16 **preservation in the Ediacaran Period.**
17
18

19 The Precambrian has long been a puzzle for palaeontologists and for many years Precambrian
20 sediments were thought to be unfossiliferous. Charles Darwin saw the lack of a Precambrian fossil
21 record as a potential problem for his theory of natural selection, a problem which has become
22 known as 'Darwin's Dilemma': "*To the question why we do not find records of these vast*
23 *primordial periods, I can give no satisfactory answer.*" (Darwin 1859). Despite this, Darwin
24 appeared confident that life had existed during the Precambrian and that fossils were yet to be
25 identified: "*Consequently, if my theory be true, it is indisputable that before the lowest*
26 *[Cambrian] stratum was deposited, long periods elapsed, as long, or probably far longer than,*
27 *the whole interval from the [Cambrian] age to the present day; and that during these vast, yet*
28 *quite unknown, periods of time, the world swarmed with living creatures.*" (Darwin 1859). It is
29 around this time that the first reports of Precambrian fossils appeared, as the Geological Survey
30 geologist J.W. Salter described trace fossils (*Arenicolites*) in addition to markings including "rain-
31 prints", "sun-cracks" and "surf-ripples" from the Long Mynd of Shropshire. This important report
32 was cryptically noted by Darwin: "*Traces of life have been detected in the Longmynd beds*
33 *beneath Barrande's so-called primordial [Cambrian] zone.*" (Darwin 1859). Salter's initial
34 discoveries therefore mark the beginning of the study of Precambrian palaeontology and
35 potentially provided Darwin with a solution to his dilemma.

36 While a variety of unusual bedding plane markings are now well known from the
37 Longmyndian Supergroup, here, we describe a variety of exceptionally preserved microbes, both
38 from Salter's material and from new collections. These microbes are preserved as carbonaceous
39 films, silicate replacements and three-dimensional impressions and reveal that some secrets of
40 the Longmyndian rocks have remained hidden for over 150 years. Exceptionally preserved
41 microbes are well known from Ediacaran carbonaceous (e.g. Miaohu; Xiao et al. 2002),
42 phosphatic (e.g. Doushantuo; Xiao & Knoll 1999) and siliceous (e.g. Doushantuo; Xiao 2004)
43 lagerstätte. However, our observations of microbial preservation by aluminosilicate
44 permineralization and as siliciclastic bedding plane impressions are somewhat unusual and
45 deserving of further description.
46
47

48 **Setting and Materials.** The Longmyndian Supergroup of Shropshire, England, has been
49 interpreted as an expanded Ediacaran siliciclastic succession, ranging from marine deltaic to
50 alluvial plain or fluvial palaeoenvironments (McIlroy et al. 2005 and references therein). No large
51 Ediacaran frondose macrofossils are known, although an array of unusual bedding plane markings
52 including Salter's putative annelid worm traces (*Arenicolites*), have been described (e.g. Salter
53 1856, 1857; Greig et al. 1968; Bland 1984; McIlroy et al. 2005). While the biogenicity of Salter's

54 holotype material for *Arenicolites* has since been disputed (e.g. Greig et al. 1968; McIlroy et al.
55 2005), markings from the Longmyndian have latterly attracted interpretations ranging from the
56 sedimentary expressions of ancient microbial mats (microbially induced sedimentary structures
57 *sensu* Noffke et al. 2001), to body or even to trace fossil taxa (see McIlroy & Walter 1997;
58 McIlroy et al. 2005).

59 Microfossils from the Longmyndian were first reported by Timofeyev (1980) while Peat
60 (1984) described carbonized, mat-forming, ribbon-like and sphaeromorph microfossils from
61 petrographic thin sections, which were compared with prokaryotes, eukaryotes and even
62 questionably with metazoans. Here, we report on a fresh study of Salter's historic material,
63 supplemented by new specimens from the Burway Formation at Ashes Hollow and the Lightspout
64 Formation in Carding Mill Valley, Shropshire (see Greig et al. 1968), focusing upon the evidence
65 for exceptional fossil preservation on a microscopic scale.

66
67 **Longmyndian Fossils. Description.** Petrographic thin sections through dark carbonaceous
68 siltstones of the Lightspout Formation, reveal abundant black carbonized filaments (Fig. 1),
69 similar to those reported by Peat (1984). The filaments are typically 15-20µm in diameter and up
70 to 1500µm in length and do not show evidence for tapering. They are non-septate and do not
71 appear to show branching of any kind. These filaments are commonly parallel to sub-parallel in
72 orientation and can overlap and form interwoven mat fabrics, much as reported by Peat (1984).
73 Variations in filament diameter along the length of a single filament are here interpreted in part
74 as taphonomic artefacts. We have not yet observed sphaeromorph structures from thin sections.
75 The lower bedding surface of the filament-bearing horizon bears an irregular crinkly texture,
76 similar to putatively microbial markings known as '*Kinneyia*' (e.g. Gerdes 2007). Our
77 observations support the microbial origin of these markings, which is significant given the
78 potential abiogenic modes of formation of wrinkle markings (Porada & Bouougri 2007; McLoughlin
79 et al. 2008) and the often limited evidence for a direct connection between microbial mats and
80 wrinkle markings in the Precambrian.

81 Sub-millimetre scale examination of siltstone bedding surfaces of the Burway Formation at
82 Ashes Hollow allows us to report a variety of distinctive white filamentous markings, which are
83 preserved within a grey-green siltstone matrix (Fig. 2). Long (mainly >1mm), thin (<20µm)
84 filaments often occur alongside markings attributed to the body fossil *Beltanelliformis minutae*
85 McIlroy and the ichnotaxon *Medusinites* aff. *asteroides* Sprigg, as described by McIlroy et al.
86 (2005). SEM imaging reveals their gentle positive relief and allows us to refute the possibility that
87 they represent surface contaminants. The filaments show no evidence of tapering and are
88 assumed to have been originally circular in cross section. Internal divisions or septation cannot
89 be seen although this may be an artefact of preservation. Significantly, the filaments show
90 unequivocal 'Y'-shaped branching, which may have implications for their biological affinity (Fig.
91 2C). The filaments can either be found sporadically on bedding planes (Fig. 2B-C) or alternatively
92 they can be observed in extremely high concentrations, where they be either random or parallel
93 in orientation and form dense, interlocking mats within thin (<1mm) sedimentary laminae (Fig.
94 2A).

95 Much larger diameter filaments can also be observed on the same bedding planes as the
96 thread-like filaments (Fig. 2D). These can be up to several hundred microns in diameter and 1-
97 2mm in length. The broad filaments are also white in colour and show no evidence for septation
98 or branching nor do they demonstrate a tendency to cluster or form mats. White circular to sub-
99 circular discoidal structures, up to 500µm in diameter, also occur on the same bedding planes, in
100 clusters of up to 20 specimens (Fig. 2E). These discoidal structures show no evidence for internal
101 architecture or evidence for mechanisms of growth. We suggest that these may originally have
102 had a sphaeromorph morphology and may be comparable to the structures reported from thin
103 section by Peat (1984).

104 In addition to carbonized filaments (Fig. 1) and white filaments and discoids (Fig. 2), we
105 also report the occurrence of filamentous markings, which are preserved as impressions and
106 moulds in three-dimensions, likewise on bedding planes. Straight to sinuous, narrow (c. 200µm),

107 thread-like features are relatively common in Salter's specimens labelled "Yearling Hill, Church
108 Stretton" (Fig. 3). These samples are thought to be from the Burway/Synalds Formation at
109 Yearlet Hill (Greig et al. 1968), although our field investigations have not revealed the exact
110 locality of these samples. These filamentous markings occur either in positive or negative relief
111 and are often found in close spatial association with (or even superimposed upon) features
112 referred to *Beltanelliformis minutae* (c.f. McIlroy et al. 2005). Features referred to *B. minutae* are
113 also found in the opposite sense of relief to the thread-like impressions (Fig. 3). These markings
114 may be comparable to the somewhat smaller "hair-like" structures reported by McIlroy et al.
115 (2005), which have been used as an indicator for ancient microbial mats. Typically the thread-like
116 markings are rather sinuous and randomly oriented. In other cases, parallel-oriented filaments
117 may reflect a palaeocurrent direction. Together, these observations are not easily interpreted as
118 minute trace fossils or even as abiogenic structures such as shrinkage cracks, current lineations
119 or groove casts and we suggest that these markings may represent the external moulds of large,
120 mat-building, microbial filaments.

121
122 *Biological Affinities.* A wide range of microbial morphologies are present in the Longmyndian,
123 which supports the presence of a diverse late Ediacaran microbial community. Resolving the
124 biological affinities of these microbes is difficult however, given the lack of characteristic and
125 diagnostic biological or morphological features. The shallow marine to fluvial depositional
126 environment of these sediments means, of course, that either a photoautotrophic or
127 heterotrophic mode of life remains possible. Potential biological affinities to be considered for
128 these microbes include cyanobacteria, eukaryotic algae, fungal hyphae or a variety of other
129 filamentous autotrophic and heterotrophic bacteria. Although many filamentous microfossils have
130 previously been interpreted largely on the basis of size (e.g. Schopf 1992), our investigations of
131 modern and ancient filaments suggest that determining the biological affinities of fossil microbes
132 using filament diameter is highly problematic.

133 The smallest (c. 20µm) carbonized and permineralized filaments (Fig. 1, 2A-C) overlap
134 with the size ranges reported from modern and putative fossil cyanobacteria (see Schopf 1992 fig.
135 5.4.27) and branching could also be compatible with cyanobacteria. Wrinkle markings observed
136 from the Longmyndian (e.g. elephant skin texture) can also be compared with microbially
137 induced sedimentary structures found within living cyanobacterial mats (e.g. McIlroy et al. 2005;
138 Gerdes 2007). We have not definitively observed features such as 'H'-shaped branching or hyphal
139 fusion which would support a fungal affinity (e.g. Butterfield 2005). Therefore, although we
140 suggest that a cyanobacterial affinity is possible, we are unable to reject eukaryotic algal or other
141 microbial possibilities. The larger white filaments (Fig. 2D) and the filamentous impressions (Fig.
142 3) could also be explained as large cyanobacterial sheaths, as bundles of microbial filaments, or
143 as eukaryotic algae. Determining the biological affinities of discoidal microfossils is equally
144 problematic, although it may be interesting to speculate whether they are comparable to the
145 Precambrian possible prokaryote *Chuarina*, which is more commonly preserved as a carbonaceous
146 film (e.g. Steiner 1994).

147 We are currently unable to satisfactorily resolve the affinities of the Longmyndian
148 microbes, although we suggest that future sampling combined with further morphological and
149 geochemical (e.g. biomarker) analysis may yet help to distinguish between the various
150 possibilities.

151
152 *Taphonomy.* As we have described, the Longmyndian microbes are preserved within three
153 distinct taphonomic modes. In the first case, microbes are preserved as carbonaceous films (Fig.
154 1). This style of preservation is well known from Proterozoic mudrocks (e.g. Hofmann 1994;
155 Steiner 1994) and ranges through the Ediacaran and into the Cambrian (e.g. Lower Cambrian
156 *Sabellidites*; Urbanek and Rozanov 1983 and the Middle Cambrian Burgess Shale; Butterfield et
157 al. 2007) but subsequently disappears from the marine fossil record as a significant mode of
158 preservation (Butterfield 1995).

159 In the second mode, the microbes are preserved three dimensionally by a distinctive white
160 mineral (Fig. 2). Energy Dispersive X-Ray (EDX) analysis reveals this to be an iron and potassium
161 aluminosilicate mineral. The fine grain size means that is not possible to observe the structure of
162 this microcrystalline mineral and the exact mineralogy remains speculative. Precambrian
163 permineralized microbes are well known to occur in lagerstätten where silica, phosphate and even
164 pyrite replace soft tissues (Grazhdankin & Gerdes 2007; Brasier et al. in press), but not hitherto
165 preserved in aluminosilicates. Preservation of soft tissues in aluminosilicate clay minerals has
166 been described from Phanerozoic lagerstätte including the Burgess Shale (Orr et al. 1998;
167 Butterfield et al. 2007) and the Ordovician Soom Shale (Gabbott et al. 2001), although the exact
168 mechanisms of aluminosilicification are not yet fully resolved. For example, it has been suggested
169 that Burgess Shale aluminosilicates were formed during late stage diagenesis/metamorphism by
170 replacement of a precursor phase (Butterfield et al. 2007). We have not, however, observed any
171 evidence for the replacement of a mineral precursor phase in the Longmyndian. It has also been
172 proposed that aluminosilicates (phyllosilicates) may be formed during the low grade metamorphic
173 devolatilization of carbonaceous films (e.g. Page et al. in press). The presence of unaltered
174 carbonaceous filaments in Longmyndian sediments is, however, less easily explained by this
175 hypothesis. In the Soom Shale it has been suggested that organic tissues acted as templates for
176 the adsorption of colloidal clay minerals, leading to their replication by aluminosilicates (Gabbott
177 et al. 2001). In this case it is the most labile organic tissues which are preserved in the greatest
178 detail. Such an observation matches our discovery of the preservation of labile microbial
179 materials by aluminosilicates. We also draw attention to the well known affinity of quartz and
180 colloidal clay particles for organic materials (Konhauser & Urrutia 1999; Martin et al. 2004). We
181 therefore propose that very early diagenetic aluminosilicate permineralization was a key factor for
182 the preservation of the Longmyndian filaments.

183 In the third mode, filaments are not preserved as carbonaceous remains, or replaced by a
184 diagenetic mineral, but are preserved as impressions and moulds by the siliciclastic sediment
185 itself. These filaments are therefore found on bedding planes as sharp positive ridges (Fig. 3A) or
186 their counterpart negative impressions (Fig. 3B). In the Ediacaran Period, this type of
187 preservation is more commonly known from large macrofossils such as *Charnia* (Narbonne 2005).
188 In comparison with the Precambrian, the preservation of soft tissues within siliciclastic sediments
189 is also notably rare from the Cambrian onwards (see Brasier et al. in press). Our investigations
190 from the Longmyndian and other Ediacaran lagerstätten suggest that this style of preservation is
191 reliant upon the rapid lithification of bedding plane interfaces. It is noteworthy that while
192 microbial mats are often invoked as important factors in the preservation of Ediacaran
193 macrofossils (Gehling 1999), there is currently no obvious explanation for the preservation of
194 microbes themselves in the same taphonomic mode.

195
196
197 **Conclusion.** The palaeontological importance of the Longmyndian Supergroup has been
198 recognized for over 150 years, but its microbial lagerstätten have not been widely reported until
199 now. We find that Longmyndian microbes are preserved as carbonaceous films, as aluminosilicate
200 permineralized filaments and as moulds and impressions on bedding planes. These observations
201 reinforce the hypothesis (Brasier & Callow 2007; Brasier et al. in press) that the Ediacaran fossil
202 record appears to be biased towards the high quality preservation of soft tissues. The relative
203 scarcity of such exceptional preservation at later times, in a variety of taphonomic modes
204 suggests that these unusual taphonomic windows significantly narrowed following the Ediacaran-
205 Cambrian transition.

206 Salter's discoveries have been important from two perspectives in addressing the paradox
207 known as 'Darwin's dilemma'. Firstly, his keen macroscopic observations revealed the first
208 evidence for an Ediacaran fossil record, an observation of particular interest to Charles Darwin
209 150 years ago. Secondly, these same rocks have been found by us to contain microbial
210 preservation at a resolution that scientists including Charles Darwin could not have dared to
211 predict.
