Short title: ICEBERG DRIFT MODELING

Abstract. The drift trajectory of giant iceberg C-7 traversing the Weddell Sea for more than 2-years was successfully simulated. Application of the "classical" driving forces like wind and ocean currents resulted in a significant discrepancy between modeled and observed iceberg velocities in the western Weddell Sea. The most realistic drift pattern in space and time was achieved by adding a sea ice force which represents the ability of a dense sea ice cover ($\geq 90\%$) to lock in icebergs and collect the momentum of the wind over an area much larger than the area of the iceberg proper. This process was parameterized using a sea ice strength P which depends on sea ice concentration and thickness, both having highest values in winter and in the western Weddell Sea which is covered with multi-year sea ice. As a consequence of the sensitivity to sea ice, the timing of the iceberg drift becomes important, revealing the region off Brunt Ice Shelf (eastern Weddell Sea) as a location where bergs either continue westward with the coastal current or follow a southern branch onto the shallow continental shelf.

1. Introduction

Icebergs released at a rate of ~ 2000 Gta^{-1} (Jacobs and others, 1992) from ice shelves of different sizes, glacier tongues, and coastal calving fronts of Antarctica may influence the physical and biological environment of the Southern Ocean. The fresh water input due to melting stabilizes the weakly stratified polar water column, hence hampering deep ocean convection and the formation of dense water masses. If originating from deep iceberg bases, this fresh water flux can be associated with an enhanced heat transfer to the surface (Jenkins, 1999). The release of material, collected by the inland ice on its advance toward the coast, related to melting provides nutrients for the ocean's euphotic zone and leaves sediment patterns on the sea floor that can be used for geological and paleo-climate studies. Stranded icebergs can "plough" the sea floor causing long-term disturbances of the local ecosystem (Gutt and Starmans, in press). Finally, drifting icebergs threatened sailing ships circumnavigating the southern tip of South America (Kozian, 1994); nowadays, they may be a problem for research and tourist ships operating more frequently in Antarctic waters.

This study focuses on the relative importance of atmosphere, ocean, and sea-ice forces acting on a "giant" iceberg (edges longer than 10 nautical miles) drifting through the Weddell Sea. Including sea ice as an active component of the iceberg drift rather than a passive (Viehoff and Li, 1995) was motivated by the observations during the drift of Ice Station Weddell (ISW-1) which indicated that, at high sea ice concentrations, icebergs move with the pack ice. With the focus on the dynamics rather than thermodynamics, we ignore iceberg melting, justified by the model results that drift trajectories did not change significantly for different (100-400 m) iceberg drafts. The impact of the fresh water input due to melting on water column stability, deep convection, and the formation of deep and bottom water participating in the global thermohaline circulation is subject of ongoing research.

Model results are compared with the observed drift of iceberg C-7, which was first seen in the western Pacific/eastern Indian sector of the Southern Ocean. For more than two years C-7 drifted through the Weddell Sea at a mean velocity of $0.11 ms^{-1}$ following closely the path of the coastal current (Fig. 1). Though other bergs like B4 followed the same path at a slightly higher mean velocity of $0.15 ms^{-1}$, C-7 was selected because its time in the Weddell Sea corresponds to the period (1985-1993) from which atmospheric data were used to drive the sea ice and ocean circulation models. The latter provided the oceanic forcing component for the iceberg drift model. The characteristics of iceberg C-7 are listed in Table 1.

2. Forces

The basic equation describing iceberg motion in ice-covered seas includes the forces due to air drag (\vec{F}_A) , and water drag (\vec{F}_W) , the Coriolis force (\vec{F}_C) , the slope of the sea surface (\vec{F}_{SS}) , and the force due to the interaction with the sea ice cover (\vec{F}_{SI}) :

$$M * \frac{d\vec{u}}{dt} = \vec{F}_A + \vec{F}_W + \vec{F}_C + \vec{F}_{SS} + \vec{F}_{SI},$$
(1)

with M being the mass and \vec{u} the velocity of the iceberg. All terms on the right hand side are evaluated for an iceberg considered as a point mass with finite area.

The drags $(\vec{F}_A \text{ and } \vec{F}_W)$ considered as the sum of the forces acting on vertical walls (form drag) and horizontal surfaces (skin drag) are determined by the general drag relationship (e.g., Smith and Banke, 1983):

$$\vec{F}_x = \left(\frac{1}{2} * \rho_x * c_x * A_{vx} + \rho_x * c_{dx} * A_{hx}\right) * |\vec{v}_x - \vec{u}| * (\vec{v}_x - \vec{u}),$$
(2)

with ρ_x as the medium density, c_x the dimensionless coefficient of resistance, set to $c_W = 0.85$ for water and $c_A = 0.4$ for air, c_{dx} the dimensionless drag coefficient for very smooth surfaces, set to $c_{dW} = 5 \times 10^{-4}$ for water and $c_{dA} = 2.5 \times 10^{-4}$ for air,

 $A_{vx}(m^2)$ the area of the iceberg wall facing the air/water flow, $A_{hx}(m^2)$ the area of the horizontal iceberg surfaces in contact with the wind (top) and ocean current (base), and $\vec{v}_x(ms^{-1})$ the wind/ocean current velocity; here, x refers to air (A) and water (W). The densities of air and water are assumed to be constant at $\rho_A = 1.293$ (kgm⁻³) and $\rho_W = 1027.5$ (kgm⁻³). The water velocity \vec{v}_W results from the vertical integration of the top layers of the ocean circulation model BRIOS-1 (Beckmann and others, 1999), starting at the sea surface down to the draft of the iceberg. The wind velocity \vec{v}_A is obtained from the 10-m winds of the NCEP/NCAR Reanalysis Project (Kalany and others, 1996).

The drift of icebergs is also influenced by the *Coriolis force* which leads in the southern hemisphere to a deflection to the left according to:

$$\vec{F}_C = 2 * M * \Omega * \sin \phi * \vec{k} \times \vec{u}, \tag{3}$$

where Ω is the rotation of the earth ($\Omega = 7.27 * 10^{-5} \text{s}^{-1}$), ϕ the latitude, \vec{k} the unit vector perpendicular to the earth surface, and \vec{u} the iceberg velocity.

The force acting on icebergs due to the *slope of the sea surface* is defined by:

$$\vec{F}_{SS} = -M\vec{g} * \sin\alpha \tag{4}$$

where \vec{g} is the acceleration due to gravity and α is the tilt of the sea surface estimated from the barotropic part of the modeled ocean velocity (Beckmann and others, 1999). A good approximation is the geostrophically balanced mean velocity of the entire water column relative to the flow at ~ 1000 m depth.

Sea ice extent and concentration in the Weddell Sea are subject to large seasonal variations. Therefore, the *force due to sea ice* is split for three categories of sea ice

concentration:

$$\vec{F}_{SI} = \begin{cases} 0 : A \leq 15\% \\ \frac{1}{2} * \rho_{SI} * c_{SI} * A_{SI} | \vec{v}_{SI} - \vec{u} | (\vec{v}_{SI} - \vec{u}) : 15\% < A < 90\% \\ - (\vec{F}_A + \vec{F}_W + \vec{F}_C + \vec{F}_{SS}) : A \geq 90\% \text{ and } P \geq P_s \end{cases}$$
(5)

with A (%) the sea ice concentration, $P(Nm^{-1})$ the sea ice strength, and $P_s(Nm^{-1})$ a threshold value (see below). Sea ice concentrations lower than 15% are considered as open water with no additional force acting on the iceberg, $\vec{F}_{SI} = 0$. For sea ice concentrations between 15% and 90%, sea ice acts as an additional drag using a coefficient of resistance of $C_{SI} = 1.0$, and A_{SI} as the product of sea ice thickness and iceberg width. For sea ice concentrations $\geq 90\%$, iceberg and sea ice form a solid block which can occur during austral winter in the inner Weddell Sea (Fig. 2). In this case, the sum of the forces is set to zero, i.e., the iceberg does not accelerate but will drift, as a first approximation, with the sea ice velocity calculated by the stand-alone sea ice model BRIOS-0 (Beckmann and others, 1999).

A measure for the resistance of the sea ice is the sea ice strength which is given by the relationship:

$$P = P^* * h * \exp\{-20(1-A)\}$$
(6)

according to Hibler (1979), where h is the sea ice thickness per unit area, A the sea ice concentration, and P^* an empirical coefficient ranging from 15000 Nm⁻² to 30000 Nm⁻² with 20000 Nm⁻² as the preferred value (Ralph Timmermann, pers. communication). Spatial and temporal coverage of sea ice concentration (A) and thickness (h) are provided by the BRIOS-0 sea ice model (Beckmann and others, 1999). The threshold value (P_s) at which sea ice resists the forces acting on an iceberg without breaking has been calculated according to Equation 5. We used the characteristics of iceberg C-7 listed in Table 1, extreme values for wind velocity ($5 - 25 \text{ ms}^{-1}$, Crepon and Houssais, 1988) and ocean current $(0.05 - 0.20 \text{ ms}^{-1})$, Muench and Gordon, 1995) representative for the western Weddell Sea, but neglected the forces due to Earth rotation and surface slope. The force per unit length ranges from 660.9 Nm⁻¹ to 14211.6 Nm⁻¹ for typical and strong (water/air) flows, respectively, equivalent to the range of minimum values for the sea ice strength P.

The minimum sea ice thickness h_{min} able to lock in an iceberg for a given sea ice concentration A and sea ice strength P follows from Equation 6 to:

$$h_{min} = \frac{P}{P^* * \exp\left\{-20 * (1-A)\right\}}$$

For typical flows ($P = 660.9 \text{ Nm}^{-1}$), the minimum thickness h_{min} reduces from h = 0.24 m at A = 90% to h = 0.03 - 0.04 m at A = 100%, while for strong flows ($P = 14211.6 \text{ Nm}^{-1}$) h_{min} decreases from h = 5.0 m to h = 0.70 m for the same range of sea ice concentration (Fig. 3). Sea ice thickness observations (Haas and others, 1992; Drinkwater and Haas, 1992) from the Winter Weddell Gyre Study (Lemke, 1992) showed a mean ice thickness of 0.88 m. Since this value is well above the calculated minimum ice thickness for typical flows, icebergs can frequently be locked by sea ice in the Weddell Sea. However, it should be noted that only forces were considered which are parallel to the sea ice plane. Shear and bending forces, which occur due to iceberg tilt and rotation, have been neglected. Therefore, the calculated minimum ice thicknesses should be treated as a lower bound of the sea ice's ability to capture icebergs.

The iceberg drift trajectory is calculated using an Eularian forward scheme with a constant time-step of $\delta t = 600$ s. Different time-steps were tested and the results compared with the observed drift of C-7. The displacement of the iceberg occurs in the geographic coordinate space of ϕ and λ to which all the forcing data are interpolated.

3. Forcing data

The iceberg drift model requires velocity fields of the *ocean*, the *atmosphere*, and the *sea ice* with additional information about sea ice thickness and concentration to calculate the sea ice strength.

The ocean velocity fields are provided by the numerical ocean circulation model BRIOS-1 (Beckmann and others, 1999), developed to study the large-scale structure of the Weddell Gyre and the importance of various processes and regions for the formation and spreading of deep and bottom waters. BRIOS-1 is a stand-alone coarse resolution circulation model with a circumpolar grid focused on the Weddell Sea sector. The velocity data from the 21^{st} year of the standard simulation, available in 3-day intervals, are vertically integrated over the 200-m draft of the model iceberg. The resulting velocity field shows the dominance of the cyclonic Weddell gyre with intensification at its southern and western boundary representing the coastal current, and a bifurcation of the latter off Brunt Ice Shelf (Fig. 4). One branch flows westward along the continental slope, the other penetrates southward onto the continental shelf where no predominant circulation pattern exists other than the flow parallel to the Filchner-Ronne Ice Shelf edge.

Sea ice concentration, thickness and drift velocity originate from a stand-alone dynamic-thermodynamic sea ice/mixed layer model (BRIOS-0) which is based on the formulations of Hibler (1979) and Lemke and others (1990). BRIOS-0 also provided the surface fluxes (momentum, heat and fresh water) for the ocean circulation model BRIOS-1. This guarantees that the forcing due to both sea ice and ocean are consistent for the iceberg drift model.

The *atmospheric* forcing results from the 2-m wind velocity fields of the Reanalysis Project of the National Center for Environmental Prediction (NCEP), used as 3-day averages of the C-7 drift period (12/89-02/92). This high resolution in time guarantees that the seasonal signal with increasing winds during austral winter is included.

4. Results

A series of simulations was conducted, all releasing an ensemble of icebergs with the parameters of C-7 (Table 1) along the Greenwich Meridian (GM) between 70°S and 67.8°S, displaced meridionally by 0.2°, on the 350^{th} day of 1989. The first series examines the sensitivity of the drift trajectories to the threshold value P_S of ice strength P, applying all driving forces. The second series reveals the relative importance of the different drivings by deactivating each single force, and the third studies the influence of the time/season icebergs are released at the GM. All experiments include some examination of the spatial variability due to the meridional stretching of the iceberg release.

4.1. Influence of sea ice strength

The threshold value P_s , depending on sea ice thickness and concentration (Equation 6), determines when an iceberg moves with the sea ice. We conducted three simulations using the minimum value of $P_s = 660 \text{ Nm}^{-1}$, and values around the maximum with $P_s = 13000 \text{ Nm}^{-1}$ and $P_s = 16000 \text{ Nm}^{-1}$ (Figs 5a–5c). Assuming ice thicknesses of 0.8-1.0 m for the western/northwestern Weddell Sea (Massom and others, 1997) this P_s -range corresponds to sea ice concentrations of 84–100%.

In all simulations icebergs drift westward into the inner Weddell Sea indicating the westward direction of the forces in atmosphere and ocean, the latter as part of the southern branch of the cyclonic Weddell gyre (Fahrbach and others, 1994; Schröder and Fahrbach, 1999). Icebergs with the southernmost release closely follow the coastline being captured by the sluggish circulation on the southern Weddell Sea continental shelf towards the end of the simulation. For P_s values even higher (not shown) this drift pattern does not change because sea ice concentrations in a norrow band off the eastern Weddell Sea coast do not exceed 90% (Fig. 2), allowing icebergs to interact but not to drift solely with the sea ice (Equation 5). Those released further north clearly show a drift dependend on the threshold value. For low P_s , icebergs get caught easier in the sea ice following trajectories similar to those of deployed sea ice drifters which show periods of slow to stagnant drift along 10°W (Kottmeier and Sellmann, 1996). The tendency of northerly flow outside the coastal current is also visible in modeled surface drift trajectories as part of the eastern cell of the Weddell gyre (Beckmann and others, 1999). At higher values, the atmospheric/oceanic forcing dominantes more allowing farther penetration into the Weddell Sea with the coastal current.

The simulations show that the iceberg drift strongly depends on sea ice characteristics and their spatial distribution, superimposed on the "background" forcing of atmosphere and ocean. While high sea ice concentrations in the eastern Weddell Sea reduce iceberg velocities relative to a strong coastal current (Fahrbach and others, 1994), a closed sea ice cover accelerates in the western Weddell Sea where the coastal current is weaker (Muench and Gordon, 1995). The best model results with respect to the drift pattern (Fig. 5b) and mean velocity (Fig. 6) of iceberg C-7 in the Weddell Sea are obtained with a threshold value of $P_s = 13000 \text{ Nm}^{-1}$, which, therefore, has been used for all following simulations. The simulation with $P_s = 660 \text{ Nm}^{-1}$ provided a mean velocity closer to the observed, but this threshold value has been rejected because of major discrepancies in the drift pattern (Fig. 5a).

4.2. Relative importance of the driving forces

The influence of the forces of wind, ocean currents, and sea ice on the iceberg drift is examined by deactivating each single force in Equation 1 but always applying the acceleration due to Coriolis force and sea surface slope.

The experiment without wind forcing (Fig. 7) shows drift trajectories similar to the results with all forces activated (Fig. 5b). This suggests that the importance of the wind is minor. However, the experiment only excludes the wind acting directly on the iceberg while a substantial part is indirectly transferred to the berg via the fact that ocean circulation and sea ice drift are primarily wind driven. The following experiments will show that in ice-covered regions the latter is a more efficient collector of this momentum.

To examine the influence of ocean currents on the iceberg drift one would tend to neglect the ocean forcing (F_W) in Equation 1. However, this would result in unrealistic high iceberg velocities \vec{u} because of the lack of friction between water and iceberg. This drag, due to the order-of-magnitude difference in density, is equal to the air/iceberg drag (F_A) at lower relative velocities (Equation 2). Therefore, the ocean velocity was set to zero $(\vec{v}_W = 0)$ to examine the importance of ocean currents. The similarity of the trajectories to those of the simulation with oceanic forcing (black vs. gray lines in Figure 8) indicates that the influence of ocean currents, driven by the wind, on iceberg drift is minor in ice-covered seas. This implies that wind momentum is transformed to iceberg movement most efficient via the sea ice cover.

Finally, to examine the influence of sea ice on the iceberg drift, the force due to sea ice (F_{SI}) has been deactivated. The significantly slower drift velocities especially when approaching the seasonally ice-covered central and southwestern Weddell Sea (Fig. 9) show the importance of sea ice for simulating realistic iceberg drifts. As for the ocean, neglecting the sea ice force suppresses a substantial part of the wind forcing. In addition, both forces are strongly correlated, i.e., winds are strong when sea ice concentration peaks (austral winter) and is able to "collect" the wind momentum over vast areas. This points to the importance of the time/season icebergs reach certain locations in the sea ice dominated Weddell Sea. Adding the friction between iceberg and sea ice but neglecting its total lock-in does not change the drift pattern shown in Figure 9. This indicates that a sea ice cover, if solid ($\geq 90\%$), compensates for a slow down of the ocean due to reduced air/ocean interaction.

4.3. Seasonal variations

All forces considered are subject to seasonal variations with atmosphere and, especially, sea ice (e.g., Gordon, 1981) showing large amplitudes. To examine the influence of the time icebergs pass the GM and arrive at certain locations in the Weddell Sea at different times of the year, icebergs were released along the GM 180 days before the standard simulation (Fig. 5b), hence on the 170th day of 1989, the begin of austral winter.

Icebergs passing the GM at the beginning of winter penetrate onto the southwestern Weddell Sea continental shelf (Fig. 10) where a slower moving sea ice cover and/or weaker shelf circulation (Fig. 4) transports icebergs to the north/northwest (e.g., the drift of iceberg A-24 in Grosfeld and others (1998)). The key location for a different drift behavior is the sea off Brunt Ice Shelf where "winter-icebergs" arrive one year after their release. They continue to drift with a thickening sea ice cover onto the continental shelf. In contrast, "summer-icebergs" arriving in the eastern Weddell Sea late winter pass the critical region without being locked in sea ice. Therefore, they follow, with a few exceptions, the coastal current toward the west. The sea ice cover of the western Weddell Sea is then consolidated enough to transport the bergs within one winter season to the northern rim of the Weddell Sea.

5. Conclusions

Our study shows that it is essential to consider the dynamic interaction between an iceberg and its surrounding sea ice in models of giant iceberg drift in order to reproduce

the observed patterns. This is based on the sea ice's ability to lock-in even big bergs and to collect the wind momentum over a huge area, both at high sea ice concentrations. In our model, this ability is parameterized by the sea ice strength P which depends on sea ice concentration and thickness. P becomes important for the compact winter sea ice cover of the whole, and the perennial sea ice of the western Weddell Sea. Simulations without the sea ice force show a significant slow-down in iceberg velocities. The importance of the various forces is relative as the ocean is the dominant component in regions with strong near-surface currents and sea ice concentrations less than 90%. However, the wind remains the ultimate force using media of different "efficiency" for transforming the atmosphere's momentum in iceberg displacement. In addition, the timing of the iceberg's arrival at certain locations often determines its fate. Such critical region exists in front of Brunt Ice Shelf where the coastal current bifurcates and heavy ice can transport bergs onto the shallow Berkner Shelf. Stranded there, icebergs might have an impact on the hydrography of the whole southern Weddell Sea including the circulation beneath Filchner-Ronne Ice Shelf (Nøst and Østerhus, 1998).

The existing differences especially between observed and modeled iceberg velocities in the western Weddell Sea could be reduced by applying the following improvements:

- Increased resolution of modeled oceanic surface currents to better represent the dynamics of the coastal current.
- Using forcing data from a coupled sea ice-ocean-atmosphere model to better represent the interaction between various components of the iceberg drift.
- The general threshold approach for ice strength P used in this study should be replaced by a *local* evaluation of the forces acting on sea ice. Additionally, the constant value of P^* , set to 20000 Nm⁻² in this study, should be smaller for regions of melting sea ice.

• Increasing the number of observations for icebergs of different sizes for model validation.

The next step will be the implementation of iceberg decay including basal and lateral melting to evaluate the freshwater flux into the ocean. Weakly stratified, the latter is susceptible to deep convection, a precursor for the formation of deep water and/or polynyas (Martinson and others, 1981). Such melting would include the release of iron, supposed to be critical for the fertilization of the euphotic zone (Smetacek and others, 1997), and other incorporated material (IRD) which might help interpreting past climate signals in sediment cores of the Southern Ocean.

Acknowledgments

We are greatful to the members of the BRIOS group, especially to A. Beckmann, G. Birnbaum, and R. Timmermann for their various contributions. The comments of K. Grosfeld and one anonymous reviewer helped to improve the original manuscript. Thanks to E. Augstein for supervising C. Lichey during his diploma thesis of which this paper is an excerpt.

Table 1. Characteristics of iceberg C-7. A_{hx} is the horizontal area in contact with air (A) or water (W), and A_{vW} and A_{vA} are the surfaces perpendicular to oceanic and atmospheric flow, respectively, calculated for a square iceberg with a length of 15 nm (1 nm = 1852 m). The latter represents the mean of the original size (10 nm×20 nm) based on measurements from satellite images, while all other values were estimated.

Variable	Value
length	27780 m
draft	200 m
${ m thickness}$	$225~\mathrm{m}$
mass	$1.597 * 10^{14} \text{ kg}$
A_{hx}	$7.717 * 10^8 \text{ m}^2$
A_{vW}	$5.556 * 10^6 \text{ m}^2$
A_{vA}	$6.945 * 10^5 \text{ m}^2$

Figure Captions

Figure 1. Drift of icebergs C-7 (solid line) and B-4 (dashed line) through the Weddell Sea from the 355^{th} day of 1989 until the 54^{th} day of 1992, and from the 191^{th} day of 1983 until the 28^{th} day of 1985, respectively, as observed by the National Ice Center (NIC). Sights are labeled by date (yy/ddd). Collision with the eastern Weddell Sea coast is an artifact due to uncertain coastline coordinates used by the plotting routine.

Figure 2. Monthly mean sea ice concentration in the Southern Ocean derived from SSM/I data for September 1987, a maximum in sea ice extend (Heygster and others, 1996). Contour intervall is 0.1 (= 10%).

Figure 3. Sea ice thickness h vs. sea ice concentration A (90%–100%), typical for winter months in the inner Weddell Sea (Fig. 2), for sea ice strengths $P = 660.9 \text{ Nm}^{-1}$ and $P = 14211.6 \text{ Nm}^{-1}$.

Figure 4. Annual mean (21^{st} year) of modeled (BRIOS-1) ocean velocity integrated over the top 200 m for the Weddell Sea sector. Thick arrows represent the bifurcation of the coastal current off Brunt Ice Shelf

Figure 5a. Representative drift trajectories of an ensemble of icebergs using the threshold value $P_s = 660 \text{ Nm}^{-1}$. Crosses mark modelled positions every 30 days. The thick solid line indicates the drift of C-7, observed positions marked with circles. The grey lines correspond to the simulation with $P_s = 13000 \text{ Nm}^{-1}$ (compare Figure 5b).

Figure 5b. Representative drift trajectories of an ensemble of icebergs using the threshold value of $P_s = 13000 \text{ Nm}^{-1}$. Crosses mark modelled positions every 30 days. The thick solid line indicates the drift of C-7, observed positions marked with circles.

Figure 5c. Representative drift trajectories of an ensemble of icebergs using the threshold value of $P_s = 16000 \text{ Nm}^{-1}$. Crosses mark modelled positions every 30 days. The thick solid line indicates the drift of C-7, observed positions marked with circles. The grey lines correspond to the simulation with $P_s = 13000 \text{ Nm}^{-1}$ (compare Figure 5b).

Figure 6. Mean drift velocities of observed (B-4 and C-7) and modeled icebergs in the Weddell Sea. Simulations were conducted with threshold values of 660 Nm^{-1} (PS6), 13000 Nm^{-1} (PS13), 16000 Nm^{-1} (PS16), and without sea ice forcing (nSI, next chapter). The modeled mean velocity represents the ensemble's mean.

Figure 7. Representative drift trajectories of an ensemble of icebergs forced by ocean currents, sea ice (threshold value $P_s = 13000 \text{ Nm}^{-1}$), Coriolis, and sea surface slope, but without wind. Crosses mark the position every 30 days. The thick solid line indicates the drift of C-7, observed positions marked with circles, and the grey lines corrspond to the modelled trajectories of icebergs forced with all forcing components and a threshold value of $P_s = 13000 \text{ Nm}^{-1}$ (Fig. 5b).

Figure 8. Representative drift trajectories of an ensemble of icebergs forced by wind, sea ice (threshold $P_s = 13000 \text{ Nm}^{-1}$), Coriolis and sea surface slope, but *not* ocean currents ($\vec{u}_W = 0$). Thick solid line represents the drift of C-7.

Figure 9. Representative drift trajectories of an ensemble of icebergs forced by ocean currents, wind, Coriolis and sea surface slope, but *not* sea ice. Thick solid line represents the drift of C-7.

Figure 10. Representative drift trajectories of an ensemble of icebergs driven by all forces but icebergs started at the Greenwich Meridian (GM) at the 170th day of the year 1989 (begin of austral winter). Thick solid line represents the drift of C-7.
