sets of primers that were identified as being potentially suitable were  
130 tested using DNA from *B. pilosicoli* strain 95/1000 as a template. After verifying that  
131 the primers yielded the appropriate results, PCRs were carried out on DNA extracted  
132 from a subset of 10 randomly selected isolates of *B. pilosicoli* (marked with an  
133 asterisk in Table 1). Each PCR reaction set included DNA from *B. pilosicoli* strain  
134 95/1000 as a positive control and distilled water as a negative control. For the loci  
135 where the PCR did not produce product, different sets of primers were designed and  
136 used in an attempt to detect the predicted tandem repeats. The sequences of these  
137 primers are shown in Supplementary Table 1.

138

139 To confirm that the PCR products were from the repeat regions, the product from five  
140 loci for strains 95/1000, OF 2 and H54 were purified with the Wizard<sup>®</sup> SV Gel and

141 PCR Clean-Up System Kit (Promega, Sydney, Australia) in accordance with the  
142 manufacturer's instructions, and were sequenced using the BigDye Terminator v3.1  
143 Cycle Sequencing Kit (Applied Biosystems, Foster City, USA). Sequencing was  
144 performed with the ABI 373A sequencing system (Applied Biosystems).

145

### 146 2.3. MLVA with *B. pilosicoli*

147

148 PCRs were carried out on DNA from all 119 isolates and strains, sequentially  
149 using the five selected primer pairs for the loci indicated in Table 3. The process was  
150 repeated using the same samples to assess the reproducibility of the procedure.

151

152 The number of tandem repeats was calculated using the estimated size of the  
153 resultant band divided by the size of the repeat. Alleles with the same number of  
154 tandem repeats were grouped together and assigned an allelic number according to  
155 their size, with the larger ones first. Those isolates that consistently produced a  
156 negative result with a particular primer pair were assigned the number 99 for the  
157 purpose of typing. The allelic number was entered into the START2 program and a  
158 rooted phylogenetic tree with 1000 bootstrap replicates was generated from the data  
159 matrix using the 'Neighbour-Joining' (NJ) with the 'Maximum likelihood' model  
160 (Jolley et al., 2001). Two of the 119 isolates that did not amplify at any of the five loci  
161 used were not included in the tree. A separate tree was generated for 20 isolates where  
162 all five alleles were amplifiable.

163

164 The discriminatory power (D) of the MLVA method was calculated as previously  
165 described (Grundmann et al., 2001). D is the average probability that the typing

166 system will assign a different type to two unrelated strains randomly sampled in the  
167 microbial population of a given taxon.

168

### 169 **3. Results**

170

171 Investigation of the genome sequence of *B. pilosicoli* 95/1000 with the Tandem  
172 Repeat Finder program identified 404 repeats in tandem. Of these, 22 were suitable  
173 candidates for MLVA due to their size and well-separated locations dispersed around  
174 the genome.

175

176 Using the 22 primer pairs with 10 isolates yielded five sets that gave amplification  
177 with most of these isolates and loci, and which produced variations between the  
178 amplicons that allowed differentiation between them. The remaining 17 primer pairs  
179 either did not produce product or/and identified little or no allelic variation. Use of the  
180 alternate primers listed in Supplementary Table 2 gave the same results, so these were  
181 not used further. The five repeats that were selected for use in MLVA were located  
182 across about two thirds of the genome of strain 95/1000. Sequencing of the products  
183 confirmed that the length polymorphism was due to differences in copy number of  
184 tandem repeats, and their characteristics as assessed using 95/1000 as the template are  
185 shown in Table 3.

186

187 A summary of the alleles carried by the 119 isolates at the five loci is presented in  
188 Table 4. The number of alleles varied from four for BPilo\_14 to nine for BPilo\_9. The  
189 number of isolates in which a locus did not amplify varied from 16 for BPilo\_14  
190 (13.4%) to 79 for BPilo\_8 (66.4%). Two isolates (UNL-3 and Q98.0072.31) did not

191 amplify at any of the five loci. Nevertheless, by including null alleles (“99”), a total of  
192 103 VNTR profiles (VTs) were generated (Supplementary Table 2). The repeated  
193 tests yielded the same results with the isolates.

194

195 Overall the discriminatory power of this method using the five loci was 0.976.

196

197 The NJ tree generated using the allelic profile from the MLVA sequencing for 117  
198 isolates is shown as Figure 1, and the identity of the isolates is shown in Table 1. A  
199 separate tree for the 20 isolates where all five alleles amplified is shown as a  
200 Supplementary Figure. Isolates from the same species of origin (pig, chicken, human)  
201 were distributed throughout the tree shown in Figure 1, without any major clustering  
202 on a species basis. Similarly, isolates from the same country or region of origin  
203 generally were not restricted to one area on the tree. Some clustering of isolates that  
204 were likely to be epidemiological linked was observed; for example certain isolates  
205 from village 1 and piggery 1 in Papua New Guinea, and certain human isolates  
206 collected from an Aboriginal community in Western Australia (marked WA in Table  
207 1; eg the two isolates with VNTR profile 63). On the other hand, there were examples  
208 where isolates from different regions and species of origin had identical VNTR  
209 profiles; for example VNTR profile 26 was shared by an isolate from a UK pig, an  
210 isolate from a human from Australia, and two isolates from humans in Italy; profile  
211 37 was shared by an isolate from a US pig and one from an Australian chicken;  
212 profile 54 was shared by an isolate from an Australian chicken and one from an  
213 Australian human being.

214

215 **4. Discussion**

216 Using the genome sequence of *B. pilosicoli* 95/1000, 22 loci were identified as  
217 being potentially suitable regions for MLVA analysis. This was very similar to the 23  
218 identified in the MLVA study conducted on *B. hyodysenteriae* (Hidalgo et al., 2010).  
219 Following further investigation only five loci were identified which were present in at  
220 least half of the tested isolates, and that had at least four variations between the  
221 amplified bands. This was in contrast to the situation with *B. hyodysenteriae* where  
222 eight suitable loci were identified (Hidalgo et al., 2010). Typically the number of loci  
223 used for MLVA for other bacteria has been between 5-8; for example, five loci have  
224 been used for *Salmonella* Typhimurium (Lindstedt et al., 2004), six for *Enterococcus*  
225 *faecium* (Top et al., 2004), and eight for *Staphylococcus aureus* (Malachowa et al.,  
226 2005). Hence, even with only five suitable loci identified, there was potential for these  
227 to be used in MVLA of *B. pilosicoli*. Locus BPilo\_8 was the least suitable of the five,  
228 since it was only present in around one third of the isolates, but it was retained in the  
229 analysis as a number of alleles were detected in the isolates from which it was  
230 amplified, and no other more suitable loci were identified.

231

232 Using these five loci with 119 isolates, 103 VTs were produced. Two isolates did  
233 not amplify with any of the loci, and indeed there were only 16 profiles (20 isolates)  
234 that included alleles from all five loci. The presence of such “null alleles” can also  
235 act as supporting evidence for strain identification, although clearly they are not as  
236 definitive as when alleles are detected. In the previous study on *B. hyodysenteriae*  
237 using eight loci (Hidalgo et al., 2010), 44 VTs were obtained from 174 isolates, and  
238 the discriminatory power was 0.938. This compared with a D value of 0.976 and 103  
239 VTs for the *B. pilosicoli* strains, which together demonstrate the existence of greater  
240 genetic variation in *B. pilosicoli* than in *B. hyodysenteriae*.

241

242 The MLVA method with five loci was a simple, rapid and replicable way to  
243 identify different strains of *B. pilosicoli*, and as such could be a very useful tool for  
244 molecular epidemiological studies. Evidence for its usefulness for strain typing can be  
245 deduced from the situation where pairs or sets of isolates from the same regions and  
246 species were shown to be similar or identical. The existence of isolates from different  
247 species with the same or similar VTs also points to the likelihood that cross-species  
248 transmission of *B. pilosicoli* strains occurs under natural conditions.

249

250 MLVA is likely less reliable than some other methods for assessing broad  
251 phylogenetic relationships of *B. pilosicoli* strains, even where all five loci are  
252 amplified (supplementary figure). The reason for this is that *B. pilosicoli* has a  
253 recombinant population structure (Trott et al., 1998), and strains show evidence of  
254 gene rearrangements (Zuerner et al., 2002) and gene loss (Mapple et al., 2012);  
255 consequently MLVA loci, which have no known selective advantage, may readily  
256 become disrupted. Indirect evidence for this was the presence of the numerous  
257 apparent “null” alleles amongst the isolates investigated. Hence these localized  
258 changes may blur understanding of the underlying core relationships between  
259 different strains as identified by MLVA. Phylogeny is probably better studied by  
260 analyzing conserved genes with core metabolic functions (“housekeeping genes”), as  
261 used in multilocus enzyme electrophoresis (Trott et al., 1998; Hampson et al., 2006)  
262 and multilocus sequence typing (Råsbäck et al., 2007; La et al., 2009).

263

264 Some modifications could be considered to improve MLVA as a typing method.

265 As five different primer sets were used, the possibility of multiplexing the reaction

266 could be explored. However, due to the variation in size between the different bands,  
267 it would be difficult to be confident that the bands produced originated from the  
268 specific VNTR locus. To get a more accurate prediction of the size of the VNTRs,  
269 capillary electrophoresis could be used, or the amplicons could be sequenced, as  
270 described in the MLVA study of *B. hyodysenteriae* (Hidalgo et al., 2010). This would  
271 be especially appropriate for the VNTRs that had a small repeat size (Bpilo\_8 and  
272 Bpilo\_16); however, to do this the MLVA method would require more sophisticated  
273 equipment, be more expensive to run and would have a longer turnover time, and this  
274 would defeat the aim of developing MLVA as a rapid and simple method for typing  
275 *B. pilosicoli* isolates in epidemiological studies.

370

371 **Fig. 1.** Phylogenetic tree for 117 *B. pilosicoli* isolates constructed using the NJ  
372 method generated with the allelic profile obtained from MLVA. The names of the  
373 isolates and the numbers on the branches correspond with those shown in Table 1.  
374 The length of the scale bar represents one locus difference per unit.

375

376 **Supplementary Figure.** Phylogenetic tree for 20 *B. pilosicoli* isolates with all five  
377 alleles available, constructed using the NJ method generated with the allelic profile  
378 obtained from MLVA. The names of the isolates and the numbers on the branches  
379 correspond with those shown in Table 1 and Figure 1. The length of the scale bar  
380 represents one locus difference per unit.
