## DEVELOPMENT OF LOW NO<sub>x</sub> LIQUID FUEL BURNER

(Keywords: Combustion, Air Swirlers, Exhaust Gas, NO<sub>x</sub> emission)

### ABSTRACT

Recently, most of the gas turbine combustion research and development involves in lowering the emissions emitted from the combustor. Emission causes adverse affect to the world and mankind especially. Main concern of the present work is to reduce the NO<sub>x</sub> emission since the CO emission could be reduced through homogeneous mixing of fuel and air. Homogeneous mixing of fuel and air is also needed in order to reduce NO<sub>x</sub> emission. A liquid fuel burner system with radial air swirler vane angle of 30°, 40°, 50° and 60° has been investigated using 163mm inside diameter combustor. Orifice plates with three different sizes of 20mm, 25mm and 30mm were inserted at the back plate of swirler outlet. All tests were conducted using diesel as fuel. Fuel was injected at two different positions, i.e. at upstream and downstream of the swirler outlet using central fuel injector with single fuel nozzle pointing axially outwards. Experiment has been carried out to compare the three emissions NO<sub>x</sub>, CO and SO<sub>2</sub>. NO<sub>x</sub> reduction of about 53 percent was achieved for orifice plate of 20mm with downstream injection compared to orifice plate of 20mm with upstream injection. CO<sub>2</sub> and SO<sub>2</sub> was reduced about 26 percent and 56 percent respectively for the same configuration. This comparison was taken using swirler vane angle of 60°. The overall study shows that larger swirler vane angle produces lower emission results compared to the smaller ones. Smaller orifice plates produce better emission reduction. Meanwhile, downstream injection position significantly decreases the emission levels compared to upstream injection position. Combination of smallest orifice plate and largest swirler vane angle with downstream injection produce widest and shortest flame length.

## **PEMBANGUNAN PEMBAKAR BAHAN API CECAIR RENDAH NO<sub>x</sub>**

(Katakunci: Pembakaran, Pemusar udara, Gas ekzos, Emisi NO<sub>x</sub>)

### **ABSTRAK**

Masa kini, kebanyakan kajian dan pembangunan ke atas pembakaran turbin gas melibatkan pengurangan emisi dari pembakar. Pencemaran memberi kesan negatif kepada dunia dan manusia khususnya. Dalam projek ini, perhatian diberikan kepada pengurangan emisi NO<sub>x</sub> kerana emisi CO dapat dikurangkan melalui percampuran yang baik di antara bahan api dan udara. Percampuran yang baik juga diperlukan untuk mengurangkan emisi NO<sub>x</sub>. Pembakar berbahan api cecair menggunakan pemusar udara aliran jejarian bersudut 30°, 40°, 50° dan 60° dikaji menggunakan pembakar berdiameter dalam 163mm. Tiga plat orifis bersaiz 20mm, 25mm dan 30mm dipasang di bahagian keluar pemusar udara. Ujikaji dijalankan menggunakan bahan api diesel. Bahan api dibekalkan pada dua kedudukan pancitan, yakni di belakang dan di hadapan pemusar udara menggunakan pemancit bahan api berlubang tunggal menghala arah paksi. Ujikaji dijalankan ke atas tiga jenis pencemar iaitu NO<sub>x</sub>, CO dan SO<sub>2</sub>. Emisi NO<sub>x</sub> dapat dikurangkan sebanyak 53 peratus bagi plat orifis 20mm menggunakan pancitan di hadapan pemusar udara berbanding plat orifis 20mm menggunakan pancitan di belakang pemusar udara. CO dan SO<sub>2</sub> pula dapat dikurangkan sebanyak 26 dan 56 peratus masing-masing untuk konfigurasi yang sama. Ujikaji menunjukkan emisi yang rendah bagi pemusar udara bersudut besar berbanding pemusar udara bersudut kecil. Plat orifis bersaiz kecil memperoleh nilai emisi yang rendah. Pancitan di hadapan pemusar udara menunjukkan pengurangan emisi yang lebih baik berbanding pancitan di belakang pemusar udara. Saiz api yang pendek dengan bukaan yang besar diperoleh apabila pemusar udara bersudut besar, plat orifis yang kecil dan pancitan di hadapan pemusar udara digunakan.

## **ACKNOWLEDGEMENTS**

We would like to thank the Ministry of Science, Technology and Innovation (MOSTI) of Malaysia for awarding the research grant for this project and Universiti Teknologi Malaysia (UTM) for supporting this research. The research was funded under the IRPA grant scheme through project number 08-02-06-0061EA255. We would also like to extend my gratitude to all technicians who has offered their assistance in fabricating some of our component and to all undergraduate and postgraduate students who has helped and supported this project. Last but not least, we would like to thank the RMC's staff and JKPP of Faculty of Mechanical Engineering, UTM for the help and assistance in making this project successful.

$d$	-	hub diameter
$D$	-	diameter
et al.	-	and others
$g$	-	acceleration due to gravity (9.81 m/s <sup>2</sup> )
$G_\theta$	-	axial flux of angular momentum
$G_x$	-	axial flux of axial momentum
$h$	-	height
HP	-	horse power
i.e.	-	id est (that is)
$I_e$	-	intensity of rotation
$L$	-	length
$\dot{m}$	-	mass flow rate
$m$	-	mass
$M$	-	Airflow Mach number
$n$	-	quantity
$P$	-	pressure
$q$	-	volumetric flow rate
$r$	-	radius
$R$	-	gas constant (8.31 J/ mol K)
Re	-	Reynolds number
$s$	-	vane thickness

$S$	-	swirl number
$T$	-	temperature
vs.	-	versus
$V$	-	Volume
$V$	-	velocity
$We$	-	Weber number
$x$	-	distance
$Z$	-	Z number
$^{\circ}\text{C}$	-	degree Celsius
$^{\circ}$	-	degree
$\Sigma$	-	summation
$\Delta$	-	differential
$\alpha$	-	vane angle
$\sigma$	-	stress
$\pi$	-	phi $\left(\frac{22}{7}\right)$
$\lambda$	-	wavelength
$\theta$	-	angle
$\rho$	-	density
$\mu$	-	dynamic viscosity
$\gamma$	-	ratio of specific heat
$\text{C}$	-	carbon
$\text{CH}$	-	methylidyne
$\text{CH}_2$	-	methylene
$\text{CH}_4$	-	methane
$\text{CHO}$	-	formyl radical
$\text{CN}$	-	cyano radical
$\text{CO}$	-	carbon monoxide
$\text{CO}_2$	-	carbon dioxide
$\text{C}_{12.5}\text{H}_{22.2}$	-	Diesel
$\text{H}$	-	hydrogen
$\text{H}_2$	-	Hydrogen
$\text{HCN}$	-	hydrogen cyanide

H <sub>2</sub> CN	-	amidogen, methylene-
HO <sub>2</sub>	-	hydrogen dioxide
NCO	-	isocyanato radical
N	-	nitrogen
N <sub>2</sub>	-	nitrogen
NO	-	nitrogen oxide
NO <sub>2</sub>	-	nitrogen dioxide
N <sub>2</sub> O	-	nitrous oxide
NO <sub>x</sub>	-	oxides of nitrogen
O	-	oxygen (atom)
O <sub>2</sub>	-	oxygen (Gas)
OH	-	hydroxyl radical
O <sub>3</sub>	-	ozone
SO <sub>2</sub>	-	sulphur dioxide
AFR	-	air fuel ratio
ASME	-	American Society of Mechanical Engineers
CFC	-	chlorofluorocarbon
EGR	-	exhaust gas recirculation
EQR	-	equivalence ratio
FAR	-	fuel air ratio
FGR	-	flue gas recirculation
FLR	-	filter, lubricator and regulator
HHV	-	higher heating value
ppm	-	part per million
RQL	-	rich-burn quench lean-burn
<i>SMD</i>	-	Sauter mean diameter
SCR	-	selective catalytic reduction
SNCR	-	selective non-catalytic reduction
UHC	-	unburned hydrocarbon

# CHAPTER I

## INTRODUCTION

### 1.1 Background

Global environmental problems such as global warming, acid rain, ozone layer depletion and photochemical smog have become serious problems all over the world. Pollution and environmental degradation are discussed in a great deal today, but it is often spoken of in a way that is disconnected from its cause. Conventional energy processes can cause major problems to the environment, and it is important to consider energy issues alongside environmental issues in order to seek solution effectively.

The increasing use of gas turbine power plants for electricity generation, motor vehicles and other industrial application causes atmospheric pollution. For several decades, the gas turbine has been the prime movers for aircrafts, due to the tremendous advantages in term of speed, fuel economy and passenger comfort.

The combustion of fossil fuels is also a major contributor of four main environmental concerns. These environmental problems are caused by air pollution that contains oxides of nitrogen, carbon monoxide and oxides of sulphur. These environmental problems concern has prompted many governing bodies to legislate new regulations regarding emissions from combustion process in the hope that these environmental problems will be reduced.

## 1.2 Review of Previous Works

Past researchers who studied on the effect of varying the swirl strength were mainly interested on the flow pattern and temperature profiles resulted from varying the swirl strength. They were emphasizing the effect of swirl on the generation of torroidal central recirculation zones and flame geometry rather than the effect of swirl strength on emissions formation.

Mikus, T. and Heywood, J.B. (1971) in their work on automotive gas turbine concluded that leaning out the primary zone or reducing the residence time of conventional combustor designs using conventional fuel injection techniques was unlikely to reduce NO emissions enough to meet emissions standard. This was due to the presence of stoichiometric fuel and air ratio in parts of the flow within the primary zone even if the excess air was present. To achieve a significant reduction in NO emissions, combustors need to be developed with both a leaner and more homogeneous fuel and air ratio distribution in the primary zone that is attainable in conventional designs.

Mestre (1974) compared the effect of swirling and non-swirling system on combustion. He demonstrated that swirl helps to improve combustion efficiency, decreases all pollutants and increases flame temperature. He also observed that during the present of swirl, a shorter blue flame was observed indicating good mixing while non-swirling system showed a longer yellow flame indicating that there is still some fuel left unvapourized.

A series of combustor tests were conducted by Mularz et. al. (1975) to evaluate three improved designs of swirl-can combustor modules, using axial swirlers and their objectives were to obtain low levels of exhaust pollutants while maintaining high combustion efficiency at combustor operating conditions. He came with an opinion that swirl-can modules consisted of three components; a carburettor, an inner swirler and a flame stabiliser. The functions of the module were to mix fuel and air, swirl the mixture, stabilise combustion in its wake and provide large interfacial mixing areas between the bypass air around the module and combustion gases in its wake. They found that swirl-can combustor model performed with high

combustion efficiency at all conditions tested but the  $\text{NO}_x$  emissions were still higher than the maximum allowable level of 20ppm which was needed to achieve the 1979 Environmental Protection Agency (EPA) emissions standards.

Meanwhile, Ballal and Lefebvre (1979), in their study, stressed that for a premixed flame, the weak extinction limits were governed mainly by inlet air temperature, to a lesser extent by air velocity and turbulence level and were almost independent of pressure.

Past researchers also have studied the effect of varying the vane angle, which in turn vary the swirl number, on combustion performance. Claypole and Syred (1981) investigated the effect of swirl strength on the formation of  $\text{NO}_x$ . At swirl number of 3.04, much of the  $\text{NO}_x$  in the exhaust gases was recirculated into the flame front. The total emissions of  $\text{NO}_x$  were reduced, however, at the expense of reduced combustion efficiency.

Noyce and Sheppard (1982) investigated the influence of equivalence ratio on air and fuel mixing. They suggested that at low and high power conditions the high CO emissions could be minimised by better mixing.

Al-Kabie (1989), on the other hand, studied the effect of radial swirler on emission reduction in gas turbine combustor. In his study, he imposes swirler expansion ratio of 1.8 to achieve adequate combustion efficiency. Al-Kabie, in his study, showed that high efficiency was not achieved in weak region until there was a significant outer expansion and associated recirculation zone. However, there was a little influence of the expansion ratio on the weak extinction limit. Alkabie have shown that if fuel is injected into the outer recirculation zone, in the corner of the dump expansion region, then  $\text{NO}_x$  emission are high as this recirculation zone has a high residence time and low refreshment rate with air. To minimise this effect for burner application, the use of an orifice restriction at the outlet of the wall fuel injector was used. The intention was to deflect any fuel in the wall region radially inwards into the shear layer. Various non-conventional fuel injection methods was studied such as swirler vane passage, radial central and wall injection were used with gaseous propane and natural gas and liquid kerosene and gas oil. The test was

conducted using lean-lean two-stage combustion concept. He demonstrated that there is no significant effect on  $\text{NO}_x$  emissions by varying the vane angle from  $20^\circ$  to  $60^\circ$ , hence varying the swirl number from 0.41 to 3.25, respectively. However, he found that at very high swirl number of 3.25,  $\text{NO}_x$  emissions were considerably higher than the rest at all associated equivalence ratios for two different inlet air temperature of 400 K and 600 K. This may be due to increased residence time in the rich stabilizing shear layer and hence increased  $\text{NO}_x$  emissions. The same effect was demonstrated when he switched from natural gas to propane. Another way to increase the strength of swirl without changing the vane angle is to decrease the vane depth of the swirler. Combustion efficiencies were also improved as the swirl strength increased. Increasing the swirl strength also extends the lean flammability limits.

Bicen et. al. (1990), have reported temperature and species measurements for annular and tubular combustors using the same axial swirler for flame stabilisation. The annular combustor was operated at an air/fuel ratio of 29 and fuelled by natural gas; it displayed a marked improvement in combustion efficiency, 94% compared to 69%, when the inlet air temperature was raised from 315K to 523K. This improvement was observed to be a result of improved fuel and air mixing. Meanwhile, the tubular combustor was operated at a leaner fuel/air ratio of 57 and fuelled by propane, showed a more modest improvement in combustion efficiency, 97.7% compared to 98.8%, when the inlet air temperature was raised from 315K to 523K. They then concluded that from detailed measurements, the increase in efficiency was due to improved mixing in the combustor. Whitelaw commented that combustor aerodynamics was more dominant characteristic compared to chemical kinetics in the primary zone combustion (Bicen, A.F. et. al, 1990).

Escott, N.H. (1993) studied the combustor flow of three methods of swirling generation namely single, coswirl and counterswirl. He used three basic fuel injection modes of swirler vane passage, central and wall injection. Escott finds that low  $\text{NO}_x$  emission was achievable through central fuel injection mode, but the lowest emission results were shown by wall injection method. However, Escott insisted that the results were strongly dependent on the input temperature and pressure provided to the flow. Escott also ran an experiment on simple fuel staged injection system and concluded that there was no improvement in either emission or stability compared to

non-staged modes. Coswirl and counterswirl combustion system with passage fuel injection into half of the air flow improved the flame stability but with unacceptable increase in  $\text{NO}_x$  emissions. From his observation, he concluded that lower  $\text{NO}_x$  emission was generated by counterswirl system with deteriorated flame stability due to more vigorous air mixing and consequently leaner fuel occurring in the interjet shear layer.

Kim, M.N. (1995), in his study, stresses on curved blade radial swirlers with wall injection and vane passage injection. The fuels were natural gas, propane and gas oil. He concluded that vane passage injection mode produce lower emission results compared to 76mm wall injection because of wall injections mode injects the fuel in the high residence time corner recirculating zone. This created locally rich zone and high thermal  $\text{NO}_x$ . He also find that natural gas produce lower emission compared to propane due to the better fuel and air mixing between natural gas and air since natural gas has a lower molecular weight than propane which means high diffusivity action and natural gas can be quickly dispersed into turbulent region of shear layer and hence low  $\text{NO}_x$  formation.

Mohd. Radzi Mohamed Yunus (2002), studied the effect of varying swirler vane angles on emissions reduction. He found that optimum swirler vane angle for  $\text{NO}_x$  emission found to be  $60^\circ$ ; for CO was  $80^\circ$  and for  $\text{SO}_2$  was  $70^\circ$ . He suggested that recirculation zone size and turbulence flow affects emissions significantly.

### **1.3 Problem Statement**

Current researchers hastily moved their intension to post combustion methods as they found out that post combustion methods could possibly reduce emissions twice of the pre combustion methods. But, take note that this would heavily increase the cost which would discourage the industries to venture in. Besides that, post combustion methods at present situation were almost impossible to apply in aircraft engines as it would increase the engine weight which opposes the aircraft applications requirement of producing low weight-high trust engines. This research

concerns on the above mentioned problems and carried out a study to discover a better solution on reducing emission from gas turbine, mainly for aircraft applications.

#### **1.4 Objective of Research**

The main objectives of this project are as follows:

- a. To investigate and select a method of reducing pollutions from liquid fuel burner.
- b. To design the liquid fuel burner system that incorporates the chosen method.
- c. To fabricate the prototype, an efficient and environmental friendly liquid fuel burner.
- d. To evaluate the performance of the prototype burner.

#### **1.5 Scopes of Research**

The scope of the research is as follows:

- a. Literature survey on existing liquid fuel burner and emissions reduction techniques.
- b. Preliminary design and dimensioning of liquid fuel burner.
- c. Preliminary design of burner components such as air swirler, atomiser, etc.
- d. Preliminary design analysis based on experimental data of the existing burner and from simulation results.
- e. Detail design of the liquid fuel burner including technical drawings for fabrication.
- f. Construction of the liquid fuel burner prototype, including other components.
- g. Testing of liquid fuel burner performance:
  - (i) Combustion stability
  - (ii) Flame development and propagation

- (iii) Emissions production/reduction
- (iv) Temperature and pressure profiles across the burner

## 1.6 Limitation of the Study

- (i) The research will be conducted using four different swirler vane angles of 30°, 40°, 50° and 60°.
- (ii) Three orifice plate diameters of 20mm, 25mm and 30mm will be used for experimental testing to study the effect of orifice plate insertion.
- (iii) Fuel injection is placed at two positions that is at 15mm upstream or downstream from the swirler exit.
- (iv) Diesel fuel used was supplied by Universiti Teknologi Malaysia, which is obtained bulkily from Petronas fuel station.
- (v) The geometry of combustion chamber, fuel injector, orifice plates and swirlers are as designed.
- (vi) Fuel and injection air are pressurized constantly at 2 bar.
- (vii) Flow rate of injection air is constant at 170 ℓ/m.
- (viii) Swirling air flow rate will be varied from 24 CFM to 9 CFM, which is from 679.608 LPM to 254.853 LPM.

## 1.7 An Outline of the Report

This report consists of seven chapters. Chapter one describes briefly on the problem statement of current research. Problem statement reveal lacks of previous researches and illustrates the significant of this research. However, there were some limitations in the study that has been expressed.

Chapter two discusses thoroughly on the literature study. Four main items of gas turbine combustor; combustion chamber, flame stabilizer, fuel injector and air-fuel system has been discussed fundamentally. The impact of the emissions towards environment and human was explained in detail. The requirement that to be fulfilled on producing a good combustion chamber, flame stabilizer, fuel injector and air-fuel supply has been discussed for better understanding. Besides that, varieties of these four items have been highlighted in this section to study the availability and manufacturability of these items.

Meanwhile, chapter three concerns on the emissions behaviour and emissions controlling methods. Main concern of this research is to improve the  $\text{NO}_x$  emissions as CO emissions could be reduced through good mixing of air and fuel.  $\text{NO}_x$  emission control techniques have been described briefly.

Chapter four, on the other hand, emphasize on the burner design concepts. This chapter explains the requirement required to build a burner. All four main items of combustor; combustion chamber, swirler, fuel injector and air fuel system design concepts has been discussed.

Chapter five elaborates on the experimental testing setup. This chapter describes clearly on the equipments and instrumentations used for the entire experimental testings. There were also guidelines on how the experiment has been conducted.

Chapter six confers about the experimental results and discussion on the combustion performance of that carried out in the experimental testing. Results has been compared between four different swirler vane angle of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using three different orifice plate sizes of 20mm, 25mm and 30mm at upstream and downstream injection position. The behaviour of the emission results and temperature profiles was discussed thoroughly.

Chapter seven concludes the emission results and temperature profiles discussions. Recommendation for future work has been stressed in this chapter to

provide inspiration for future researchers to continue delivering improvement in emission reduction from pre combustion burners.

## **CHAPTER II**

### **LITERATURE REVIEW**

#### **2.1 Introduction**

Gas turbine technology has developed gradually and continuously over the past fifty years. Despite continued advances in the technology of gas turbine combustors, the need to protect the environment from combustion gaseous has led to considerable demand to improve the combustor design.

Combustion chamber, flame stabilizer, injector and air-fuel mixture system are the components in a combustor that should be carefully studied in order to achieve a low emission burner system. In this thesis, the research will focus more on the swirler vane angles as the main parameter is on lowering burner emission.

#### **2.2 Environmental Problems**

The use of fossil fuels is a major source of air pollution, in particular, emissions of oxides of nitrogen, oxides of carbon and oxides of sulphur. Fossil fuels combustion is a major contribution of four pressing environmental concerns, which is, global warming, acid rain, photochemical smog and ozone depletion. This concern has prompted many governing bodies to legislate regulations on emissions from combustion process in the hope that these environmental problems will be reduced.

### **2.2.1 Acid Rain**

Acid rain has several damaging effects on ecological system. Acid rain falls and polluted the lakes, river and sea. Lake acidification tends to reduce the population of its inhabitants. Many lakes around the world are losing their fish population due to the lake acidification. Acid rain also causes damage to plants and human health. The main source of acid rain is oxides of sulphur and nitrogen, predominantly from the combustion processes. In general  $\text{SO}_2$  contributes about 60 percent of such precipitation, whereas  $\text{NO}_x$  contributes about 35 percent.  $\text{SO}_2$  content can be reduced by desulphurization process in the combustion chamber but this process will tend to increase the  $\text{NO}_x$  in the combustion chamber (Mellor, A.M., 1990).

### **2.2.2 Ozone Depletion**

Ozone layer has the ability to absorb ultra-violet (UV) radiation from the sun. A direct UV ray can kill plants and animal cells. It also can cause skin cancer to human. As the ozone layer absorbs ultra-violet, it may change the temperature structure of the atmosphere and hence alter the atmospheric circulation. Ozone in the troposphere is a greenhouse gas. It absorbs the infrared radiation and will trap heat hence cause the earth to become warmer. The formation and destruction of the ozone layer should always be in equilibrium to preserve the ozone layer that is protecting the earth. However, the increased in the concentration of pollution gases in the atmosphere such as oxides of nitrogen from the combustion processes has led to an imbalance in this equilibrium. The destruction of the ozone layer occurs at the faster rate than its formation. The clear sign of ozone depletion was the 'ozone hole' that was reported in 1984 (Mellor, A.M., 1990). Since then, ozone hole was reported each year.

### 2.2.3 Global Warming

Global warming or known as greenhouse effect is a phenomenon described by a rise in the earth atmospheric temperature. This rise of temperature is caused by the imbalance of the energy of the earth. Greenhouse gases play an important role to reflect back the ultraviolet radiation that penetrates the earth's atmosphere as infrared radiation. Greenhouse gases are carbon dioxide (CO<sub>2</sub>), methane (CH<sub>4</sub>), ozone (O<sub>3</sub>), nitrous oxide (N<sub>2</sub>O) and chlorofluorocarbon (CFC).

Atmosphere emits less energy into space than the earth's surface. This is because the atmosphere's average temperature is lower, roughly -18°C. The difference between the energy emitted by the earth and the atmosphere is absorbed by the atmosphere. This energy trapping process is called the greenhouse effect. The greenhouse effect keeps the global temperature at a habitable 15°C rather than a hostile -18°C (Mellor, A.M., 1990). However, if the concentration in the atmospheric carbon dioxide increases, the global temperature will be higher. This phenomenon will cause global climate change. CO<sub>2</sub> is the biggest contributor to global warming. The effect of the doubling in carbon dioxide concentration will raise the global average surface temperature by  $2 \pm 1$  K (Mellor, A.M., 1990).

### 2.2.4 Photochemical Smog

Photochemical smog is a phenomenon that happened when there are air stagnation, abundant sunlight and high concentration of hydrocarbon and oxides of nitrogen in the atmosphere (Escott, N.H., 1993).

Smog arises from photochemical reactions in the lower atmosphere by the interaction of hydrocarbons and nitrogen dioxide released by the exhausts of motors and combustion processes. This interaction results in a series of more complex reactions producing secondary pollutants such as ozone, aldehydes, ketones and peroxyacyl nitrates.

### 2.3 Combustor Exhaust Emissions

Generally there are four major pollutants from any combustion processes. These are oxides of nitrogen ( $\text{NO}_x$ ), carbon monoxide (CO), unburned hydrocarbon (UHC) and smoke. Sulphur dioxide ( $\text{SO}_2$ ) is present if the fuel used during the combustion processes contained sulphur. In this research, concern was on the three hazardous pollutants that are oxides of nitrogen, carbon monoxide and sulphur dioxide since these pollutants has detrimental effect on the health and environment. Table 2.1 shows the amount these emissions form varies sources.

**Table 2.1:** Source of Atmospheric emissions (Jabatan Alam Sekitar, 1997)

Pollutants	Pollution Source	Present (1992)	Future (2005) (unit: ton/year)	
			Without Measures	With Measures
<b>SO<sub>x</sub></b>	Factories

Figures in parentheses are amount of reduction in percentage

### 2.3.1 Oxides of Nitrogen

Oxides of nitrogen ( $\text{NO}_x$ ) are the term given for the combustion product of nitrogen such as nitric oxide (NO), nitrogen dioxide ( $\text{NO}_2$ ) and nitrous oxide ( $\text{N}_2\text{O}$ ).  $\text{NO}_2$  is the dominant form of  $\text{NO}_x$  in fuel lean burning but NO is the dominant form of  $\text{NO}_x$  from combustion processes. The major source of nitrogen in combustion processes is the air itself.

#### 2.3.1.1 Nitric Oxide

Nitric oxide (NO) is the direct precursor of  $\text{NO}_2$ . The rate of oxidation from NO to  $\text{NO}_2$  is too slow to give significant conversion during the short time of resident time in the combustion process. This reaction, however, has ample time to take place once released into the atmosphere. NO has some harmful effects on health but these effects are substantially less than those of an equivalent amount of  $\text{NO}_2$ . NO and  $\text{NO}_2$  interact with the smog producing atmospheric photolytic cycle in different ways. Concentration of  $\text{NO}_2$  are generally lower than those of NO but large concentration of  $\text{NO}_2$  as a primary pollutant can reduce the induction time for photochemical smog since the relatively slow NO to  $\text{NO}_2$  oxidation steps is bypassed. NO does not irritate the lungs but forms methemoglobin when absorbed. NO is an endogenous modulator of the vascular pressure (Al-Kabie, H.S., 1989).

An additional augmentation of NO formation is the temperature fluctuation. In turbulent flames instantaneous temperature levels will exceed the time average temperature level due to mixing imperfection and NO formation will be increased above the level predicted on the basis of the time average temperature (Kim, M.N., 1995). The fluctuation occurs due to variation in the mixture ratio and bulk movement of the flame.

NO can be produced by three different mechanism that is thermal NO, prompt NO and fuel NO.

Thermal NO is produced by oxidation of atmospheric nitrogen in the post flame gases and refers to NO formation in the combustion of lean and near stoichiometric fuel-air mixtures as suggested by the Zeldovich chain mechanism. The concentration of O<sub>2</sub> is low in fuel rich combustion therefore Reaction (1.3) is less important than in fuel lean combustion. Meanwhile, high activation energy is needed to break the N<sub>2</sub> triple bond in Reaction (1.2) therefore this reaction was concern in very high temperature combustion that is greater than 1500°C (Escott, N.H., 1993).

Prompt NO is produced by high speed reactions at the flame front for hydrocarbon fuels. Term prompt NO is used because the NO is formed in the flame front and not in the post flame gases like thermal NO. Flame temperature does not rely on the prompt NO. Kim (1995) suggested that prompt NO is the major source of NO emission in lean burning swirl stabilized flame. Meanwhile Fenimore (1970) observed that the amount of prompt NO increased markedly as the flame passes from fuel lean to fuel rich condition. The N atom produced in Reactions (1.4), (1.6) and (1.7) then react with O<sub>2</sub> in Reaction (1.3) to produce more NO (Escott, N.H., 1993).

Fuel NO is produced by oxidation of nitrogen contained in the fuel. The fuel nitrogen is converted to HCN in the flame zone and depending on the degree of nitrogen conversion; the fuel NO represents a considerable portion of the total NO. For liquid fuel, kerosene does not contain fuel bound nitrogen, but gas oil contains significant amount of nitrogen. Fuels that contain sulphur and organically bound nitrogen produce complicated interactions that promote the formation of further NO.

### 2.3.1.2 Nitrogen Dioxide

Nitrogen dioxide (NO<sub>2</sub>) has been known to have adverse effect on the human respiratory system. It has an affinity for haemoglobin, which carries oxygen to body tissues. It also forms acid in the lungs. Nitrogen dioxide is much more toxic than CO for the same concentrations. Besides that, it also forms smog from a series of photochemical reactions. Epidemiological studies of exposure to the nitrogen dioxide released during cooking with gas indicate an increase frequency of respiratory illness among children. NO<sub>2</sub> is formed by the oxidation of NO as shown below (Escott, N.H., 1993).

In hot regions of the flame the reverse of Reaction (1.9) occurs. The conversion of NO to NO<sub>2</sub> by Reaction (1.10) is generally slow because HO<sub>2</sub> concentration is low, however in fuel lean conditions HO<sub>2</sub> concentration increases (Flagan, R.C. and Seinfeld, J.H., 1988).

### 2.3.1.3 Nitrous Oxide

The increase of nitrous oxide (N<sub>2</sub>O) concentration in the atmosphere contributes to the greenhouse effect and depletes the stratospheric ozone layer and this would increase ultraviolet radiation to the earth's surface and with it the occurrence of skin cancer in the population (Crutzen, P.J., 1970) and (Sothorn, A., 1979). Nitrous oxide is formed mainly from biological activity of the soil. This gas is not a potential health problem, nor does having a damaging effect on vegetation. Only 20% of this gas is produced by fossil fuel combustion.

N<sub>2</sub>O normally formed due to fuel NO where the fuel itself is nitrogen bounded. However, Escott (1993) suggested that N<sub>2</sub>O could be formed through

prompt NO as well as in the fuel NO. The reaction of combustion product to form N<sub>2</sub>O is as shown below (Escott, N.H., 1993).

The NCO radical then reacts with NO to form:

Studies have shown that temperature is a vital factor in the formation of N<sub>2</sub>O with the maximum concentration of N<sub>2</sub>O occurring around 750°C. At temperature lower than 750°C, Reaction (1.11) dominated thus N<sub>2</sub>O prevented. As temperature increases above 750°C, N<sub>2</sub>O is prevented by the reaction (Escott, N.H., 1993):

### 2.3.2 Carbon Monoxide

Carbon monoxide (CO) has a strong affinity to the haemoglobin of the bloodstream and is a dangerous asphyxiates. It produces carboxyhaemoglobin when it reacts with the proteins in the lungs. Carboxyhaemoglobin reduces the oxygen-carrying capacity of the blood and has the potential to starve the brain and other tissues of oxygen. At a low concentration, it has potential to cause headaches, slow reflexes, reduce manual dexterity, decrease exercise capability and cause drowsiness. At a high concentration, carbon monoxide can cause death.

Rapid reaction between hydrocarbons from the fuel and the air in the combustion process generates CO emission. This rapid reaction between hydrocarbon fuels and air will form  $\text{CH}_2\text{O}$  and  $\text{CHO}$  that will then further react with other radicals to form CO (Escott, N.H., 1993).

Emission level of CO can only be minimised by completing its oxidation to carbon dioxide ( $\text{CO}_2$ ). Conditions favourable to the oxidation of CO are high temperature, oxygen availability, high pressure and long residence time. The predominant mechanism for CO oxidation is:

### 2.3.3 Unburned Hydrocarbon

Unburned hydrocarbon (UHC) is also a product of incomplete combustion. A complete combustion does not produce hazardous emission, but it is impossible to produce complete combustion because the fuel-air mixing and ignition occur at a very rapid process. Unburned hydrocarbon is usually formed due to poor atomisation, inadequate burning rates and the chilling effects of burner walls or any combination of these. Some hydrocarbon species does not provide a serious health hazard. Other hydrocarbons could cause cancer when its deposition is above certain level. UHC also acts as a precursor to the formation of photochemical smog.

The inability to complete the combustion of the fuel affects the combustion efficiency. So maximising the combustion efficiency could reduce emission of hydrocarbons. Besides that, excess air also could reduce the combustion efficiency due to the lowering of temperatures and the increase in heat losses arising as mass

flow rate of exhaust gases increased. Residence time is also another factor to satisfy for good mixing in the combustor. Combustor should not be overloaded, that the heat extraction during the combustion is controlled, so that exhaust gases are not quenched before the combustion reactions can go to completion. This entire variable is interrelated.

#### **2.3.4 Oxides of Sulphur**

Sulphur dioxide ( $\text{SO}_2$ ) presents in the combustion process when there are sulphur content in the fuel used in the combustion process. Normal persons who inhale sulphur dioxide for a brief period could exhibit shallower and more rapid breathing. The presence of aerosol may sweep the sulphur dioxide molecules deep into the respiratory system that may cause respiratory illnesses. Besides that, low concentration of sulphur dioxide, in association of other irritant gases and particles that are present, are sufficient to impair the function of the lungs (Crutzen, P.J., 1970). Oxides of sulphur also act as precursor to the formation of acid rain.

#### **2.3.5 Carbon Dioxide**

Carbon dioxide emission ( $\text{CO}_2$ ) is stable and non-toxic but it is a greenhouse gas and can contribute to global climate change. There is no effective process to reduce this emission. The only way to reduce this emission is to burn less carbon. The only way of achieving this is by using lower carbon fuels (Kim, M.N., 1995).

## 2.4 Gas Turbine Combustor

Gas turbine engines are widely used in aircraft, marine, power generation and industrial application due to largely tremendous advantages in term of range, speed, fuel economy, passenger comfort, compactness and high power output.

Conventional gas turbine combustion chamber essentially consists of three main sections. These are primary, intermediate and dilution zones. The most vital section for the combustion chamber designer is the primary zone since combustion of fuel is initiated in this section (Al-Kabie, H.S., 1989). The achievement of complete combustion in the primary zone is the aim of the present work which reduces the need for other sections of the combustors fulfilling the requirement of small size and light weight of gas turbines.

### 2.4.1 Operation of a Gas Turbine Combustor

**Figure 2.1:** Typical Combustor Cross Section (Lefebvre, A.H., 1983)

The combustor is divided into three separate regions; those are primary zone, intermediate zone and dilution zone. If all the air and fuel supplied to the gas turbine

engine were supplied into the combustor directly, the resulting mixture would have a fuel-air ratio lower than the lean flammability limits. Thus the combustion is initiated and stabilized by the controlled mixing of fuel and air in the primary zone and the exact fuel-air ratio of the mixture will depend on the approach to emission reduction that is adopted, either lean, stoichiometric or rich. Stoichiometry refers to the amount of air required theoretically to combust completely a particular amount of fuel.

The role of the primary zone in the combustor is to ensure complete combustion of the fuel by providing sufficient time, temperature and turbulence. The intermediate zone serves as an extension to the primary zone providing an increased residence time at high temperature prior to cooling and virtual freezing of reaction in the dilution zone. Meanwhile, the role of the dilution zone is to admit the air remaining after the combustion and wall cooling requirement have been met, and to provide an outlet stream with a mean temperature and a temperature distribution that are acceptable to the turbine.

## **2.4.2 Combustor Arrangement**

There are three common combustor arrangement; tubular, annular and tuboannular type combustors. Tubular combustor is also known as can-type combustor.

### **2.4.2.1 Tubular Combustor**

Tubular combustor as shown in Figure 2.2 has one combustor on a central axis or several combustors arranged equidistant on the same pitched circle diameter. Each combustor consists of an inner flame tube or liner cylinder mounted on the same axis inside an outer casing cylinder. Tubular combustor is mainly used in industries, marine, vehicular and aircraft application. However modern aircraft applications are more concerned with the engines weight-thrust ratio and so

combustors that have a larger combustion volume, hence more thrust, are preferred. The advantages and disadvantages of tubular combustor were shown in Table 2.2.

**Figure 2.2:** Tubular Combustor (Treager, I.E., 1995)

**Table 2.2:** Advantages and Disadvantages of Tubular Combustor (Treager, I.E., 1995)

Advantage	Disadvantage
1. Mechanically Robust	1. Bulk and weight
2. Small variation between individual combustor in combustion and aerodynamic performance	2. Ignitor for each combustor increases complexity of design except for single combustor
3. Rig testing can be performed with just one combustor using a fraction of the total engine air and fuel mass flow	3. Interconnection tubes between combustors for the air flow except for single combustor
	4. Problems associated with the initiation in combustion in all combustors except for single combustor
	5. High pressure loss

### 2.4.2.2 Annular Combustor

Annular combustor as shown in Figure 2.3 consists of an inner annulus mounted on the same axis inside an outer casing annulus. Annular combustor is widely used in modern aircraft application particularly in military aero engines. The advantages and disadvantages of annular combustor were shown in Table 2.3.

**Figure 2.3:** Annular Combustor (Treager, I.E., 1995)

**Table 2.3:** Advantages and Disadvantages of Annular Combustor (Treager, I.E., 1995)

Advantage	Disadvantage
1. Minimum Length and weight	1. Buckling problems on outer liner leading to disruption of cooling air flow and variation in outlet gas temperature creating possible thermal stresses in the turbine blades
2. Minimum pressure loss	2. Rig testing requires use of total engine air and fuel mass flow
3. Minimal problems with light around	3. Even distribution of fuel and air is difficult to achieve around the annular

### 2.4.2.3 Turboannular Combustor

Turboannular combustor as shown in Figure 2.4 is a hybrid of the previous two types of combustors. This combustor consists of several cylindrical liners arranged equidistant on the same pitched circle diameter are mounted inside a single outer casing annulus. The advantages and disadvantages of turboannular combustor were shown in Table 2.4.

**Figure 2.4:** Turboannular Combustor (Treager, I.E., 1995)

**Table 2.4:** Advantages and Disadvantages of Turboannular Combustor (Treager, I.E., 1995)

Advantage	Disadvantage
1. Mechanically robust	1. Suffers from the problem of light around
2. Low pressure loss	2. Less compact than annular combustor
3. Shorter and lighter than tubular combustor	3. Even distribution of air is difficult to achieve around the annulus
4. Rig testing requires use of just one combustor, using fraction of total engine air and fuel flow	4. Ignitor for each combustor increases the complexity of design

### 2.4.3 Combustor Design Requirement

The basic function of a combustor is to convert admitted fuel and air mixture to a temperature rise for the turbine stage. However there are wide varieties of criteria that also need to be considered in order to achieve the best combustor design. The criteria are (Fricker,N. and Leuckel,W., 1976):

1. The combustor must be capable of reliable and smooth ignition over a wide range of ambient conditions.
2. After ignition, the flame must stay alight over wide range of inlet temperature, pressure and equivalent ratio.
3. The fuel should be completely burned so that all of its chemical energy is liberated as heat, typically modern combustors achieve combustion efficiencies of 99.9 percent over a wide range of equivalent ratios.
4. The pressure loss of the combustor should be low, between 2-7 percent of the combustor inlet pressure. Higher pressure loss would result in higher compressor pressures.
5. The temperature distribution at the exit of the combustor often needs to be altered in order to increase the life of turbine blades.
6. Low emissions of carbon monoxide, unburned hydrocarbons, oxides of nitrogen, oxides of sulphur and soot will be necessary to pass ever more stringent emission limits.
7. All combustor types must be designed to be durable and safe.
8. Aero engine requires short combustor length to keep the engine light weight.
9. Stationary and vehicular engines often require multifuel capability.

### 2.5 Flame Stabilizer

One of the main basic requirements of the combustor is to support combustion over a wide range of operating conditions. This could be achieved by an appropriately designed flame stabilizer. Flame stabilization could be achieved if a sheltered region is provided to entrain and recirculates some of the hot combustion

burnt gases with the fresh incoming fuel and air mixture. There are several types of flame stabilizer such as bluff bodies, opposed jets, jet mix and grid mix, axial swirler and radial swirler.

### 2.5.1 Bluff Body

The bluff body flame stabilizer causes a flow recirculation by creating a low pressure zone in its near wake region.

**Figure 2.5:** Bluff Body Flame Stabilizers

### 2.5.2 Opposed Jet

Opposed jet stabilizers cause a recirculation zone by the action of jets impinging either on one another or by the action of a jet being directed upstream into the oncoming main flow.

**Figure 2.6:** Opposed Jet Flame Stabilizers

### 2.5.3 Sudden Expansion

A sudden expansion in the diameter of the combustor also could generate recirculation zone hence stabilize the flame.

**Figure 2.7:** Sudden Expansion Flame Stabilization

### 2.5.4 Grid Mix and Jet Mix

Flame stabilization in the grid mix and jet mix is actually stabilized by injection of the fuel into the base of the fuel and air shear layer.

**Figure 2.8:** Grid Mix Flame Stabilizer

### 2.5.5 Axial and Radial Swirler

Axial and radial swirlers stabilize the flame through the generation of central recirculation zone that is formed when the vortex breakdown occur. Both of these swirlers attempt to inject the fuel into the base of the swirling shear layer to increase flame stability.

**Figure 2.9:** Axial or Radial Swirler

## 2.6 Injection System

**Figure 2.10:** Injector (Mellor, A.M., 1990)

Fuel injection system also plays a major role in gas turbine combustion performance. Most combustion chambers employ high pressure fuel system in which the liquid fuel is forced through a small orifice to form a conical spray of fine droplets (atomization) in the primary zone. This is to produce a high ratio of surface to mass in the liquid phase, resulting in very high evaporation rates. The most obvious requirement in fuel injection is that the time required for burning of the spray (vaporize) must be kept short. The injector is also referred to as atomizer as its main function is to atomize the fuel.

### 2.6.1 Injectors Requirement

An ideal fuel injectors would possess all the following characteristics (Lefebvre, A.H., 1983) and (Bent, R.D. and McKinlay, J.L., 1985) :

1. Good atomization over the entire range of fuel flows.
2. Rapid response to changes in throttle settings.
3. Freedom from flow instabilities.
4. Low susceptibility blockage by contamination and carbon deposition on the nozzle.
5. Low susceptibility to gum formation by heat soakage.
6. Capability for scaling, to provide design flexibility.
7. Low cost, lightweight, ease of manufacture and ease of removal for servicing.
8. Low susceptibility to damage during manufacture and installation.
9. Freedom from vaporization icing, thus making it unnecessary to use carburettor heat except under the most severe atmospheric conditions.
10. More uniform delivery of the fuel-air mixture.
11. Improved control of the fuel-air ratio.
12. Reduction of maintenance problems.
13. Instant acceleration of the engine after idling, with no tendency to stall.
14. Increase engine efficiency.
15. An easy ignitable mixture.
16. A ratio of maximum to minimum fuel flow that exceeds the ratio of maximum to minimum combustor airflow.
17. Controlled dispersion of the fuel throughout the primary combustion zone.
18. An exit gas temperature distribution that is insensitive to variations in fuel flow rate.

## 2.6.2 Atomization Process

In gas turbine combustion chambers, atomization is normally accomplished by spreading the fuel into a thin sheet to induce instability and promote disintegration of the sheet into drops. Thin sheets could be obtained by discharging the fuel through orifice with specially shaped approach passage by forcing it through narrow slots, by spreading it over a metal surface or by feeding it to the centre of a rotating disk. The function of the atomizer is to attenuate the fuel into a fine jet or thin sheet from which ligaments and ultimately drops will be produced and distribute the resulting drops throughout the combustion zone in a controlled pattern and direction.

### 2.6.2.1 Jet Break Up

Several modes of jet disintegration have been identified, but in all cases the final mechanism involves the break up of unstable threads of liquid into rows of drops conforming to the classical mechanism postulated by Rayleigh (Lefebvre, A.H., 1983).

According to Rayleigh's theory, liquid becomes unstable and breaks into drops when the amplitude of a small disturbance, symmetrical about the axis of the jet, grows to one half the diameter of the undisturbed liquid jet. This occurs when  $\lambda/d_o = 4.5$ , where  $\lambda$  is the wavelength of the disturbance and  $d_o$  is the initial jet diameter. For this value of 4.5, the average drop diameter of break up is  $1.89 d_o$ , which is almost double of the diameter of initial jet diameter. In Rayleigh's theory, liquid viscosity is not considered. This theory later extended by Weber to include the effect of liquid viscosity effect on the break up (Lefebvre, A.H., 1983). According to Weber, the ratio of  $\lambda/d_o$  required to produce maximum instability for viscous jets is given by :

$$\frac{\lambda}{d_o} = \left[ \pi \sqrt{2T} + \frac{3\mu_L}{\sqrt{\rho_L \sigma d_o}} \right]^{0.5} \quad (2.24)$$

When  $\mu_1 = 0$ , the value of  $\lambda/d_o = 4.44$ , which is almost the same as the value of Rayleigh's prediction. However, when a liquid with viscosity of 0.86 kg/ms is experimented, the ratio of  $\lambda/d_o$  for maximum instability ranged from 30 to 40. This clearly differs from Rayleigh's prediction.

In the case of liquid jet disintegration due to the influence of the surrounding air, the drop size obtained is governed by the ratio of disruptive aerodynamic force  $\rho_A U^2 R$  to the consolidating surface tension force  $\sigma/d_o$ . This dimensionless ratio is also known as Weber number.

$$We = \frac{\rho_A U^2 R d_o}{\sigma} \quad (2.25)$$

In the case of liquid jet disintegration without the influence of the surrounding air, the atomization quality is dependent on jet diameter, liquid properties density, surface tension and viscosity. This break up mechanism is dependent to Z number.

$$Z = \frac{We^{0.5}}{Re} = \frac{\mu_L}{\sqrt{\sigma \rho_L d_o}} \quad (2.26)$$

### 2.6.2.2 Sheet Break Up

Fraser and Eisenklam, has identified three modes of sheet disintegration, described as rim, wave and perforated sheet disintegration (Bent, R.D. and Mckinlay, J.L., 1985).

In the rim disintegration mode, forces were created by surface tension causes the free edge of a liquid sheet to contract into a thick rim, which then breaks up by a mechanism corresponding to the disintegration of a free jet. When this occurs, the resulting drops continue to move in the original flow direction, but they remain attached to the receding surface by thin threads that also rapidly break up into rows of drops. This mode of disintegration is most prominent where the viscosity and

surface tension of the liquid are both high. It tends to produce large drops, together with numerous small satellite droplets.

In perforated sheet disintegration, holes appear in the sheet at a certain distance from the orifice. The holes are delineated by rims formed from the liquid that was initially included inside. These holes grow rapidly in size until the rims of adjacent holes coalesce to produce ligaments of irregular shape that finally break up into drops of varying size.

Atomizers that discharge the fuel in the form of sheet are usually capable of exhibiting all three modes of sheet disintegration. Sometimes two different modes occur simultaneously, and their relative importance can greatly influence both the mean drop size and the drop size distribution.

### **2.6.3 Spray Characteristic**

Combustion performance is also dependence on spray characteristic such as mean drop size, drop size distribution, spray pattern, cone angle, dispersion and penetration. Mean drop size and drop size distribution are important in designing the atomizer meanwhile spray pattern, cone angle, dispersion and penetration are governed partly by atomizer design and partly by the aerodynamics influence to which the spray is subjected after atomization is completed.

#### **2.6.3.1 Mean Drop Size**

Mean diameter plays an important role in determining the evaporation rate and atomization qualities of various sprays. The general idea of the mean diameter is to replace the given spray with imaginary drops which have the same diameter while retaining certain criteria of the original spray. The sauter mean diameter (SMD) is the one which is most common and widely used. It is defined as the diameter of a

drop having the same volume/surface ratio as the entire spray (Hoe, Y.M., 2000).

Table 2.5 shows some mathematical definitions of mean drop size.

$$SMD = \frac{\sum nD^3}{\sum nD^2} \quad (2.27)$$

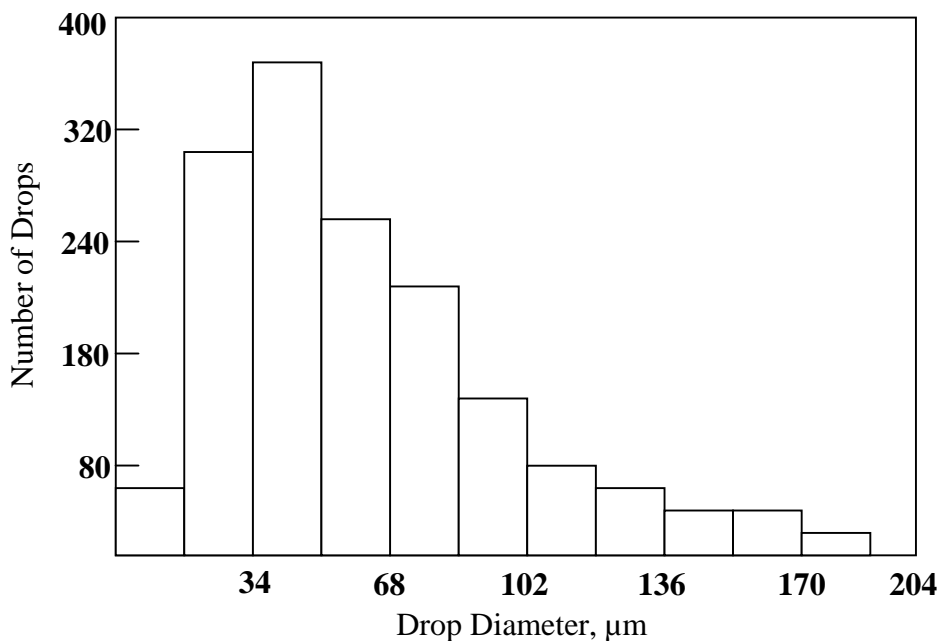

**Table 2.5:** Some Mathematical Definitions of Mean Drop Size (Hoe, Y.M., 2000)

Parameter	Description	Symbol for Mean Diameter	Mathematical Definition of Mean Diameter
Diameter	Linear mean diameter of drops in spray	$D$ or $D_1$	$\frac{\sum nD}{\sum n}$
Area Length	Diameter of a drop having the same surface/diameter ratio as the entire spray	$D_o$	$\frac{\sum nD^2}{\sum nD}$
Volume-Surface Diameter	Diameter of a drop having the same volume/surface ratio as the entire spray	$SMD$	$\frac{\sum nD^3}{\sum nD^2}$
Area Diameter	Diameter of a drop whose surface area is equal to the mean surface area of all the drops in the spray	$D_2$	$\left[ \frac{\sum nD^2}{\sum n} \right]^{0.5}$
Volume (Mass) Diameter	Drop diameter below or above which lie 50% of the mass of the drops	$MMD$	$\left[ \frac{\sum nD^3}{\sum n} \right]^{0.33}$

### 2.6.3.2 Drop Size Distribution

The drop size distribution is most difficult to predict theoretically and to determine experimentally. An instructive picture may be obtained by plotting a histogram of drop size, each ordinate representing the number of drops whose

dimensions fall between the limits  $x \pm \Delta x/2$ . A typical histogram of drop size distribution is shown in Figure 2.11 in which  $\Delta x = 17 \mu m$ .

**Figure 2.11:** Typical drop-size histogram (Hoe, Y.M., 2000)

### 2.6.3.3 Spray Pattern and Cone Angle

The uniformity of the distribution of fuel in a conical spray is referred as spray pattern. Poor spray pattern adversely affects many important aspects such as combustion performance, pattern factor and pollutant emissions.

The spray cone has a strong influence on ignition, stability limits and exhausts emission. In plain orifice atomizer, the cone angle is narrow and fuel drops is fair evenly dispersed throughout the entire spray volume. It is possible to produce solid cones with swirl atomizers, but, for gas turbine applications, the spray is usually in the form of a hollow cone of wide angle with most of the drops at the periphery.

As plain orifice atomizers produce a narrow and compact spray in which only small proportion of the drops are subjected to the effects of air resistance, the

distribution of the spray as a whole is dictated mainly by the magnitude and direction of the velocity imparted to it on exiting from the atomizers orifice. With swirl atomizers however the hollow conical structure of the spray incurs appreciable exposure to the influence of the surrounding air. Normally, an increase in spray cone angle increases the extent of this exposure, leading to improve atomization and an increase in the proportion of drops whose distribution is dictated by the aerodynamics of the primary zone.

**Figure 2.12:** Spray Pattern (Hoe, Y.M., 2000)

**Figure 2.13:** Cone Angle (Hoe, Y.M., 2000)

#### **2.6.3.4 Dispersion and Penetration**

Dispersion could be expressed as the ratio of the volume of the spray to the volume of the fuel contained within it. The advantage of a good dispersion is that the fuel mixes rapidly with the surrounding gas. This could increase the evaporation rate and heat release. Dispersion is small in narrow spray angle and high in wide spray angle (Hoe, Y.M., 2000). In swirl atomizers, dispersion are governed mainly by mean drop size, drop size distribution, cone angle, surrounding medium and fuel properties. However, those factors that increase the spray cone angle also tends to improve the spray dispersion.

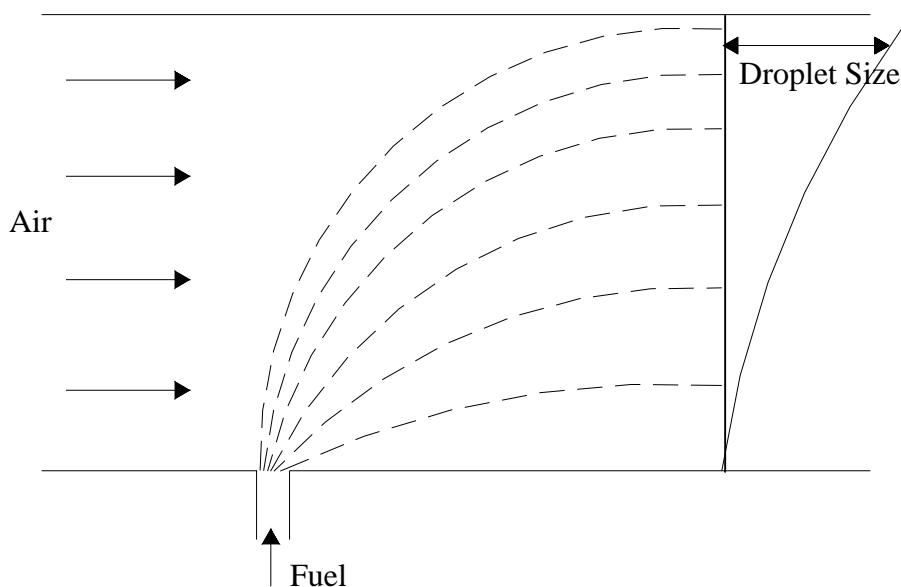

Meanwhile, penetration of a spray may be defined as the maximum distance of fuel reaches when injected into stagnant air. It is governed by the relative magnitudes of two opposing forces: (1) the kinetic energy of the fuel jet and (2) the aerodynamic resistance of the surrounding gas. The initial jet velocity is high, but as atomization proceeds and the surface area of the spray increases, the kinetic energy of the fuel is gradually dissipated by frictional losses to the gas. When, the drops have finally exhausted their kinetic energy, mainly gravity and the movement of the surrounding gas dictate their trajectory (Hoe, Y.M., 2000). In general, a compact, narrow spray will have high penetration, while a well atomized spray of wide cone angle, incurring more air resistance, will tend to have low penetration. In all cases, the penetration of a spray is much greater than that of a single drop. The first drop to be formed impart their energy to the surrounding gas, which begins to move with the spray; the gas therefore offers less resistance to the following drops that consequently penetrate further.

#### **2.6.4 Types of Atomizers**

There are several atomizers that are used for combustion applications. Several types of atomizers are briefly described in this section. Relative merits of these atomizers were simplified and accessible in Appendix A.

### 2.6.4.1 Plain Orifice Atomizer

Plain orifice atomizer is widely used in afterburners, where the fuel injection system normally consists of one or more circular manifolds. The spray produced by plain orifice atomizer usually has a cone angle between  $5^\circ$  and  $15^\circ$ . The narrow spray angle exhibited by plain orifice atomizer makes it impractical for most application.

**Figure 2.14:** Plain Orifice Atomizer (Hoe, Y.M., 2000)

### 2.6.4.2 Simplex Atomizer

Simplex atomizer has a wider cone spray angle than plain orifice atomizer. Swirling motion is imparted to the fuel so that, under the action of centrifugal force, spread out in the form of hollow cone as soon as it leaves the orifice. Simplex atomizer is the simplest form of pressure swirl atomizer. A major drawback of the simplex atomizer is that its flow rate varies as the square root of the fuel injection pressure (Hoe, Y.M., 2000).

**Figure 2.15:** Simplex Atomizer (Hoe, Y.M., 2000)

### 2.6.4.3 Wide Range Atomizer

The major drawback in simplex atomizer has led to the development of wide range atomizer such as duplex, dual orifice and spill atomizer. These atomizers have ratio of maximum to minimum fuel output about 20 with fuel injection pressure not exceeding 7 MPa. There are two types of wide range atomizers that are duplex atomizer and dual orifice atomizer (Hoe, Y.M., 2000).

The different between duplex atomizer and simplex atomizer is that its swirl chamber employs two sets of tangential swirl port. One set is the pilot or primary ports for the low flows encountered when the engine is idling or at high altitudes and the other set comprises the main passage for the large flow required under normal operating condition. This atomizer is widely used in aircraft engine application.

Dual orifice atomizer is also known as duplex atomizer. It is comprised of two simplex atomizer that are fitted concentrically, one inside the other. At a low fuel flows all the fuel is supplied from pilot atomizer. When the fuel pressure reaches a predetermine value, the pressuring valve open and admits fuel to the main atomizer (Hoe, Y.M., 2000).

**Figure 2.16:** Duplex Orifice Atomizer (Hoe, Y.M., 2000)

**Figure 2.17:** Dual Orifice Atomizer (Hoe, Y.M., 2000)

#### 2.6.4.4 Spill Return Atomizer

Basically, spill return atomizer is almost similar to simplex atomizer. Spill return atomizer differs from simplex atomizer such that the rear wall of the swirl chamber instead of being solid, it contains an annular passage which fuel can be spilled away from the atomizer. Fuel is supplied to the swirl chamber at high pressure and high flow rate(Hoe, Y.M., 2000).

**Figure 2.18:** Spill Return Atomizer (Hoe, Y.M., 2000)

#### 2.6.4.5 Fan Spray Atomizer

Fan spray atomizer is usually obtained by cutting slots into plane or cylindrical surfaces and arranging for the fuel into each slot from two opposite directions. In the single hole fan spray atomizer, there is only one single orifice; this orifice forces the liquid into two opposite streams within itself, so that a fan spray issues from the orifice and spreads out in the shape of a sector of a circle of about  $75^\circ$  angle. An air shroud is usually fitted around the atomizer tip, using the pressure differential across the linear wall (Hoe, Y.M., 2000).

**Figure 2.19:** Fan Spray Atomizer (Hoe, Y.M., 2000)

#### 2.6.4.6 Rotary Atomizer

In a rotary atomizer, liquid fuel is fed onto a rotating surface, where it spreads out quite uniformly under the action of centrifugal force. The rotating surface may take the form of a flat disk, vane disk, cup or slotted wheel. A coaxial air blast is used to assist atomization. This system has extreme versatility and has been shown to atomize successfully liquids that vary widely in viscosity (Hoe, Y.M., 2000).

#### 2.6.4.7 Air Assist Atomizer

An example of this atomizer is the use of shroud air on fan spray and simplex atomizer. This atomizer's swirl port is sized to pass the maximum fuel flow at the maximum fuel injection pressure, then the fuel pressure differential is too low to give good atomization at the lowest fuel flow. Internal mixing air assist atomizer is very suitable for highly viscous fuels and good atomization can be obtained (Hoe, Y.M., 2000).

**Figure 2.20:** Air Assist Atomizer (Hoe, Y.M., 2000)

#### 2.6.4.8 Air Blast Atomizer

In principle, the air blast atomizer functions in exactly the same manner as the air assist atomizer because both employ the kinetic energy of a flow airstreams to shatter the fuel jet or sheet into ligaments and then drops. The main difference

between these two systems lies in the quantity of air employed and its atomising velocity (Hoe, Y.M., 2000).

#### **2.6.4.9 Slinger System**

In slinger system, fuel is supplied at low pressure along the hollow main shaft and is discharged radially outwards through holes drilled in the shaft. These injection holes vary in number from 9 to 18 and in diameter from 2.0 to 3.2 mm. The holes may be drilled in the same plane as a single row but some installations feature a double row holes. The holes never run full; they have a capacity that is many times greater than the required flow rate. They are made large to obviate blockage. However, it is important that the holes be accurately machined and finished, since experience shown that uniformity of flow among injection holes depends on their dimensional accuracy and surface finish. If one injection holes supplies more fuel than others, a rotating hot spot will be formed in the exhaust gases, with disastrous consequence for the particular turbine blade on which the hot spot happens to impinge.

The advantage of the slinger system is that it is low in cost and simple. Only low pressure fuel pump is needed and atomization quality depends on engine speed. The influence of fuel viscosity is small, so the system has a potential multifuel capability. One drawback of the slinger system is its slow response to changes in fuel flow. A more serious problem is that of high altitude relighting performance. With the engine wind milling, the rotational speed is quite low and consequently the atomization quality is relatively poor. This system is suitable for small engines. The problems of wall cooling could arise if the system were applied to engines with high pressure ratios (Hoe, Y.M., 2000).

## 2.7 Air Fuel System

Stoichiometric combustion occurs when all the oxygen atoms in the oxidizer react chemically to appear in the products. The oxidizer in this case is the air mixing with the fuel in the combustion chamber. The chemical reaction is given by:

where:

$a_1, b_1, c_1, d_1$  = molar coefficients

$a, b, c, d$  = fuel components

The stoichiometric fuel to air ratio can be calculated with:

$$\text{Fuel Air Ratio (FAR}_s) = 1 \text{ mole of fuel} / a_1(O_2 + 3.76N_2) \quad (2.29)$$

Table 2.6 below shows the stoichiometric air fuel ratios for various fuels. As the fuel used for the experimental testing was diesel, so stoichiometric air fuel ratio used was 14.5 which means that one unit of diesel needs 14.5 units of air to obtain stoichiometric level.

**Table 2.6:** Air Fuel Ratio for Various Fuels (Blas, Luis Javier Molero de, 1998)

Fuel	Chemical Formula	HHV	Air/Fuel Ratio Stoichiometric	Fuel/Air Stoichiometric
		[kJ/kg] [kg air/kg fuel]		
Methane	CH <sub>4</sub>	55,500	17.2	0.05814
Propane	C <sub>3</sub> H <sub>8</sub>	50,300	15.6	0.06410
Octane	C <sub>8</sub> H <sub>18</sub>	47,900	15.1	0.06623
Methanol	CH <sub>3</sub> OH	22,700	6.5	0.15385
Ethanol	C <sub>2</sub> H <sub>5</sub> OH	29,700	8.99	0.11123
Hydrogen	H <sub>2</sub>	141,600	27.2	0.03677
Gasoline	C <sub>8</sub> H <sub>15</sub>	47,300	14.6	0.06849
Diesel	C <sub>12.5</sub> H <sub>22.2</sub>	44,800	14.5	0.06897

Meanwhile, Table 2.7 shows the influence of various primary zone mixture strengths on the combustion process. The mixture strengths are essential to be determined before a combustor is operated.

**Table 2.7:** Influence of Various Primary Zone Mixture Strengths (Mellor, A.M., 1990).

<b>Primary Zone Mixture Strength</b>	<b>Advantages</b>	<b>Disadvantages</b>
Stoichiometric	<ol style="list-style-type: none"> <li>1. Maximum heat release rate</li> <li>2. Low luminosity flame</li> <li>3. Little exhaust emission</li> <li>4. No carbon deposits</li> </ol>	<ol style="list-style-type: none"> <li>1. High rate of heat release to liner walls</li> <li>2. Requires intermediate zone</li> <li>3. High nitric oxide emissions</li> </ol>
Fuel Rich	<ol style="list-style-type: none"> <li>1. Low recirculation velocity gives “weak extinction” point and easy ignition</li> <li>2. ## CHAPTER III

### EMISSION CONTROL

#### 3.1 Introduction

The main problem with the control of pollutants from the gas turbines is that the reduction of  $\text{NO}_x$  emissions can result in the increase in either CO or UHC emissions (Escott, N.H., 1993). This problem can be seen in Figure 3.1.

**Figure 3.1:** Emission Characteristic of a Gas Turbine (Escott, N.H., 1993)

The main approach to this problem is to ensure that CO emission is minimized by the homogeneous mixing of the fuel and air than to concentrate on the reduction of  $\text{NO}_x$  emissions (Mikus, T. and Heywood, S.B., 1971). In practical gas turbine combustors, this can be validated by achieving combustion efficiencies better than 99.5 percent at idle approaching 100 percent at full power. Homogeneous mixing can often be achieved by premixing the fuel and air, but low  $\text{NO}_x$  system must

also ensure that flame stability is maintained over a wide range of operating conditions.

Most  $\text{NO}_x$  reduction techniques basically involve the reduction of the peak flame temperature to ensure that thermal NO is not formed. A reduction in the combustor inlet temperature would reduce the formation of thermal NO but this is not a practical solution because higher turbine inlet temperatures are required to increase the gas turbines thermal efficiency.

### **3.2 Factors Influencing $\text{NO}_x$ Formation**

Three main factors influences the formation of  $\text{NO}_x$  are flame temperature, flue gas residence time and the turbulence effect (Kim, M.N., 1995). The  $\text{NO}_x$  emission is proportional to the flame temperature.  $\text{NO}_x$  emission increases with the rise of flame temperature. Low flame temperature produces less  $\text{NO}_x$  emission. Flue gas residence time should be long enough to allow more time for combustion reaction. If the mixing rate between fuel and air is high, flue gas residence time could be reduced. Besides that, strong turbulence effect is needed to reduce  $\text{NO}_x$  emission. This could be achieved by creating pressure drop in the combustion zone that would generate turbulence energy in the shear layer region and increases mixing rate of fuel and air significantly (Kim, M.N., 1995).

### **3.3 $\text{NO}_x$ Control Techniques**

There are number of ways of combustion methods to reduce  $\text{NO}_x$  emission. Basically these methods could be categorised into two techniques; prevention of  $\text{NO}_x$  formation and destruction of  $\text{NO}_x$ .

### 3.3.1 Prevention of NO<sub>x</sub> Formation

This category refers to measures that do not necessitate major process alteration or plant construction. This category generally required modifications to the conventional burner designs or operating condition. Capital expenditure and installation time are usually less than those needed for major retrofit work. This technique involves pre-combustion methods such as homogeneous mixing of fuel and oxidant and lean combustion.

Lean combustion is the main and earliest technology of low NO<sub>x</sub> combustion. Lean combustion that works with low temperature is the easiest way of NO<sub>x</sub> reduction as this technique eliminate thermal NO formation as suggested by Zeldovich chain mechanism.

Further studies show that low flame temperature together with homogeneous mixing could further reduce NO<sub>x</sub> emission. This could be achieved with the use of swirler or premixed flame.

#### 3.3.1.1 Premixed Combustor

**Figure 3.2:** Premixed Combustor (Leonard, G. and Stegmaier, J., 1993)

In premixed combustor (Figure 3.2), the air and fuel are mixed before they are passed through a jet into the combustion zone and sufficient initial air is mixed to prevent soot formation. The velocity of the mixture through the combustor jet is

important. If the velocity is too low (below the burning velocity of the mixture) the flame can light back into the mixing region, whereas if the velocity is too high the flame can lift off from the combustor to the extent where it can be extinguished by entrainment of additional air around the burner. However, it has been noted that the fully premixed combustion system has several severe problems such as flame stability, auto ignition and combustion efficiency and stabilizer durability. Therefore, attention has been switched to rapid fuel and air mixing rather than premixing.

### 3.3.1.2 Rapid Mixing Combustor

**Figure 3.3:** Rapid Mixing Combustor (Beer, J.M. and N.A. Chigier., 1972)

Rapid fuel and air mixing could be achieved using swirlers. Swirler could act as flame stabilizer that promotes the mixing by generating turbulence in the combustion chamber. Swirl flow forms central recirculation zone that could stabilize the flame resulting in better mixing and combustion. The recirculation zone is formed in both cold and combusting flows. The formation of such a flow pattern in the vicinity of the fuel injector results in stable combustion and rapid heat release. This is attributed to the enhanced mixing rates between the fuel and air and supply of energy required for ignition. Figure 3.3 is an example of a combustor applying swirler.

### 3.3.1.3 Variable Geometry Combustor

**Figure 3.4:** Variable Geometry Combustor (Escott, N.H., 1993)

A variable geometry combustor (Figure 3.4) seems to be the ideal solution to overcome both the high power and low power operating range of combustor. For minimum combustor emissions, if the thermal input is reduced from 50 kW to 5 kW at constant excess air then the airflow is reduced by a factor of 10. For a fixed flow blockage combustor this reduces the pressure loss by a factor of 100 that reduce the fuel and air mixing and the flow turbulence. If the combustor flow area is reduced so that it acts as a flow control valve then the combustor pressure loss is constant as the flow reduced. Mechanical complexities involved seem to repulse combustor designers from developing this technique. However, the considerable potential that variable geometry holds for emissions reduction has led to a renewal of interest in its application. In gas turbine combustor variable geometry is required to overcome flame stability problems in the lean low  $\text{NO}_x$  primary zones as the power is reduced by reducing the fuel flow at constant air flow (Mohammad Nazri, 1997).

### 3.3.1.4 Lean Premixed Prevapourized Combustor

**Figure 3.5:** Lean Premixed Prevapourized Combustor (Willis, J.D. et al., 1993)

Another attractive technique for reducing nitric oxide emissions is the lean premixed prevapourized combustion for liquid fuel. The key factor is to attain complete evaporation of the fuel and complete mixing of fuel and air prior to combustion. By avoiding droplet combustion, operating the burner in fuel-lean with low reaction temperature and the elimination of hot spots in the combustion zone drastically reduced nitric oxide emissions (Lyon, R.K., 1975). However, there are some drawbacks for this technique. Risks of auto ignition and flashback in the premixing duct were perhaps the most severe problems. Other problems involved ensuring flame stability, stabilizer stability and combustion efficiency. The use of flame stabilizers removes the need for a premixing duct. Good fuel and air mixing is achieved by swirl stabilizers (Jeffs, E., 1992). Lean premixed prevapourized combustor is shown in Figure 3.5.

### 3.3.2 Destruction of NO<sub>x</sub>

These processes generally involve the treatment of the flue gases after the combustion has occurred in the chamber and before exiting to the stack. Very high reduction of NO<sub>x</sub> is possible (up to 90 percent) using selective reduction technique. However, these methods need more capital intensively and required more frequent maintenance procedures.

### 3.3.2.1 Staged Combustor

**Figure 3.6:** Fuel Staging Combustor  
(Jamieson, J.B., 1990)

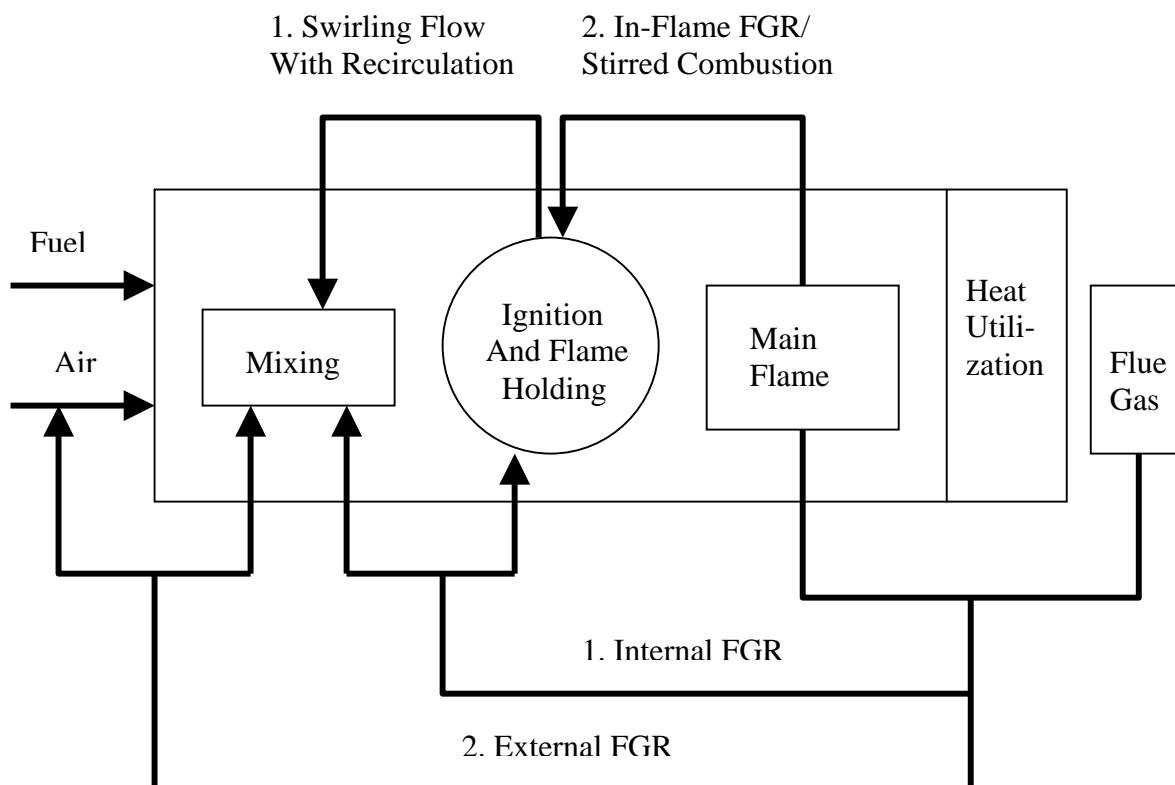

**Figure 3.7:** Air Staging Combustor  
(Jamieson, J.B., 1990)

Staged combustion is divided into two sections that are fuel staged combustor and air staged combustor. In fuel staged combustor, as shown in Figure 3.6, at low power conditions the fuel is supplied to the first stage only for flame stability. However, as the required power increases to a certain critical point the fuel is supplied to both stages. As well as fuel, the air is also introduced in the second stage to ensure lean burn operation is achieved over the entire power range.

Air staging in a burner is often called two-stage combustion and is an exaggerated form of low excess air combustion whereby the primary combustion zone air is reduced to such an extent that a sub-stoichiometric region exists in the lower chamber. The additional air necessary to complete combustion is added, progressively at points further downstream.  $\text{NO}_x$  formation does not take place at lower temperatures and where levels of oxygen present in the combustion zone are low. Fuel-bound nitrogen volatilised in the fuel rich region has more opportunity to form molecular nitrogen than  $\text{NO}_x$ . Generally, between 10 percent and 30 percent of the total combustion air is used for staging. Figure 3.7 is an example of air staging combustor.

### 3.3.2.2 Flue Gas Recirculation Combustor

**Figure 3.8:** Schemes of flue gas recirculation (Masataka A., 2000)

From the viewpoint of low oxygen and lean combustion, flue gas recirculation (FGR) that was commonly used as exhaust gas recirculation (EGR) in internal combustion engine was considered as an effective way to reduce  $\text{NO}_x$  emission. The flue gas was recirculated into the chamber that acts as an inert gas to decrease the flame temperature hence reduces the  $\text{NO}_x$  emission. This method is not so popular but its system is partially employed in many combustion systems (Masataka A., 2000). There are many types of flue gas recirculation that could be applied such as swirling flow with recirculation, in-flame FGR, internal FGR and external FGR. Figure 3.8 shows schemes of flue gas recirculation.

### 3.3.2.3 Rich-Burn Quench Lean-Burn Staged Combustor

**Figure 3.9:** Rich-Burn Quench Lean-Burn Staged Combustor (Jamieson, J.B. 1990)

Rich-burn quench lean-burn staged combustor (RQL) achieves low  $\text{NO}_x$  emissions by having a rich-burn first stage, reduces  $\text{NO}_x$ , followed by a lean-burn second stage, which completes CO and UHC oxidation. In order to ensure that temperatures in the main reaction zone are lowered before entering second stage, a rapid quenching zone is required. Completion of combustion products of CO and UHC is then achieved at leaner equivalence ratios where  $\text{NO}_x$  formation reaction is at a minimum. One of the main problems associated with simple two stage and RQL combustion systems is that the reactions involving the oxidation of CO and UHC could well quenched by the addition of the secondary quenching air, but if the addition of the secondary quenching air is too slow local high temperature  $\text{NO}_x$  products region could arise. Figure 3.9 shows scheme of RQL combustor.

### 3.3.2.4 Selective Catalytic Reduction Combustor (SCR)

**Figure 3.10:** Selective Catalytic Reduction Combustor (McLaughlin, B.R. et al., 1997)

This process involves the treatment of the flue gases after combustion has occurred in the chamber and before exiting to the stack.  $\text{NO}_x$  in the flue gases are reduced by injecting ammonia in the presence of a catalyst to form nitrogen and water. As the reaction is selective, ammonia should not be oxidized at the correct operating temperature. A number of catalyst materials can be employed. They are chosen according to prevailing criteria such as available flue gas temperature, permissible ammonia slip and  $\text{NO}_x$  reduction required. SCR systems as shown in Figure 3.10 are becoming more widespread, however problems associated with catalyst degradation and poisoning and storage ammonia emission through various channels are restricting and delaying further implementation due to financial and safety concerns.

### 3.3.2.5 Selective Non-Catalytic Reduction Combustor (SNCR)

**Figure 3.11:** Selective Non-Catalytic Reduction Combustor (Cremer, M.A. et al., 2002)

This method of  $\text{NO}_x$  control uses chemicals in controlled thermal reaction to reduce  $\text{NO}$  selectively. A higher efficiency of  $\text{NO}_x$  reduction can be achieved without a catalyst although chemical consumption levels are high. A number of different chemical compounds can be used although the majority comprise of ammonia and its derivatives such as urea and cyanuric acid. The reduction reactions occur within a limited temperature range between  $800^\circ\text{C}$  to  $1150^\circ\text{C}$  for most common additives although the use of enhancing agents or an alteration of the combustion conditions can lower or widen this window of operation. Mixing of the injected chemicals with the flue gas is paramount to achieve good  $\text{NO}_x$  reduction rates. Problems encountered here include the high viscosity of the flue gas, the positioning of the type of injectors, availability of chemicals and the extent of allowable ammonia slip. Selective non-catalytic combustor diagram is shown in Figure 3.11.

### 3.4 Practical Low NO<sub>x</sub> Combustor

It has been discussed previously that CO and UHC emissions are minimized when the fuel and air mixing of the combustion chamber system is thorough. It is assumed that any NO<sub>x</sub> combustion system will automatically ensure that the CO and UHC emissions kept at a minimum by good fuel and air mixing. However, this does depend on the emission technique employed. There are two main approaches to NO<sub>x</sub> reduction techniques. One approach is to make minor changes to the existing combustor such as to provide better fuel atomisation and distribution that will promote homogeneous mixing of fuel and air. This approach has seen a modest reduction in average NO<sub>x</sub> emission level from aero engines over the past 25 years. The second approach involves major combustor design modification such as staged, premixed, variable geometry and catalytic approaches. NO<sub>x</sub> emission can be highly dependent on the flame temperature within the combustor and the flame temperature itself is dependent on combustor inlet temperature and the air-fuel ratio.

There are two ways of reducing NO<sub>x</sub> emission by altering the operating range of equivalence ratio (EQR). One is to operate at fuel rich EQR and the other is fuel lean EQR. The justification for this approach is shown by the variation of NO<sub>x</sub> formation with EQR in Figure 3.12. Flame temperature is higher near stoichiometric combustion.

**Figure 3.12:** Effect of Reaction Zone Equivalence Ratio on NO<sub>x</sub> Emission (Escott, N.H., 1993)

Burning in the fuel rich region of EQR could present problems with soot formation and the necessary addition of air after the reaction zone could lead to stoichiometric conditions and thus increase  $\text{NO}_x$  emission. Burning in fuel lean region of EQR avoids these problems but is susceptible to lean flammability and flame blow off problems. Designing a combustor with low  $\text{NO}_x$  emission approaches present problems because the combustor has to operate over a wide range of overall EQR, thus the air and/or the fuel is normally staged.

## **CHAPTER IV**

### **BURNER DESIGN CONCEPT**

#### **4.1 Introduction**

This chapter provides the complete description of the laboratory scale experimental set up designed for testing the emission characteristic of a liquid fuel burner. The designs are extensively dependent to the employed operating parameters such as fuel flow rate, injection air flow rate, fuel pressure and injection air pressure.

Ideal gas turbine combustor should provide low  $\text{NO}_x$  formation and negligible CO and UHC combined with good flame stability. The success of this ideal combustor will depend upon the thorough mixing of the fuel and air in the primary zone. Information about the fuel and air mixing can only be adequately retrieved by measuring local gas composition within the combustor. Mellor et al. (1972) reported the measurements of species and temperature in an Allison J-33 combustor and the results indicated that for a well atomized fuel spray, due to turbulence, the mixing controls the local equivalence ratios and hence reduce the pollution formation.

## 4.2 Combustion Chamber Design

The specification of combustion chamber should be determined in order to build a chamber that operates in the desired performance. There are many factors affecting the combustion chamber size, such as length to diameter ratio, pressure loss parameter and mass flow parameter. The combustion chamber used was a modified standard of existing combustion chamber.

### 4.2.1 Length and Diameter

Combustion chamber length and diameter are the most important parameter in designing the combustor. An appropriate length and diameter of combustion chamber would allow more time for complete combustion with high combustion efficiency hence reduce emissions. The length to diameter ratio ( $L_c / D_c$ ) should be in the range of 1.5 to 5.

**Table 4.1:** Researcher's suggestion on Length to Diameter Ratio (Mellor, 1990)

Researcher	Suggestion on $L_c / D_c$
Boyce, M.P. (theory)	2 - 5
Boyce, M.P. (Practical)	
Small Combustor	2
Large Combustor	3 - 4
Hawthorne H.R. & Olson W.T.	1.5
Lefebvre A.H. & Norster E.R.	1.5

The suggested ratio of  $L_c / D_c$  for the combustion chamber is 2. This is because practically for small combustor the ratio of length to diameter for combustion chamber should be small as shown in the Table 4.1. Besides that, shorter combustor could reduce the formation of NO<sub>x</sub> emission and reduces the weight of the combustor.

### 4.2.2 Pressure Loss Parameter

Two dimensional pressure loss parameters are of importance in combustor design. One is the ratio of the total pressure drop across the combustor to the inlet total pressure ( $\Delta P_{3-4} / P_3$ ), and the other is the ratio of the total pressure drop across the combustor to the reference dynamic pressure ( $\Delta P_{3-4} / q_{ref}$ ). The term ( $\Delta P_{3-4} / q_{ref}$ ) is also called pressure loss factor. The two parameters are related by the equation (Escott, N.H., 1993):

$$\frac{\Delta P_{3-4}}{P_3} = \frac{\Delta P_{3-4}}{q_{ref}} \frac{R}{2} \left( \frac{\dot{m}_3 T_3^{0.5}}{A_{ref} P_3} \right)^2 \quad (4.1)$$

Both of the parameters are of prime importance in combustion engineering, since it denotes the flow resistance introduced into the air stream between the compressor outlet and the turbine inlet. Aerodynamically, it may be regarded as equivalent to a drag coefficient. Meanwhile the quantity  $(R/2) \left( \dot{m}_3 T_3^{0.5} / A_{ref} P_3 \right)^2$  in Equation (4.1) is effectively a measure of combustor reference velocity.

For low fuel consumption, the overall pressure loss of the chamber,  $\Delta P_{3-4} / P_3$ , must be low. However, if the chamber is small and has adequate mixing, both pressure loss factor and combustor reference velocity must be large.

Table 4.2 shows some typical values of pressure loss in practical chambers. From the table, the annular chamber has the lowest pressure loss factor.

Type of Chamber	$\frac{\Delta P_{3-4}}{P_3}$	$\frac{\Delta P_{3-4}}{q_{ref}}$	$\frac{\dot{m}_3 T_3^{0.5}}{A_{ref} P_3}$
<b>Tubular</b>	0.07	37	0.0036
<b>Tuboannular</b>	0.06	28	0.0039
<b>Annular</b>	0.06	20	0.0046

**Table 4.2:** Pressure Losses in Combustion Chambers (Mellor, 1990)

The relationship between size and pressure loss for the optimal cross sectional area of the casing,  $A_{ref}$  for straight combustors in most industrial combustors and some aircraft combustors are (Mellor, 1990):

$$A_{ref} = \left[ \frac{R \dot{m}_3 T_3^{0.5}}{2 P_3} \frac{\Delta P_{3-4}}{q_{ref}} \left( \frac{\Delta P_{3-4}}{P_3} \right)^{-1} \right]^{0.5} \quad (4.2)$$

### 4.3 Swirler Design

Swirling jets were used for stabilization and control of flame and to achieve a high intensity combustion. The common method of generating swirl is by using angled vanes in the passages of air.

Most conventional combustors employ the axial flow type swirlers. The swirler vanes were usually flat for ease of manufacture, but curved vane was sometimes used for their better aerodynamics properties (Lefebvre, 1983). Ahmad, et al. (1986) found problems in the achievement of adequate combustion efficiency and stability with lean primary zones using large air flow axial swirler with central fuel injection (Kim, 1995). Alkabie, et al. (1988) showed that these problems could be overcome by the use of radial swirler followed by a dump expansion with their quite different near swirler aerodynamic. For large air flow, the axial swirler has disadvantages for accommodating more air because the expansion from the swirler is reduced by the requirement to increase the swirler diameter. Increasing the air flow would reduce the flow expansion to the combustor diameter. The expansion ratio should be more than 1.5 to create a corner recirculation zone. However, this problem is not encountered with radial swirlers since the radial swirler outlet can be maintained constant and the vane depth increased to accommodate more air to achieve the pressure loss required. Alkabie (1989) found the noticeable improvement in performance and  $\text{NO}_x$  emission of the radial swirler over the axial swirler due to the immediate contact of fuel with the turbulent swirled air as it leaves the central

fuel injector. As proven, radial swirler provides better advantages over the axial swirler. So, in this research, the radial swirlers would be used.

#### **4.3.1 Rapid Mixing System**

There are number of ways of producing better mixing between air and fuel. One of the ways is by creating rapid mixing combustion system. Rapid fuel and air mixing are best produced by using swirlers.

To achieve rapid fuel and air mixing, turbulence must be generated to promote the mixing. Turbulence energy is created from pressure energy dissipated downstream of the stabilizer. In swirlers, increasing the blockage or pressure drop of the swirler can generate turbulence. Swirler pressure drop could be done in number of ways:

- (a) Increasing the swirler vane angle
- (b) Decreasing the swirler outlet diameter ( $d/D$ ) or increasing the swirler hub diameter, both of which increase the swirler flow blockage
- (c) Increasing the number of vanes

Besides the effect of rapid fuel and air mixing, all of these factors also increase the size of the recirculation zone. An increase in the size of the recirculation zone together with the turbulence generated in the shear layer region can increase fuel and air mixing significantly.

#### **4.3.2 Swirl Flow**

Swirl flow is a main flow produced by air swirled in burner system. Such flow is the combination of swirling motion and vortex breakdown. Swirling flow is widely used to stabilize the flame in combustion chamber. Swirling flow induces a

highly turbulent recirculation zone that stabilizes the flame resulting in better mixing and combustion. An advantage of swirling flow is the fact that a centrifugal force field, present in swirling, tends to accelerate the mixing of two flows having different densities and thus increase the reaction rate in the combustion process (Fricker, N. and Leuckel, W., 1976).

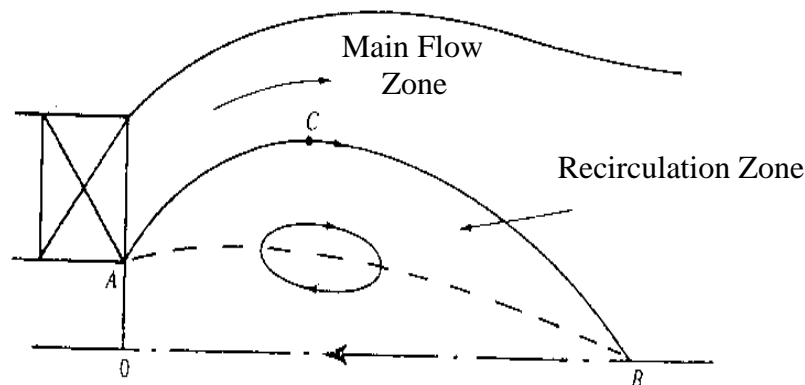

The primary function of this flow is to achieve a mixture that can sustain continuous, and to maintain or stabilize combustion over a wide range of operating conditions. Air is introduced tangentially into the combustion chamber and forced to change its path, which contributes to the formation of swirling flow. The strength of the flow is dependent on the swirler vane angle and the air pressure supplied.

Swirl is widely used in industrial application ranging from gas turbine combustors to diesel engines. It is often dictates that the supported flame must be short and intense in continuous combustion system such as gas turbine combustor in order to achieve the maximum heat release quickly. Long flames are generally less well mixed, this can be gauged by the apparent of yellow flame and contribute more to pollutant formation as the residence time is higher. Additionally yellow flames, as there are more rich regions, the temperature is less uniform across the flame and fluctuations in temperature can have a profound increasing effect on the  $\text{NO}_x$  emissions (Escott, N.H., 1993).

### **4.3.3 Effect of Swirl**

The introduction of swirl has been applied extensively in industrial furnace and combustion chambers in order to improve flame stabilization (Wu, H. L. and Fricker, N., 1976). Swirl also has been used as a mean of controlling flame shape and combustion intensity in furnace flames. The effect of swirl is to decrease the velocity gradient at the exit of burner thus causing a faster decay of the velocities in the flow field with increase of swirl flow (Chervinsky, A. and Manheimertiment, Y., 1968). One of the main effects of the application of swirl into a flow is the central reverse flow zone that is formed and a highly complex turbulent flow field created.

**Figure 4.1:** Recirculation Zone (Kim, M.N., 1995)

The reverse flow zone or recirculation zone, as shown in Figure 4.1, has traditionally been regarded as a reservoir or store of heat and active chemical species. It cyclically transports hot combustion products from downstream regions into the flame region. The high temperature products, despite the dilution effect, serve as an energy source for preheating and ignition assistance. Between the forward flow and the reverse flow zone boundary is a region of steep velocity gradients and high intensity turbulence, which promotes high entrainment rates and rapid mixing between the fuel and air. As a result of the high entrainment and homogeneous mixing, swirl reduces both flame lengths and flame attachment lengths and consequently shortens the combustion chamber length necessary for complete combustion (Kim, M.N., 1995). Swirl also promotes high combustion efficiency, easy ignition, reactant recirculation zone residence time, pollutant optimisation potential, widened stability and blow off limits.

Geometry of the combustor also affects the reverse flow zone. The precise effect of swirl on a flow field is found to be depending on many factors as well as on the swirl number. For example:-

- Nozzle Geometry – The presence of a central hub encourages a larger recirculation zone.
- Size of Enclosure – Central recirculation zone can be more pronounced in enclosures than those of comparable free jets.
- Exit Velocity Profile – Recirculation zones tend to be longer when the flow is produced via swirl vanes as opposed to an axial and tangential entry swirl generators.

The location and the shape of the recirculation zone are a function of the various inlets and swirl generator configurations, enclosure size, extent of reaction and any other factor that manipulates the imposed pressure gradient. Syred and Dahman (1965) suggest that smaller chamber diameters reduce the interference between the flow field and furnace enclosure, thus providing a recirculation zone that is longer and more advantageous for flame stabilization.

#### **4.3.4 Swirl Stabilized Flame**

The primary zone airflow pattern of gas turbine combustors is of major importance of flame stability. Various types of airflow pattern are employed, but one feature common to all is the creation of a torroidal reverse flow. This torroidal vortex system plays an important role in flame stabilization since it entrains and recirculates a portion of the hot combustion product to mix with the incoming air and fuel.

One of the most effective ways to induce recirculation flow in the primary zone is by fitting a swirler around the fuel injector. This type of recirculation zone may provide better mixing than that obtained by other means such as bluff body. This is because of the strong shear regions, high turbulence and rapid mixing rates produced by the swirling action. Besides that, the presence of a solid surface exposed to the high temperature is reduced and the deposition of coke such as occur on bluff bodies in heterogeneous combustion is also reduced.

Swirl increases the production of turbulence above that generated by non-swirling flows because the presence of the tangential velocity component provides additional velocity gradient. Swirling also increases the turbulence burning velocity to ensure blow off does not occur. Besides that, recirculation vortex produced by swirl acts as a heat source forcing combustion product to move upstream and mix with the partially premixed reactant. This increases the amount of contact between fuel, air and hot combustion products (Syred, N. and Beer, J.M., 1974). An additional factor that explains why swirl has a stabilizing effect is that stagnation points are found at upstream and / or downstream positions of central recirculation zone. This

stagnation point would act as a bluff body with the flame attaching in the sheltered downstream near wake region.

#### 4.3.5 Swirler Pressure Drop

Swirler pressure drop is equal to the different in pressure between the plenum chamber and the combustor. The swirler pressure drop was calculated as follows (Escott, N.H., 1993):

$$\Delta P = P_{1T} - P_{3T} = (h_{1T} - h_{3T})\rho_w g \quad (4.3)$$

where  $P_{1T} = P_{1S} + P_{1D} + \rho_1 \cdot g \cdot \Delta h_1 + P_a \quad (4.4)$

and  $P_{3T} = P_{3S} + P_{3D} + \rho_3 \cdot g \cdot \Delta h_3 + P_a \quad (4.5)$

$P_{nS}$  and  $P_{nD}$  are the static and dynamic pressure in the  $n$  region.  $P_a$  is the atmospheric pressure. As the combustor is placed horizontally, it was assumed that  $\Delta h_1 \approx \Delta h_3 \approx 0$  and  $\rho_1 = \rho_3$ . Thus, the equations (4.4) and (4.5) can be combined to yield:

$$\Delta P = (P_{1S} + P_{1D}) - (P_{3S} + P_{3D}) \quad (4.6)$$

Values of pressure loss in a typical gas turbine combustor lie between 2 percent to 7 percent at reference Mach number of 0.047 (Clements, T.R., 1976). The pressure loss can be calculated by using the following equation:

$$\frac{\Delta P}{P} = \frac{\gamma}{2} \left( \frac{M}{C_D} \times \frac{A_1}{A_2} \right)^2 \quad (4.7)$$

where,

$\Delta P/P$  = Swirler Pressure loss

$C_D$  = Swirler discharge efficiency

$\gamma$  = Ratio of specific heat

$A_1, A_2$  = Combustor and swirler open area

$M$  = Airflow Mach number

#### 4.3.6 Swirl Number

Experimental studies have shown that the flame size, shape, stability and combustion intensity are affected by the degree of swirl imposed on the flow. This degree of swirl is denoted by the swirl number  $S$ , which is a non-dimensional number characterizing the amount of rotation imposed to the flow. An advantage of swirling flow combustion is the fact that a centrifugal force field, present in swirling or vortex flow, tends to accelerate the mixing of two flows having different densities and thus increase the reaction rate in the combustion process.

The common method of generating swirl is by using angled vanes in the passages of air. The characteristic of the swirling flow depends on the swirler vane angle. Basically there are two types of swirler design; axial swirler and radial swirler. Most conventional combustor employs the axial flow type of swirler. The swirler vane is usually flat for ease of manufacture, but curved vane is sometimes performed for their better aerodynamic properties.

Alkabie, et al (1988) found problems in the achievement of adequate combustion efficiency and stability with lean primary zones using large air flow axial swirler with central fuel injection. Alkabie, et al (1988) showed that these problems could be overcome by the use of radial swirler followed by dump expansion with their quite different near swirler aerodynamic. Flat vane swirler is inefficient because they run under stalled condition.

Swirl number represents the axial flux of swirl momentum divided by the axial flux of axial momentum and is widely used for characterizing the intensity of swirl in enclosed and fully separated flow. That is (Kim, M.N., 1995)

$$S = \frac{G_{\theta}}{G_x \times D/2} \quad (4.8)$$

Where:

$G_{\theta}$  = Axial flux of angular momentum

$G_x$  = Axial flux of axial momentum

$D/2$  = Nozzle radius

This is a very basic calculation of a swirl number. There is better suggestion on the calculation for the swirl number. Claypole and Syred (1981) proposed a geometrical swirl number,  $S_g$  which was taken as non-dimensional measure of the tangential momentum supplied to the flow and if perfect mixing and conservation of momentum is assumed, then the swirl number can be defined in terms of the geometry of the combustor.

$$S_g = r_o \pi r_e / A_t \text{ (tangential flow / total flow)}^2 \quad (4.9)$$

where:

$A_t$  = Area of tangential inlets                       $r_e$  = Radius of the exit of the combustor

$r_o$  = Radius of the tangential inlets from the centre of the combustor

In the present work, swirl number calculation based on Leuckel method would be employed. This method would not much represent the real situation. However, Leuckel method was a basic method used to simulate the effectiveness of fuel and air mixture for a particular swirler vane angle. Past researchers agree that there is an optimum value of swirl number, where above that value, the emissions will begin to increase. Kim (1995) proposed that swirl number higher than 3.25 would raise the emissions. From, the Leuckel method swirl number calculation, swirl vane angle of  $70^\circ$  and above were not recommended. Swirl number,  $\sigma$  calculation based on Leuckel method was as follow (Appendix B):

$$\psi = \frac{n.s}{2\pi r_1 \cdot \cos \alpha} \quad (4.10)$$

$$\sigma = \frac{\tan \alpha}{1 - \psi} \quad (4.11)$$

Where,

$n$  = number of Vanes

$s$  = Thickness of Vanes

$r_1$  = Swirler Outlet Area

$\alpha$  = Swirler Vane Angle

#### 4.4 Fuel Injector Design

Fuel injection could be provided by three distinct injection methods: central fuel injection, vane passage fuel injection and wall fuel injection. The common method of fuel injection in swirl stabilized flows is injection axially through the centre of the swirler. However, another variation from conventional central axial fuel injection is to inject the fuel radially from the central axis across the entering air jet. The present work is involved with the former method of fuel injection. In this research, fuel injector would not be emphasized much as the rationality of having injector in this research is to serve its purpose of injecting fuel into the combustion chamber. However, for the intention of optimizing emissions reduction, injector could be one of a major contributor.

## **CHAPTER V**

### **EXPERIMENTAL SET UP**

#### **5.1 Introduction**

In this chapter, the experimental rig set up and procedures used for the assessment of various radial swirler angle performances were described. Combustion rig description, fuel injection and exhaust gas sampling shall also be described.

#### **5.2 Experimental Set Up**

The general rig set-up for the liquid fuel burner test is shown in Appendix C. The rig was placed horizontally on a movable trolley. The combustion zone consists of 4 chambers that are plenum chamber, combustion chamber, extension chamber and safety chamber.

The air is introduced through the inlet pipe and flows axially into the plenum chamber before entering the combustion chamber through the radial swirler of 40 mm outlet diameter that is installed at exit plane of plenum chamber. The amount of air entering the combustor is controlled by the air swirler's minimum area.

The rig is equipped with a central fuel injector. The inside diameter of the combustor is 163 mm and the total length is 852 mm. The combustor was cooled by convection from the ambient air. The length of the combustion chamber is representative of the minimum used in aero engines but is generally shorter than the combustors used in gas turbines. Diesel fuel was used for the testing, which was supplied by Universiti Teknologi Malaysia, obtained from Petronas fuel station.

An extension chamber was introduced because the test is conducted in both fuel lean and fuel rich regions where the flames in the fuel rich region are generally long. An additional chamber was also introduced for the safety of gas sampling probe and gas measurement purpose. The gas analyzer will be placed at the exit plane of safety chamber.

Tests on exhaust emission were carried out using 4 different swirler vane angles of 30°, 40°, 50° and 60°. Central fuel injector was placed in dual situations, upstream (Figure 5.3) and downstream (Figure 5.4) of the swirler exit plane. Besides the swirler vane angles, orifice plates with different orifice sizes also will be varied. Orifice sizes of 20mm, 25mm and 30mm will be used.

The exhaust gas sampling probe was placed at the end pipe of combustion chamber. The gas analyzer used in these tests was the portable Kane May gas analyzer that could measure oxides of nitrogen, sulphur dioxide and carbon monoxide emission.

### **5.2.1 Liquid Fuel Burner**

A liquid fuel burner has been developed after considering on its design concepts. Burner consists of three main components that are combustion chamber, swirler and fuel injector. Modification on the existing combustion chamber and injector were performed to produce desired output of stable combustion over wide range of equivalence ratio with combustion temperature of less than 1200°C. The temperature shall be less than 1200°C because it is difficult to work under very hot

environment. Furthermore, the allowable temperature to reach gas analyzer sensors is 40°C. Temperature of less than 1000°C was hardly achievable as the desired output was to hold combustion over wide range of equivalence ratio that is from 0.55 to 1.1.

### **5.2.1.1 Combustion Chamber**

The entire burner system consists of four chambers; plenum chamber, combustion chamber, extension chamber and safety chamber. The plenum chamber was built at  $L_c/D_c$  of 1.5. Air and fuel were delivered to plenum chamber before there were introduced into the combustion chamber. Fuel injector was located in the plenum chamber. Combustion chamber was built at  $L_c/D_c$  ratio of 2. Combustion chamber was built at diameter of 163mm with length of 338mm. An extension chamber is designed at  $L_c/D_c$  ratio of 1.5 for a fuel rich region experimental purpose, as the flame obtained in this region is generally long. An additional safety chamber is mounted at the end of extension chamber for a safety and measurement purpose. This will allow lower temperature of combustion product to be measured by gas analyzer, as the gas analyser should not be exposed to high temperature of combustion product. The detail of plenum chamber, combustion chamber, extension chamber and safety chamber were as shown in Appendix D, Appendix E, Appendix F and Appendix G respectively.

### **5.2.1.2 Swirler and Orifice Plate**

The experiment was conducted using four existing radial swirlers with swirler vane angle of 30°, 40°, 50° and 60°. The swirlers were prepared by previous researcher using CNC machine in Kolej Universiti Tun Hussein Onn, Batu Pahat, Johor. Orifice plate of 25mm and 30mm were also been in place when this research was conducted. An additional 20mm orifice plate was fabricated to investigate performance of smaller orifice plate size. All swirlers and orifice plates were

fabricated using mild steel. The detail of swirler design and orifice plate design were in the appendix H and Appendix I respectively.

### **5.2.1.3 Injector Design**

Injector consists of two components; nozzle connector and the nozzle. The nozzle was made using a recyclable hollow pin with an opening of 1mm as shown in Appendix J. This injector upholds the principle of an air assisted plain orifice atomizer, combination of plain atomizer and air assist atomizer. An air assist injector was used in the present work as this injector is very suitable for highly viscous fuels and good atomisation could be obtained. Besides that, it could provide good atomisation at low fuel flow rate. Meanwhile, the nozzle connector was fabricated to deliver fuel and atomizing air to the nozzle. The nozzle connector allows the atomizing air pumped to nozzle evenly all around. The nozzle connector design was shown in Appendix K.

Other components designs such as fuel air nozzle flange, downstream injection extension, swirler-orifice plate attachment flange were as shown in Appendix L, Appendix M and Appendix N respectively. The overall burner assembly drawing was also attached in Appendix O.

### **5.2.2 Fuel System**

Fuel transportation system consists of fuel tank and a compressed air supply. Fuel was drawn vertically into the nozzle connector with the assist of compressed air. This is to increase the fuel pressure. The fuel should be pressurized to improve its atomizing properties while injected into the combustion chamber. The air and fuel should be properly delivered into the combustion chamber to get good mixing of fuel and air in order to produce low emission combustion. Diesel fuel was also introduced

into the combustion chamber through the nozzle connector. The fuel was delivered with constant air pressure of 2 bar and fuel flow rate of 50 ml/min.

#### **5.2.2.1 Fuel Tank**

The fuel tank was prepared using cylindrical recyclable tank that could uphold compressed air until 10 bar. A safety pressure valve was placed on the left top of the tank for safety reason. The tank was pressurized by compressed air at 2 bar. The fuel was drawn from bottom of the tank so that the fuel could flow smoothly and pressurized by the compressed air. The tank capacity is 15 litres.

#### **5.2.2.2 Air Compressor**

An air compressor with 0.373 kW output power and pressurizing capacity of 10 bar was used to serve a purpose of assisting the fuel to be delivered into the combustion chamber.

### **5.2.3 Air Supply System**

Besides the fuel system, air supply system was another system which requires attention. Air is an equally important as a fuel to be in the combustion chamber as it is needed to promote mixing of fuel and air. The air was introduced into the plenum chamber in two different ways. Swirling air was introduced in the plenum chamber with constant pressure of 2 bar while the air flow rate was varied. This air was forced to change its path by swirler's vane angle that contributes to the formation of swirling flow. Meanwhile, the atomizing air that was used to assist the fuel was introduced in the combustion chamber through a nozzle connector with constant pressure of 2 bar.

### **5.2.3.1 Air Compressor**

An air compressor with 1.865 kW output power and pressurizing capacity of 10 bar was used for air atomizing purpose. Bigger compressor was essential for this process as to provide sufficient air for atomizing purpose. Smaller tank capacity air compressor unable to deliver high flow rate of air.

### **5.2.3.2 Blower**

A 0.249 kW blower was used in this experimental testing. This blower could provide air capacity of 0.707925 m<sup>3</sup>/min (25 CFM). The blower was used to provide air for swirling option. For the point of swirling motion, air flow rate was the main concern rather than the air pressure. The volume of air should be sufficient enough to generate desired equivalence ratio.

### **5.2.4 Instrumentation**

Filter, Lubricator and Regulator gauges, flow meters, pressure gauges, gas sampling probe, thermocouples and gas analyzer were additional instruments needed in this experimental testing. Flow meters, thermocouples and gas analyzer were calibrated due to experimental testing. The flow meter, on the other hand, was calibrated for the desired medium prior to experimental testing. The water flow meter was calibrated for diesel as the fuel used was diesel. The calibration chart was as shown in Appendix P. Meanwhile, thermocouples were calibrated for its sensitivity and accuracy using ice cubes and boiled water. The calibration results were attached in Appendix Q.

#### **5.2.4.1 Filter, Lubricator and Regulator Gauge**

Three Filter, Lubricator and Regulator (FLR) were used in this experimental testing. The FLR was mounted one each for both compressors and another one for the blower. The purpose of the FLR is to filter out water from compress air, lubricate the joints and regulate the pressure for stable pressure supply.

#### **5.2.4.2 Flow Meters**

Two air flow meters and a water flow meter that was calibrated for diesel was used for experimental testing. The air flow meters are used to measure airflow rate supplied for swirling and fuel atomizing. Meanwhile the fuel flow meter is used to measure the flow rate of the fuel.

#### **5.2.4.3 Pressure Gauge**

Pressure gauge was used to measure and control the pressure supplied to the tank and combustor. Three pressure gauges were used in this experimental testing. One pressure gauge was used for air swirling pressure control and the others for fuel pressurizing and fuel atomizing control.

#### **5.2.4.4 Gas Sampling Probe**

An '8' configuration gas sampling probe was used for mean exit sampling. The flue gas sample will be drawn to the gas analyser through the '8' configuration gas sampling probe to measure oxides of nitrogen, carbon monoxide and sulphur dioxide. It consisted of a '8' configuration bended stainless steel tube and welded at the end. The gas sampling probe is shown in Figure 5.1

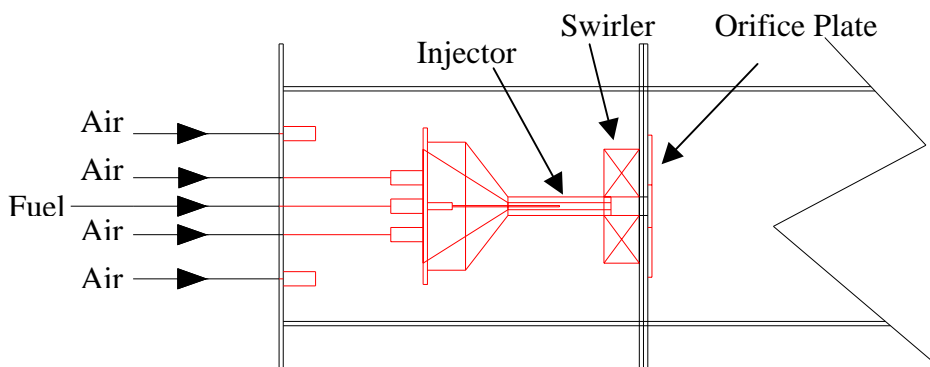

**Figure 5.1:** Gas Sampling Probe

#### **5.2.4.5 Gas Analyzer**

Kane May 9106 gas analyzer was used in this research. This device was used to measure gaseous such as oxides of nitrogen, carbon monoxides and sulphur dioxide. The analyzer has a single emission probe, which could be inserted directly into the flue gas. The analyzer has a suction pump, which sucks the hot flue gas through the probe. The analyzer also has a series of filters, long tube and different gas sensors. The flue gas has to flow through different gas sensors before exhausting to the air. When the flue gas enters into the sensors, its temperature should not exceed 40°C and free of water particles, chemical and dust. These were achieved by using long tube to radiate the heat, water filter, dust filter and chemical filter. The analyzer was purged frequently, to draw fresh air into the sensors for accurate functions of the sensors. The sensors detect the presence of the toxic gases and display the results directly on the screen.

### 5.3 General Test Procedure

1. A swirler vane angle of  $30^\circ$  and 30mm orifice plate with upstream injection configuration is mounted at the exit plane of plenum chamber.
2. The gas analyzer system is switched on 10 minutes prior to experimental testing to stabilize the analyzer's electronics. The thermocouple recorder, compressors and blower should also be switched on.
3. The air blower valve is turned on. Once the compressor reaches its upper pressure limit, the compressor valve should be turned on. All pressure gauges and flow meter is checked to be in the operating conditions.
4. The air blower is set at 24 CFM to provide equivalence ratio of 0.562.
5. Fuel valve is turned on and the fuel is ignited to start the combustion using a torch. Pressure gauges and flow meters are rechecked to be in the operating conditions.
6. Once the flame is stabilized, the emissions are measured using the gas analyzer. The temperatures obtained from the thermocouple are recorded.
7. The air blower capacity is lessen to designate the flow rate. All 8 reading at each fuel setting is repeated to determine the emissions and temperatures.
8. Steps one to seven are repeated for swirler vane angle of  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  with orifice plate sizes of 30mm, 25mm and 20mm with upstream injection configuration.
9. Steps two to seven are once again repeated with swirler vane angle  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  swirler vane angle for orifice plate sizes of 30mm, 25mm and 20mm with downstream injection configuration.

**Figure 5.2:** Experimental Set up for Upstream Injection

**Figure 5.3:** Experimental Set up for Downstream Injection

#### 5.4 Experimental Testing Parameters

Table 5.1, Table 5.2 and Table 5.3 below clearly illustrates the parameters used for current experimental testing. The parameters were divided into three main categories of constant parameters, manipulated parameters and measured parameters. The calculation of combustion equivalence ratio was shown in Appendix R. Meanwhile an example of detail calculations of equivalence ratio was shown in Appendix S.

**Table 5.1:** Experimental Testing Constant Parameters

<b>CONSTANT PARAMETERS</b>		
1	Fuel	<b>Diesel</b>
2	Fuel Pressure, $P_f$ (bar)	<b>2</b>
3	Fuel Flow rate, $V_f$ (mℓ/min)	<b>50</b>
4	Injection Air Pressure, $P_a$ (bar)	<b>2</b>

**Table 5.2:** Experimental Testing Manipulated Parameters

<b>MANIPULATED PARAMETERS</b>		
1	Swirling Air Flow Rate, $V_{as}$ (LPM)	<b>24, 22, 20, 18, 15, 13, 11, 9</b>
2	Swirler Vane Angle	<b>30°, 40°, 50°, 60°</b>
3	Injection Position	<b>Upstream, Downstream</b>
4	Orifice Plate Size (mm)	<b>20, 25, 30</b>

**Table 5.3:** Experimental Testing Measured Parameters

<b>MEASURED PARAMETERS</b>		
1	Combustion Temperature (°C)	<b>450 to 1100</b>
2	Emission (ppm)	<b>NO<sub>x</sub>, CO, SO<sub>2</sub></b>

## 5.5 Temperature Measurement

Wall fixed thermocouples were located at nine different axial positions along the whole length of the 168 outer diameter combustor. The measurement was taken from the end of upstream flange of combustion chamber as shown in Figure 5.4. The positions are given in Table 5.1. The K-type thermocouple is used in this experimental testing which measures temperature range from 0°C to 1300°C.

**Table 5.4:** Combustor Wall Thermocouple Position

<b>Position</b>	<b>A</b>	<b>B</b>	<b>C</b>	<b>D</b>	<b>E</b>	<b>F</b>	<b>G</b>	<b>H</b>	<b>I</b>
<b>Thermocouple Position (mm)</b>	10	40	110	170	230	290	345	395	625

## **CHAPTER VI**

### **EXPERIMENTAL RESULTS AND DISCUSSION ON COMBUSTION PERFORMANCE**

#### **6.1 Introduction**

A single radial air swirler with swirler vane angles of 30°, 40°, 50° and 60° using orifice plates of 20mm, 25mm and 30mm has been investigated for combusting flow condition using experimental techniques for both downstream and upstream injection.

The curved vane angle swirler was designed to avoid flow separation in the chamber with the added advantages of lower pressure loss. Four different swirler vane angles of radial swirler were designed to study the effect of vane angles on both swirl number and strength of swirl. Three different orifice plates were designed to investigate the consequence of orifice plate insertion on the air and fuel mixing improvement. Meanwhile two injection position of upstream and downstream were designed to examine the effect of these positions on the emissions results. All these variables do help in improving the combustion stability and emissions reduction in various ways.

## 6.2 Upstream Injection

As discussed in the previous chapter, upstream injection is that the central fuel injector was placed upstream of the swirler exit plane. Investigation has been carried out using 3 different orifice plates of 20mm, 25mm and 30mm for 4 different swirler vane angles of 30°, 40°, 50° and 60°.

### 6.2.1 Temperature Profile in Accordance to Equivalence Ratio along the Combustion Chamber Using Orifice Plate of 30mm with Upstream Injection

**Figure 6.1:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of 30° and Orifice Plate of 30mm with Upstream Injection

The combustion temperature as a function of the axial distance from swirler exit for swirler vane angle of 30° is shown in Figure 6.1. The highest temperature was produced at the equivalence ratio of 0.703 for this setting. This was apparently highest along the chamber. Theoretically highest NO<sub>x</sub> emission and lowest CO

emission should occur at this equivalence ratio. Myers and Lefebvre (1986) noted that the flame speed increase with the fuel/air ratio and attain their maximum value at mixture strength close to stoichiometric. This might be because of the flame spread was slow where incoming fuel from the swirler is blocked in that region for the reason of slow outgoing fuel towards the end of combustor. So, more fuel needs to be burned in this region which then increases the temperature. Ahmad et. al. (1985) suggested that larger expansion ratio from the swirler was necessary to ensure rapid flame spread. Since equivalence ratio of 0.703 produces highest temperature, so the highest flame speed occurs at this equivalence ratio. Higher equivalence ratios also seem to enhance the flame towards the wall region. This was due to the more effective penetration of the fuel jet to the jet boundary of the incoming flow from the swirler that give rise to the higher  $\text{NO}_x$  emission and lower CO emission (Al-Kabie H.S., 1989). At about the first 100mm from the swirler exit, there was no significant variation of temperatures between all equivalence ratios. The starting flame temperature for all equivalence ratios was about  $650^\circ\text{C}$ . Flame temperature in fuel rich region was lower than the temperature in fuel lean region. This is because there is still some fuel left unburned in fuel rich region resulting in lower temperature and bad air and fuel mixing.

**Figure 6.2:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $40^\circ$  and Orifice Plate of 30mm with Upstream Injection

Figure 6.2 shows the combustion temperature in accordance to equivalence ratio along the combustion chamber for swirler vane angle of  $40^\circ$  using orifice plate of 30mm with upstream injection. Apparently for all flame, the highest temperature was shown at the distance of 230mm. At this distance, flame at equivalence ratio of 0.703 shows the highest temperature. This once again shows that highest flame speed occurs at equivalence ratio of 0.703. The temperatures rise along the chamber, and reach its peak at distance of 230mm before the temperature reduces back towards the end of combustor. It is noted by Al-Kabie (1989) that highest temperature occurs at lean equivalence ratio near to the core of the flame. In this experimental testing, the flame reaches its peak at the distance of 230mm from the swirler exit which also means that highest flame speed occurs at the distance of 230mm from the swirler exit. So the highest flame speed occurs at equivalence ratio of 0.703 at the distance of 230mm from the swirler exit for this setting. This also could be concluded that the flame length is about 230mm for this setting as fundamental of flame temperature suggested that the highest flame temperature occurs near to the flame tail.

**Figure 6.3:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $50^\circ$  and Orifice Plate of 30mm with Upstream Injection

Figure 6.3 shows the combustion temperature in accordance to equivalence ratio along the combustion chamber for swirler vane angle of  $50^\circ$  using orifice plate

of 30mm with upstream injection. The temperature at equivalence ratio of 0.562 shows very low temperature compared to other equivalence ratios at the flame front. The lowest temperature was shown by equivalence ratio of 1.125 that is 694.7°C at the combustor exit. At the flame front, flame with equivalence ratio of 0.888 produces highest temperature, meanwhile flame with equivalence ratio of 0.703 produces highest temperature at the flame tail. This shows that higher flame speed was shown by equivalence ratio of 0.888 at the flame front while equivalence ratio of 0.703 produce higher flame speed in the flame tail. Once again, the maximum temperature was shown by flame with equivalence ratio of 0.703 at the distance of 230mm from the swirler exit. From the results, it could be concluded that for different setting of swirler vane angles, the variance on the highest and lowest temperature at the flame front and flame tail occur with different equivalence ratios. This was mainly because of different swirler vane angles produce different profile of turbulence structure which changing the flame profile and temperature along the combustion chamber.

**Figure 6.4:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of 60° and Orifice Plate of 30mm with Upstream Injection

Figure 6.4 on the other hand, shows the combustion temperature in accordance to equivalence ratio along the combustion chamber for swirler vane angle

of  $60^\circ$  using orifice plate of 30mm with upstream injection. The highest temperature of less than  $950^\circ\text{C}$  was obtained along the combustion chamber. Besides that, the highest temperature at the flame tail was also less than the swirler vane angles of  $30^\circ$ ,  $40^\circ$  and  $50^\circ$ . The maximum temperature at distance of 230mm from the swirler exit was shown by the flame with equivalence ratio of 0.649. However, flame with equivalence ratio of 0.703 shows highest temperature at the flame tail. It was noticed that the flame length in this setting was about the same with the  $50^\circ$  swirler vane angle configuration. Highest flame speed occur at equivalence ratio of 0.649 which means that the changing of swirler vane angles does vary the turbulence structure and swirling profile in the combustion chamber which in turn produce dissimilar temperature contour that create various highest and lowest temperature point with different equivalence ratios.

### 6.2.2 Emission Investigation Using Orifice Plate of 30mm with Upstream Injection

**Figure 6.5:**  $\text{NO}_x$  Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 30mm with Upstream Injection

Figure 6.5 shows  $\text{NO}_x$  emission versus equivalence ratio for 4 different swirler vane angles of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using orifice plate of 30mm with upstream injection. Even though swirler vane angle of  $60^\circ$  produces better results compared to other swirler vane angles, the results pattern are not convincing as the emission results were not stable. Swirler vane angle of  $30^\circ$  produce highest  $\text{NO}_x$  emission compared to all other swirler vane angles. Swirler vane angle of  $40^\circ$  produced  $\text{NO}_x$  emission less than swirler vane angle of  $30^\circ$  but higher than swirler vane angle of  $50^\circ$ . At equivalence ratio of 0.803,  $\text{NO}_x$  emission was reduced about 44 percent, 24 percent and 28 percent for swirler vane angle of  $60^\circ$ ,  $50^\circ$  and  $40^\circ$  compared to swirler vane angle of  $30^\circ$ , respectively.

**Figure 6.6:** CO Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 30mm with Upstream Injection

Figure 6.6 shows CO emission versus equivalence ratio for 4 different swirler vane angles of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using orifice plate of 30mm with upstream injection. High CO emission was produced at equivalence ratio of 0.562 that was about 450 ppm for swirler vane angle of  $30^\circ$  and about 200 ppm for swirler vane angle of  $60^\circ$ . CO emission decreases with respect to equivalence ratio until equivalence ratio of 0.7 and increases back with respect to equivalence ratio through the fuel rich region. There was no significant different in CO emission between all

swirler vane angles except in very fuel lean region. However, swirler vane angle of  $60^\circ$  produced better emission results compared to others. The CO emission reduction was about 20 percent for swirler vane angle of  $60^\circ$  compared to swirler vane angle of  $30^\circ$  at equivalence ratio of 0.803. CO emission reduction was about 4 percent for swirler vane angle of  $40^\circ$  compared to swirler vane angle of  $30^\circ$ . Meanwhile the CO emission reduction was about 6 percent for swirler vane angle of  $60^\circ$  compared to swirler vane angle of  $50^\circ$ . All comparison was taken at equivalence ratio of 0.803.

**Figure 6.7:** SO<sub>2</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 30mm with Upstream Injection

Figure 6.7 shows SO<sub>2</sub> emission versus equivalence ratio for 4 different swirler vane angles of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using orifice plate of 30mm with upstream injection. SO<sub>2</sub> emission decreases with respect to equivalence ratio in low fuel lean region. The emission increases with respect to equivalence ratio from the equivalence ratio of 0.7 through the fuel rich region. But, SO<sub>2</sub> emission was almost in level for swirler vane angle of  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  at very fuel lean region that is at equivalence ratio of 0.55 to 0.7. For swirler vane angle of  $40^\circ$ , SO<sub>2</sub> emission was reduced about 19 ppm compared to swirler vane angle of  $30^\circ$  at equivalence ratio of 0.803. Emission reduction of about 20 percent was achieved for swirler vane angle of  $50^\circ$  compared to swirler vane angle of  $40^\circ$  at equivalence ratio of 0.803. Meanwhile

SO<sub>2</sub> emission reduced about 10 percent for swirler vane angle 60° as compared to swirler vane angle of 50° at equivalence ratio of 0.803.

### 6.2.3 Temperature Profile in Accordance to Equivalence Ratio along the Combustion Chamber Using Orifice Plate of 25mm with Upstream Injection

The temperature profile in accordance to equivalence ratio along the combustion chamber using orifice plate of 25mm with upstream injection for four different swirler vane angles of 30°, 40°, 50° and 60° was shown in Figure 6.8, 6.9, 6.10 and 6.11, respectively.

**Figure 6.8:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of 30° and Orifice Plate of 25mm with Upstream Injection

Referring to Figure 6.8, the highest temperature for swirler vane angle of 30° was shifted to the distance of 345mm from the swirler exit except for the equivalence ratio of 0.888, 0.992 and fuel rich region. Flame with these equivalence ratios shows

highest temperature at the distance of 230mm from the swirler exit. Once again, the highest temperature at distance of 345mm from the swirler exit was produced by flame with equivalence ratio of 0.649. The highest temperature at flame tail was produced by flame with equivalence ratio of 0.649. The lowest flame tail temperature is 675.9°C shown by fuel rich flame. Generally, this setting with orifice plate of 25mm shows that the flame was a bit longer compared to the configuration with orifice plate of 30mm. This was proved by the detection of highest temperature spot at the distance more downstream compared to the configuration with orifice plate of 30mm. This situation occurs might be because of smaller opening of orifice plate limited the flame to be spread widely which in turn become more longer to complete the combustion further downstream of the combustion chamber. This limitation also creates shear boundary layer turbulences to improve the upstream mixing of fuel and air.

**Figure 6.9:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of 40° and Orifice Plate of 25mm with Upstream Injection

As shown in Figure 6.9, the highest temperature was produced at the distance of 295mm from the swirler exit except for the last two equivalence ratios where the highest temperature was at 230mm from the swirler exit. The flame length was shorter with swirler vane angle of 40° compared to swirler vane angle of 30°. This is

because of bigger swirler vane angle creates larger swirler pressure drop that generates greater turbulence effect which makes the flame wider. At fuel lean region with equivalence ratio of 0.55 to 0.65, the temperature of less than 600°C was exhibited. The highest temperature near the swirler exit was shown by flame with equivalence ratio of 0.888. The lowest temperature at the end was exhibited by fuel rich equivalence ratio.

**Figure 6.10:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of 50° and Orifice Plate of 25mm with Upstream Injection

Meanwhile, the lowest temperature near the swirler exit and at the end of the combustor for swirler vane angle of 50° using orifice plate of 25mm with upstream injection was the flame with equivalence ratio of 1.125 as shown in Figure 6.10. For this configuration, the highest temperatures for all equivalence ratios were at the distance of 230mm from the swirler exit. The highest temperature at the end is 793.4°C which was shown by flame at equivalence ratio of 0.703. The temperature different between the highest temperature and the lowest temperature at distance of 230mm from the swirler exit was 67.3°C where the highest temperature was shown by flame at equivalence ratio of 0.803, meanwhile the lowest temperature was shown by flame at equivalence ratio of 1.125. From these results, it could be concluded that bigger swirler vane angles produce shorter flame length compared to smaller swirler

vane angles as for swirler vane angle of  $50^\circ$ , the highest temperature point was further shifted more upstream compared to both swirler vane angles of  $30^\circ$  and  $40^\circ$ .

**Figure 6.11:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $60^\circ$  and Orifice Plate of 25mm with Upstream Injection

From Figure 6.11, we could clearly see that flame at equivalence ratio of 1.125, shows overall lower temperature compared to other flames. The highest temperature at this equivalence ratio is  $881.3^\circ\text{C}$ . The highest temperature was shown by flame with equivalence ratio of 0.703, which was  $1010.5^\circ\text{C}$  at distance of 230mm from the swirler exit. This temperature exceeds  $1000^\circ\text{C}$ , which was not shown by previous settings. There was not much temperature different at this distance between the flame with equivalence ratios of 0.649, 0.703 and 0.803. The different between one another was less than  $3^\circ\text{C}$ . The highest temperature at the combustor end was shown by the flame with equivalence ratio of 0.649.

## 6.2.4 Emission Investigation Using Orifice Plate of 25mm with Upstream Injection

Figures 6.12, 6.13 and 6.14 shows  $\text{NO}_x$ , CO and  $\text{SO}_2$  emission investigation using orifice plate of 25mm with upstream injection for 4 different swirler vane angles of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$ .

**Figure 6.12:**  $\text{NO}_x$  Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 25mm with Upstream Injection

The results show that  $\text{NO}_x$  emission increases with respect to equivalence ratio until the equivalence ratio of 0.7 and decreases with respect to equivalence ratio after that value as shown in Figure 6.12. The turning point occurs at the equivalent ratio from 0.7 to 0.8, where at this point  $\text{NO}_x$  emission was highest for a particular setting. The graph also shows that  $\text{NO}_x$  emission decreases when the swirler vane angle was increased from  $30^\circ$  to  $60^\circ$ . Higher swirler vane angle produced better emission reduction because it could produce stronger swirling effect and better turbulence flow which further increase the pressure drop in the combustion chamber (Escott, N.H., 1993). The  $\text{NO}_x$  emission was reduced about 28 percent for swirler vane angle of  $40^\circ$  compared to swirler vane angle of  $30^\circ$  at equivalence ratio of 0.803. The emission was further reduced about 26 percent when the swirler vane

angle was increased to  $50^\circ$  at the same equivalence ratio. The  $\text{NO}_x$  emission was again reduced to 18 ppm that is about 28 percent reduction for swirler vane angle of  $60^\circ$  compared to swirler vane angle of  $50^\circ$  at equivalence ratio of 0.803.

**Figure 6.13:** CO Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 25mm with Upstream Injection

Figure 6.13 shows CO emission results for 4 different swirler vane angles using orifice plate of 25mm with upstream injection. Until the equivalence ratio of 0.7, CO emission does not show significant reduction for all swirler vane angles except for swirler vane angle of  $30^\circ$  at equivalence ratio of 0.562. CO emission decreases about 100 ppm for swirler vane angle of  $40^\circ$  compared to swirler vane angle of  $30^\circ$  at equivalence ratio of 0.562. CO emission increases significantly after the equivalence ratio of 0.7 for all swirler vane angles. There are great difference of emission reduction between swirler vane angles of  $30^\circ$  and  $40^\circ$  with swirler vane angles of  $50^\circ$  and  $60^\circ$  at fuel rich region. Swirler vane angle of  $50^\circ$  and  $60^\circ$  generate small amount of emission in fuel rich region. However, this emission is still higher than the emission generated in fuel lean region. The different of CO emission between highest swirler vane angle and lowest swirler vane angle is 31 ppm. Meanwhile, emission reduction of about 37 percent was achieved between swirler vane angle of  $50^\circ$  and  $30^\circ$ . Comparison was taken at equivalence ratio of 0.803.

**Figure 6.14:** SO<sub>2</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 25mm with Upstream Injection

Figure 6.14 shows SO<sub>2</sub> emission versus equivalence ratio for 4 different swirler vane angles using orifice plate of 25mm with upstream injection. Between the equivalence ratios of 0.55 and 0.7, the SO<sub>2</sub> emission is almost constant where the emission increases very slowly. After the equivalence ratio of 0.7, the SO<sub>2</sub> emission increases rapidly for all swirler vane angles. Although, the emission increases rapidly for all swirler vane angles, swirler vane angle of 30° shows highest emission that is 183 ppm at equivalence ratio of 1.125. Swirler vane angle of 60° shows better emission result compared to all other swirler vane angles. At equivalence ratio of 0.803, the SO<sub>2</sub> emission was reduced about 40 percent for swirler vane angle of 60° compared to swirler vane angle of 30°.

### 6.2.5 Temperature Profile in Accordance to Equivalence Ratio along the Combustion Chamber Using Orifice Plate of 20mm with Upstream Injection

Besides experimental testing for temperature profile using orifice plate of 30mm and 25mm, another orifice plate configuration is orifice plate of 20mm. 4 graphs of temperature profile in accordance to equivalence ratio along the combustion chamber with upstream injection were plotted. The same swirler vane angles were used.

**Figure 6.15:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $30^\circ$  and Orifice Plate of 20mm with Upstream Injection

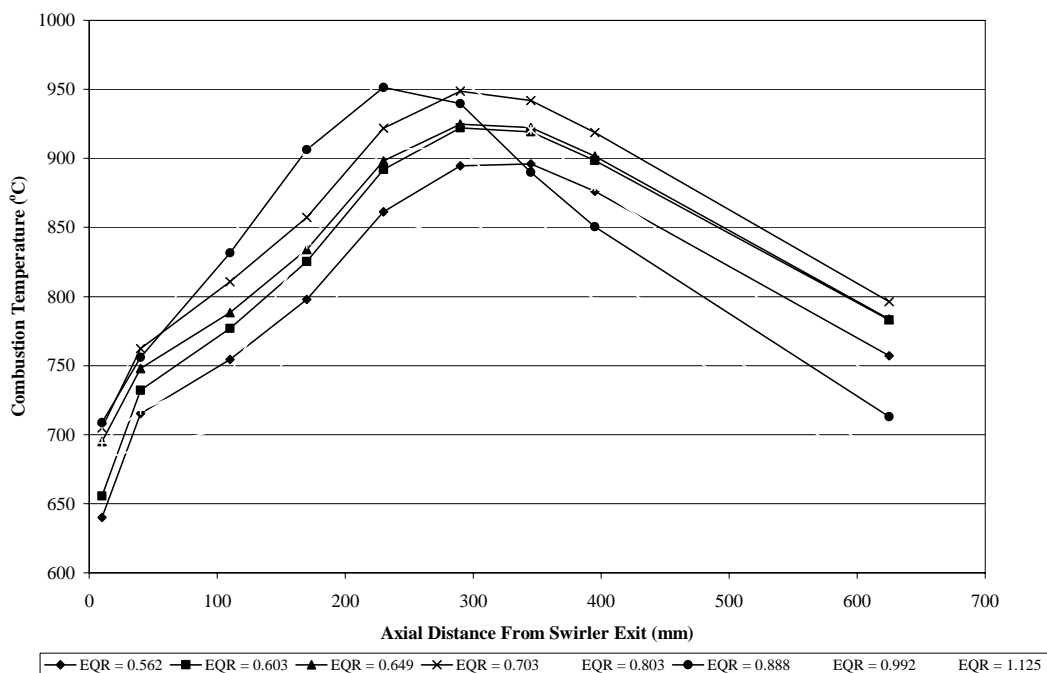

The temperature profile provided by swirler vane angle of  $30^\circ$  shows that temperature increases along the chamber and reaches its peak before decreasing back towards the exit of combustion chamber as shown in Figure 6.15. Flame with fuel rich equivalence ratio produces lowest temperature from the distance of 300mm towards the end of combustion chamber. The rapid decrease of temperature for this equivalence ratio was due to some fuel left unburned as less air is provided for combusting the flame. The highest temperature of less than  $1000^\circ\text{C}$  was exhibited in

this setting. Flame at equivalence ratio of 0.703; produced highest temperature at the end of combustion chamber.

**Figure 6.16:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $40^\circ$  and Orifice Plate of 20mm with Upstream Injection

Based on Figure 6.16, overall temperature of less than  $1000^\circ\text{C}$  was obtained for swirler vane angle of  $40^\circ$ . The temperature profiles were about the same, where temperature increases along the chamber and reaches its peak before decreasing back towards the end of combustion chamber. Flames with equivalence ratio of less than 0.703, shows peak temperature further downstream compared to the flames with equivalence ratio of more than 0.703. Lowest temperature at the exit of combustion chamber was shown by the flame at equivalence ratio of 1.125, while highest temperature at the same spot was shown by flame at equivalence ratio of 0.603. The highest peak temperature was shown by flame at equivalence ratio of 0.803.

**Figure 6.17:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $50^\circ$  and Orifice Plate of 20mm with Upstream Injection

Figure 6.17 shows the temperature profile in accordance to equivalence ratio along the combustion chamber using orifice plate of 20mm with upstream injection. Generally, highest temperatures for all equivalence ratio fall at distance of 290mm from the swirler exit except for equivalence ratio of 0.803 and 0.888 which fall at the distance of 230mm from the swirler exit while for equivalence ratio of 0.562 falls at the distance of 345mm from the swirler exit. For orifice plate of 20mm, leanest equivalence ratio of 0.562 produces longest flame length meanwhile richer equivalence ratio produces shorter flame length. This might be because of too much excess air present in the mixture with equivalence ratio of 0.562 which unable to maximize the shear layer boundary turbulence to spread the flame wider. The flame length increases to complete the combustion further downstream of the combustion chamber. Near the swirler exit, flame at equivalence ratio of 0.562 produces lowest temperature while highest temperature was shown by the flame at equivalence ratio of 0.888. Flame at equivalence ratio of 1.125, exhibits overall lowest temperature except near the swirler exit.

**Figure 6.18:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $60^\circ$  and Orifice Plate of 20mm with Upstream Injection

Figure 6.18 shows similar pattern to Figure 6.20, where flames with equivalence ratio of less than 0.703, produce peak temperature further downstream compared to flames with equivalence ratio more than 0.703 except for flame at equivalence ratio of 0.649, which produces peak at the distance of 230mm. The lowest temperature near to swirler exit and at the exit of combustion chamber was shown by flame at equivalence ratio of 0.992. This is quite different compared to the other results which mostly show lowest temperature at the exit was flame with equivalence ratio of 1.125. Meanwhile the lowest peak temperature is  $793.7^\circ\text{C}$  produced by the flame at equivalence ratio of 0.562. The highest peak temperature was exhibited by flame at equivalence ratio of 0.803.

### 6.2.6 Emission Investigation Using Orifice Plate of 20mm with Upstream Injection

The measured  $\text{NO}_x$ , CO and  $\text{SO}_2$  emissions as a function of the gas analysis metered equivalence ratio using orifice plate of 20mm with upstream injection are shown in Figures 6.19, 6.20 and 6.21, respectively. The emission pattern for all three emissions is almost the same as the emission investigation results using orifice plate of 25mm. However, the emission values are much lesser for orifice plate of 20mm compared to the results in orifice plate of 25mm.  $\text{NO}_x$  emission below 50 ppm was obtained for all swirler vane angles. Meanwhile,  $\text{SO}_2$  emission below 200 ppm was obtained for all swirler vane angles.

**Figure 6.19:**  $\text{NO}_x$  Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 20mm with Upstream Injection

Referring to Figure 6.19, swirler vane angle of  $30^\circ$  generates highest  $\text{NO}_x$  emission. Meanwhile, swirler vane angle of  $60^\circ$ , generates lowest  $\text{NO}_x$  emission. However, swirler vane angle of  $50^\circ$  produced better emission results compared to swirler vane angle of  $60^\circ$  below the equivalence ratio of 0.7. This order disagree with the theory which indicates that swirler vane angle of  $60^\circ$  should provide better emission results compared to swirler vane angle of  $50^\circ$ . The emission decreased

about 29 percent for swirler vane angle of  $60^\circ$  compared to swirler vane angle of  $50^\circ$  at equivalence ratio of 0.803. At the same equivalence ratio,  $\text{NO}_x$  emission was reduced about 58 percent for swirler vane angle of  $60^\circ$  compared to swirler vane angle of  $40^\circ$ . Meanwhile, the emission reduction was about 60 percent for swirler vane angle of  $60^\circ$  compared to swirler vane angle of  $30^\circ$  at equivalence ratio of 0.803. The emission reduction between swirler vane angle of  $40^\circ$  and  $30^\circ$  was only 2 ppm.

**Figure 6.20:** CO Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 20mm with Upstream Injection

CO emission also shows poor results where the emission results disagree with the theory. In fuel lean region below the equivalence ratio of 0.7, swirler vane angle of  $40^\circ$  produces better emission results while in high fuel lean region which is at equivalence ratio from 0.7 to 0.9, swirler vane angle of  $50^\circ$  generates lowest emission results. Meanwhile, in fuel rich region, the lowest emission results were shown by swirler vane angle of  $60^\circ$ . However at equivalence ratio of 0.803, the emission reduction was similar to the theory where swirler vane angle of  $60^\circ$  produces lowest emission followed by swirler vane angle of  $50^\circ$ ,  $40^\circ$  and  $30^\circ$ .

**Figure 6.21:** SO<sub>2</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 20mm with Upstream Injection

Referring to Figure 6.21, SO<sub>2</sub> emission is almost constant in fuel lean region below the equivalence ratio of 0.7 and increases rapidly since then through the fuel rich region. Swirler vane angle of 60° shows lowest emission result that is about 130 ppm at equivalence ratio of 1.125. SO<sub>2</sub> emission of less than 200 ppm was generated for all swirler vane angles using orifice plate of 20mm with upstream injection.

### 6.3 Downstream Injection

Besides the investigation on upstream injection, downstream injection was another method carried out in this study. Fuel injector was placed further downstream into the combustion chamber. Results were compared between these two methods. Investigation has been carried out using 3 different orifice plates of 20mm, 25mm and 30mm for 4 different swirler vane angles of 30°, 40°, 50° and 60°.

### 6.3.1 Temperature Profile in Accordance to Equivalence Ratio along the Combustion Chamber Using Orifice Plate of 30mm with Downstream Injection

**Figure 6.22:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $30^\circ$  and Orifice Plate of 30mm with Downstream Injection

Figure 6.22 shows combustion temperature in accordance to equivalence ratio along the axial length of the combustion chamber for swirler vane angle of  $30^\circ$  using orifice plate of 30mm with downstream injection. The temperature profile scattered along the combustion chamber. The lowest temperature was  $515.7^\circ\text{C}$  shown by flame with equivalence ratio of 0.562 at the distance of 110mm from the swirler exit. Mainly in the flame front, the temperature does not increase steadily along the combustion chamber. The temperature increases and then decreases along the chamber. Steep increase of temperature was found at distance of 290mm to 345mm from the swirler exit. Highest temperature was shown at the distance of 345mm from the swirler exit. Flame at equivalence ratio of 0.562 produces lowest temperature along the combustion chamber except at the end where flame with equivalence ratio of 1.125 shows lowest temperature. Meanwhile, highest temperature was shown by flame with equivalence ratio of 0.803 at the combustion chamber exit.

**Figure 6.23:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $40^\circ$  and Orifice Plate of 30mm with Downstream Injection

Figure 6.23 shows temperature profile for swirler vane angle of  $40^\circ$  in accordance to equivalence ratio using orifice plate of 30mm with downstream injection. Flames for the low equivalence ratios produce lower temperature compared to flames with higher equivalence ratios near to the swirler exit. However, lowest temperature was exhibited by flame with equivalence ratio of 0.803 at the distance of 110mm from the swirler exit. Looking at the graph, it is noticed that equivalence ratio of 0.803 provides with lower temperature for equivalence ratios below 0.7. This shows that for this setting with swirler vane angle of  $30^\circ$  and orifice plate of 30mm using downstream injection, probably the best pressure drop and turbulence structure occurs at equivalence ratio of 0.803. This could be because of the even temperature distribution throughout the chamber as fuel spreads widely to occupy the entire combustion chamber. Meanwhile, highest temperature was exhibited at the distance of 230mm from the swirler exit by flame at equivalence ratio of 0.562. The major factor of this circumstance was because of narrow flame and higher flame speed at the distance of 230mm from the swirler exit. At the chamber exit, the lowest temperature was shown by equivalence ratio of 1.125 while highest temperature was produced by flame at equivalence ratio of 0.703.

**Figure 6.24:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $50^\circ$  and Orifice Plate of 30mm with Downstream Injection

Referring to Figure 6.24, the temperature gradient for higher equivalence ratio was low where they show temperature of less than  $900^\circ\text{C}$ . Steeper temperature gradient was shown by lower equivalence ratios along the combustion chamber. Highest temperature was exhibited by flame with equivalence ratio of 0.603 at the distance of 290mm from the swirler exit. Flame with equivalence ratio of 1.125; produce highest temperature near to the swirler exit and lowest temperature at the combustion chamber exit. Highest temperature at the exit was shown by flame with equivalence ratio of 0.703.

**Figure 6.25:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $60^\circ$  and Orifice Plate of 30mm with Downstream Injection

Temperature profile of about the same pattern with Figure 6.27 was observed in Figure 6.25, where temperature gradients for higher equivalence ratio were lower than those with lower equivalence ratios. The first three equivalence ratios exceed the temperature of  $1000^\circ\text{C}$  at the peak area at distance of 230mm from the swirler exit. Peak area for higher equivalence ratios flame was produced further downstream in the combustion chamber compared to those lower equivalence ratios flame. The highest temperature near the swirler exit was exhibited by fuel rich flame. Meanwhile, lowest temperature at the combustion chamber exit was shown by flame with equivalence ratio of 0.562. Highest temperature at the exit was produced by flame with equivalence ratio of 0.703.

### 6.3.2 Emission Investigation Using Orifice Plate of 30mm with Downstream Injection

**Figure 6.26:** NO<sub>x</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 30mm with Downstream Injection

Figure 6.26 shows NO<sub>x</sub> emission versus equivalence ratio for 4 different swirler vane angles of 30°, 40°, 50° and 60° using orifice plate of 30mm with downstream injection. For swirler vane angle of 30°, NO<sub>x</sub> emission produced by the downstream injection was almost twice lower than the NO<sub>x</sub> emission produced by the upstream injection for all swirler vane angles. However, the flame was not stable, produces less convincing NO<sub>x</sub> emission results. High NO<sub>x</sub> emission was shown by this setting. Once again, the results show that swirler vane angle of 60° produces better results compared to other swirler vane angles. Swirler vane angle of 30° produces highest NO<sub>x</sub> emission results for the entire swirler vane angles. This match the theory, which states that stronger swirling flow helps in mixing of fuel and air, thus reduces the emissions. At equivalence ratio of 0.803, the emission reduction was not significant where it reduced only about 8 ppm for swirler vane angle of 60° compared to swirler vane angle of 30°. This value contributes about 32 percent of reduction between these two swirlers. Meanwhile, NO<sub>x</sub> emission decreased about 13 percent for swirler vane angle of 50° compared to swirler vane angle of 40°.

**Figure 6.27:** CO Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 30mm with Downstream Injection

Figure 6.27 shows CO emission versus equivalence ratio for 4 different swirler vane angles of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using orifice plate of 30mm with downstream injection. CO emission decreases with respect to equivalence ratio in fuel lean region below equivalence ratio of 0.7 and increases with respect to equivalence ratio at equivalence ratio of 0.7 through the fuel rich region. There is no significant different of CO emission between all the swirler until equivalence ratio of 0.8. Swirler vane angle of  $60^\circ$  produces lowest CO emission. Meanwhile, swirler vane angle of  $30^\circ$  produces highest CO emission. However, these emissions results are much lesser compared to the emissions produced by upstream injection. The CO emission reduction for Swirler vane angle of  $60^\circ$  with downstream injection and upstream injection is about 230 ppm. This might be because of better mixing of fuel and air was enhanced in the downstream injection as the fuel, which enters the combustor, were in turbulence flow. Meanwhile in upstream injection, the fuel goes through a laminar flow before changing to turbulence flow. Turbulence profile of the mixture produces thorough and proper air fuel mixing. This generates good combustion and low pollution formation. The two structure of mixture profile in upstream injection causes poor combustion performances and generates higher pollution. At equivalence ratio of 0.803, CO emission increases slowly from swirler

vane angle of  $30^\circ$  to swirler vane angle of  $50^\circ$  and dropped for swirler vane angle of  $60^\circ$ . The slow increase was about 3 percent that was 6 ppm for swirler vane angle of  $50^\circ$  compared to swirler vane angle of  $30^\circ$ . The emission then dropped about 18 percent for swirler vane angle of  $60^\circ$ .

**Figure 6.28:** SO<sub>2</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 30mm with Downstream Injection

Figure 6.28 shows SO<sub>2</sub> emission versus equivalence ratio for 4 different swirler vane angles of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using orifice plate of 30mm with downstream injection. SO<sub>2</sub> emission increases with respect to equivalence ratio. Until the equivalence ratio of 0.7, SO<sub>2</sub> emission increases slowly, this indicates that the emission is almost constant. The emission increases rapidly from that point through the fuel rich region. The highest SO<sub>2</sub> emission was produced by swirler vane angle of  $30^\circ$  that is 62 ppm while the lowest SO<sub>2</sub> emission was produced by swirler vane angle of  $60^\circ$  that is 23 ppm. Downstream injection shows lower emission results for all swirler vane angle compared to upstream injection at the same orifice plate configuration.

### 6.3.3 Temperature Profile in Accordance to Equivalence Ratio along the Combustion Chamber Using Orifice Plate of 25mm with Downstream Injection

The next four figures shows the temperature profile in accordance to equivalence ratio along the combustion chamber for four different swirler vane angle of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using orifice plate of 25mm with downstream injection.

**Figure 6.29:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $30^\circ$  and Orifice Plate of 25mm with Downstream Injection

Figure 6.29 shows the temperature profile for swirler vane angle of  $30^\circ$  using orifice plate of 25mm with downstream injection. The temperature increases and decreases along the combustion chamber. The highest temperature was shown further downstream at distance of 395mm compared to upstream injection configuration where upstream injection configuration mostly shows the peak at distance of 230mm from the swirler exit. Actually, the flame was shorter in downstream injection configuration compared to upstream injection configuration. This conclusion was taken based on visual observation throughout the experimental testing. The above phenomena occurs because of the flame was shifted further downstream as the injector position was in the combustion chamber. Besides that, the highest

temperature point occurs at the flame tail for downstream configuration while for upstream configuration, the highest temperature point occur at the core of the flame, just after the flame middle portion. The detail of the flame highest temperature point was shown in Figure 6.30 and Figure 6.31 for upstream injection and downstream injection respectively. The highest temperature was produced by flame with equivalence ratio of 0.803. The lowest temperature at the combustion chamber exit was shown by fuel rich flame.

**Figure 6.30:** Upstream Flame Profile

**Figure 6.31:** Downstream Flame Profile

**Figure 6.32:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $40^\circ$  and Orifice Plate of 25mm with Downstream Injection

As shown in Figure 6.32, this is the temperature profile for swirler vane angle of  $40^\circ$ , the temperature increases steadily along the combustion chamber until the distance of 395mm from the swirler exit and decreases at the chamber end. The lowest temperature at the end of combustion chamber was shown by flame with equivalence ratio of 1.125. The highest temperature was produced by flame with equivalence ratio of 0.703, while flame with equivalence ratio of 0.803 produces highest temperature at the chamber end.

**Figure 6.33:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $50^\circ$  and Orifice Plate of 25mm with Downstream Injection

Figure 6.33 shows the temperature profile for swirler vane angle of  $50^\circ$  using orifice plate of 25mm with downstream injection. Near the swirler exit, flame with equivalence ratios of 0.562 and 0.603 produce temperature of less than  $550^\circ\text{C}$ . The peak area falls at the distance of 345mm from the swirler exit. This distance is more upstream compared to two earlier temperature profiles. The highest temperature was shown by flame with equivalence ratio of 0.803. Meanwhile highest temperature at the chamber exit was exhibited by flame with equivalence ratio of 0.703. Once again, the lowest temperature at the chamber end was exhibited by fuel rich flame.

**Figure 6.34:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $60^\circ$  and Orifice Plate of 25mm with Downstream Injection

Figure 6.34 shows the temperature profile for swirler vane angle of  $60^\circ$  using orifice plate of 25mm with downstream injection. Excluding the flame with equivalence ratios of 0.992 and 1.125, other flames produce temperatures of less than  $500^\circ\text{C}$  at the front portion of the flame. This is the lowest temperature produced compared to other swirler vane angles. The temperature increases steadily until the distance of 345mm from the swirler exit and reduces towards the exit. Flame with equivalence ratio of 1.125; produce highest temperature near the swirler exit and lowest temperature at the exit of combustion chamber. The different between these two temperatures was about  $100^\circ\text{C}$ . The highest temperature was found at the distance of 345mm from the swirler exit by flame with equivalence ratio of 0.703. This temperature did exceed  $1000^\circ\text{C}$ . The same flame exhibits highest temperature at the exit of combustion chamber.

### 6.3.4 Emission Investigation Using Orifice Plate of 25mm with Downstream Injection

**Figure 6.35:** NO<sub>x</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 25mm with Downstream Injection

Figures 6.35, 6.37 and 6.38 shows NO<sub>x</sub>, CO and SO<sub>2</sub> emission investigation using orifice plate of 25mm with upstream injection for 4 different swirler vane angles of 30°, 40°, 50° and 60°. The emission pattern is almost the same as for orifice plate of 30mm. However, the NO<sub>x</sub> emission was quite deteriorated for swirler vane angle of 30°, 40° and 50° indicating that the flame is not stable for those swirler vane angles setting. The flame is quite stable for swirler vane angle of 60° that produces stable emission results. However, the NO<sub>x</sub> emission for this swirler vane angle at fuel rich region does not show any reduction. NO<sub>x</sub> emission reduction of about 26 percent was achieved for swirler vane angle of 40° compared to swirler vane angle of 30°. The emission was then further reduced about 20 percent for swirler vane angle of 50°. NO<sub>x</sub> emission once again shows reduction of about 24 percent when swirler vane angle was increased to 60°. Once again, comparison was taken at equivalence ratio of 0.803. Comparison was taken after the highest temperature point because lower emission results were spotted at this stage. The purpose of the study was to produce low emission with high power. Even though, equivalence ratio of .888 would produce high power with lower temperature which would produce lower NO<sub>x</sub>

emission with high CO emission. So, ideal equivalence ratio of 0.803 was chosen for comparison. Equivalence ratio of 0.803, probably produce higher NO<sub>x</sub> emission with lower CO emission. Detail was shown in Figure 6.36.

**Figure 6.36:** Temperature Profile for Various Equivalence Ratios

**Figure 6.37:** CO Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 25mm with Downstream Injection

Even though, CO emission for this orifice plate configuration with downstream injection shows not much different between swirler vane angles of  $50^\circ$  and  $60^\circ$ , but, as for overall, these results were much lesser compared to upstream injection results. The highest CO emission produced by swirler vane angle of  $60^\circ$  for this orifice plate configuration with downstream injection is 196 ppm that is at fuel rich region. Swirler vane angle of  $30^\circ$  generates highest CO emission among all swirler vane angles. There is not much different in CO emission results between all swirler vane angles in the region of 0.65 to 0.75 equivalence ratios. The emission decreased from swirler vane angle of  $30^\circ$  to  $50^\circ$  but increased for swirler vane angle of  $60^\circ$ . However, as mentioned earlier the increase was small that is about 4 percent for swirler vane angle of  $60^\circ$  compared to swirler vane angle  $50^\circ$ . Meanwhile, emission reduction of about 25 percent was achieved for swirler vane angle of  $50^\circ$  compared to swirler vane angle of  $40^\circ$ . Comparison was again performed at equivalence ratio of 0.803.

**Figure 6.38:** SO<sub>2</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 25mm with Downstream Injection

Meanwhile, SO<sub>2</sub> emission was almost constant until the equivalence ratio of 0.8 and increases rapidly from that equivalence ratio through to the fuel rich region. As the flame was not stable, the emission results also vary. Even though swirler vane

angle of  $30^\circ$  produces highest emission in fuel rich region, but most of the time, swirler vane angle of  $40^\circ$  shows higher emission. Meanwhile, lowest emission was shown by the  $50^\circ$  swirler vane angle rather than swirler vane angle of  $60^\circ$ . Only in the fuel rich region, swirler vane angle of  $60^\circ$  shows better  $\text{SO}_2$  emission results.

### 6.3.5 Temperature Profile in Accordance to Equivalence Ratio along the Combustion Chamber Using Orifice Plate of 20mm with Downstream Injection

**Figure 6.39:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $30^\circ$  and Orifice Plate of 20mm with Downstream Injection

Figure 6.39 shows the temperature profile for swirler vane angle of  $30^\circ$  using orifice plate of 20mm with downstream injection. The highest temperature was produced at the distance of 395mm for flames with equivalence ratio of less than 0.8 while the highest temperature at distance of 345mm was produced for flames with equivalence ratio higher than 0.8. Flame with equivalence ratio higher than 0.8 produce bigger pressure drop which forces the flame becomes wider. Meanwhile, its counterpart produces narrower flame profile and pushes the flame longer. Overall

temperature of less than  $1000^{\circ}\text{C}$  was shown in this figure. The highest temperature at the flame front was shown by the flame with equivalence ratio of 0.888. The lowest temperature at the flame front was shown by the flame with equivalence ratio of 0.562.

**Figure 6.40:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $40^{\circ}$  and Orifice Plate of 20mm with Downstream Injection

Scattered temperature profile was shown by swirler vane angle of  $40^{\circ}$  using orifice plate of 20mm with downstream injection. Lowest temperature was once again found near the swirler exit by flame with equivalence ratio of 0.562 as shown in Figure 6.40. Highest temperature at the exit of combustion chamber was produced by flame with equivalence ratio of 0.649 while lowest temperature at the same spot was shown by flame with equivalence ratio of 1.125. Flames with equivalence ratio of 0.562 and 0.603, exhibit highest temperature at the distance of 395mm from the swirler exit. Flames with equivalence ratios of 0.649, 0.703, 0.803 and 0.888 exhibit highest temperature further upstream at distance of 345mm from the swirler exit. Meanwhile, flames with equivalence ratio of 0.992 and 1.125 exhibit highest temperature furthest upstream at 230mm from the swirler exit. The causes of the above phenomena have been discussed in section 6.4.3.

**Figure 6.41:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $50^\circ$  and Orifice Plate of 20mm with Downstream Injection

As shown in Figure 6.41, flame with equivalence ratio of 1.125 produces overall lowest temperature along the combustion chamber except at the ignition point where at this point, flame with equivalence ratio of 0.562 produces lowest temperature. Flames with equivalence ratios of 0.649 and 0.703 share same highest temperature at the distance of 345mm from the swirler exit. However, highest temperature at the combustion chamber exit was shown by flame with equivalence ratio of 0.649.

**Figure 6.42:** Combustion Temperature vs. Axial Distance from Swirler Exit for flames at Different Equivalence Ratios Using Swirler Vane Angle of  $60^\circ$  and Orifice Plate of 20mm with Downstream Injection

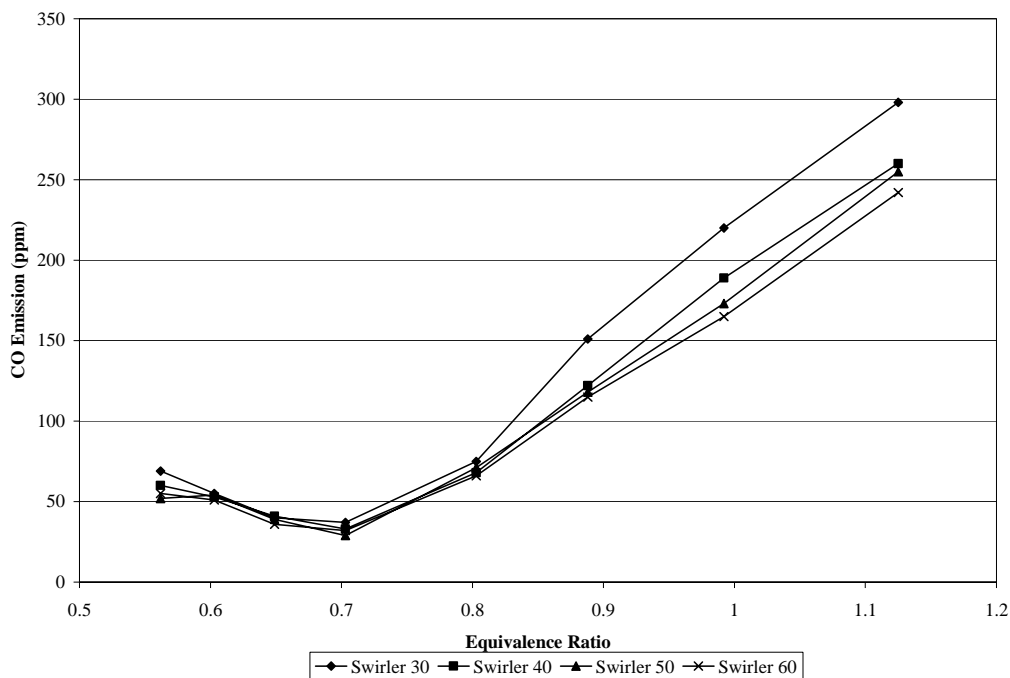

Figure 6.42 shows combustion temperature in accordance to equivalence ratio for swirler vane angle of  $60^\circ$  using orifice plate of 20mm with downstream injection. Along the combustion chamber, the fuel rich flame exhibits lowest temperature. At the distance of 345mm from the swirler exit, the lower equivalence ratio flames produce higher temperature compared to the higher equivalence ratio flames. However, flames with equivalence ratios of 0.562 and 0.603 exhibit lower temperatures compared to flame with equivalence ratios of 0.649. The highest temperature was found at the distance of 345mm by flame with equivalence ratio of 0.649. This shows that the flame speed was the highest at this equivalence ratio for current setting. Meanwhile, highest temperature at the chamber exit was shown by flame with equivalence ratio of 0.562. The configuration using orifice plate of 20mm with downstream injection shows highest temperature at equivalence ratio of 0.649 which is lower than most other downstream settings at 0.703 equivalence ratio.

### 6.3.6 Emission Investigation Using Orifice Plate of 20mm with Downstream Injection

**Figure 6.43:** NO<sub>x</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 20mm with Downstream Injection

Figure 6.43 shows NO<sub>x</sub> emission versus equivalence ratio for 4 different swirler vane angles using orifice plate of 20mm with downstream injection. NO<sub>x</sub> emission of less than 25 ppm was achieved for this setting. Swirler vane angle of 30° produced highest NO<sub>x</sub> emission for the entire equivalence ratios. The NO<sub>x</sub> emission decreased as swirler vane angle was increased to 40°. The emission was further reduced as swirler vane angle was increased to 50° and 60°. In this setting, even though, swirler vane angle of 60° generates lowest emission, the emission different between swirler vane angle 60° and 50° is only about 2 ppm at equivalence ratio of 0.803. There was only 1 ppm reduction for swirler vane angle of 40° compared to swirler vane angle of 30°. At this equivalence ratio, highest reduction occurs for swirler vane angle of 50° that is about 36 percent compared to swirler vane angle of 40°.

**Figure 6.44:** CO Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 20mm with Downstream Injection

CO emission versus equivalence ratio for 4 different swirler vane angles of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using orifice plate of 20mm with downstream injection was shown in Figure 6.44. CO emission result decreases with respect to equivalence ratio from equivalence ratio of 0.562 until 0.7, and then increases with respect to equivalence ratio from equivalence ratio of 0.7 to 1.125. Lowest CO emission and highest  $\text{NO}_x$  emission appear at equivalence ratio of 0.7 for all swirler vane angles for most of the settings. There is no significant CO emission difference between swirler vane angles of  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  for the entire equivalence ratio. This was similar for swirler vane angle of  $30^\circ$  except at fuel rich region where swirler vane angle of  $30^\circ$  shows slightly higher CO emission.

**Figure 6.45:** SO<sub>2</sub> Emission vs. Equivalence Ratio for Various Swirlers Using Orifice Plate of 20mm with Downstream Injection

SO<sub>2</sub> emission of less than 10 ppm is generated in fuel lean region below 0.8 equivalence ratio for all swirler vane angles as shown in Figure 6.45. The emission increases rapidly from the equivalence ratio of 0.7 to 1.125. SO<sub>2</sub> emission of less than 160 ppm was produced for all swirler vane angles. The emission reduction between swirler vane angles of 60° and 30° was 40 ppm that contributes about 67 percent of reduction. The decrease was small for swirler vane angle of 40° compared to swirler vane angle of 30° that is only 3 ppm. The emission was reduced about 37 percent for swirler vane angle of 50° compared to swirler vane angle of 40°. Further increase in swirler vane angle to 60° reduces the SO<sub>2</sub> emission about 49 percent. These results of 60° swirler vane angle show lowest SO<sub>2</sub> emission compared to other settings.

### 6.3.7 Temperature Profile for Various Swirlers Using Orifice Plate of 30mm with Upstream Injection at Equivalence Ratio of 0.803

**Figure 6.46:** Combustion Temperature vs. Axial Distance from Swirler Exit for Various Swirler Using Orifice Plate of 30mm with Upstream Injection at Equivalence Ratio of 0.803

Referring to Figure 6.46, combustion temperature increases with respect to axial distance from swirler exit and decreases at 230mm from swirler exit towards the combustor exit. Temperature profile for swirler vane angle of  $30^\circ$  shows lowest temperature at near the swirler exit. Meanwhile, swirler vane angle of  $60^\circ$  shows lowest temperature at the combustor exit. This is mainly because swirler vane angle of  $30^\circ$  produces longer flame compared to swirler vane angle of  $60^\circ$ . Generally, swirler vane angle of  $40^\circ$  shows highest temperature along the combustion chamber. However, higher temperature was shown by swirler vane angle of  $50^\circ$  at the combustor exit. Swirler vane angle of  $60^\circ$  produces the lowest temperature range where the range of temperature was about  $200^\circ\text{C}$  between lowest temperature and highest temperature for the swirler using orifice plate of 30mm with upstream injection.

Meanwhile, from the flame observation, swirler vane angle of  $60^\circ$  produces wider and shorter flame compared to the other swirler vane angles. Swirler vane

angle of  $30^\circ$  produces most narrow and longest flame length. All the swirler vane angles produce yellow reddish flame.

### 6.3.8 Temperature Profile for Various Swirlers Using Orifice Plate of 25mm with Upstream Injection at Equivalence Ratio of 0.803

**Figure 6.47:** Combustion Temperature vs. Axial Distance from Swirler Exit for Various Swirler Using Orifice Plate of 25mm with Upstream Injection at Equivalence Ratio of 0.803

Generally, orifice plate of 25mm produces lower combustion temperature compared to orifice plate of 30mm except for swirler vane angle of  $60^\circ$  as shown in Figure 6.47. Swirler vane angle of  $60^\circ$  shows highest combustion temperature at the flame front which is about 300mm from the swirler exit. However, combustion temperature for this setting decreases drastically since then towards the combustor exit where it shows lowest temperature at the end compared to the other swirler vane angles. Swirler vane angle of  $40^\circ$  shows lowest combustion temperature from the distance of 100mm from the swirler exit until the distance of 300mm from the swirler exit and highest combustion temperature since then towards the combustor

exit. At the flame front, swirler vane angle of  $30^\circ$  exhibit the lowest combustion temperature.

Meanwhile, from the flame observation, once again swirler vane angle of  $60^\circ$  produces wider and shorter flame length compared to the other swirler vane angles. Swirler vane angle of  $30^\circ$  produces most narrow and longest flame length. All the swirler vane angles produced yellow reddish flame. However, the flame length is shorter and wider compared to that using orifice plate of 30mm. The flame is more stable compared to orifice plate of 30mm.

### 6.3.9 Temperature Profile for Various Swirlers Using Orifice Plate of 20mm with Upstream Injection at Equivalence Ratio of 0.803

**Figure 6.48:** Combustion Temperature vs. Axial Distance from Swirler Exit for Various Swirler Using Orifice Plate of 20mm with Upstream Injection at Equivalence Ratio of 0.803

Orifice plate of 20mm produces lowest combustion temperature for all swirler vane angles with upstream injection. The temperature of lower than  $1000^\circ\text{C}$  was produced for this setting as shown in Figure 6.48. The highest temperature for

all swirler vane angles using any investigated orifice plate with upstream injection was basically falls at the distance of 230mm from the swirler exit. The major factor of this circumstance was because of narrow flame and highest flame speed at the distance of 230mm from the swirler exit. In the flame front, swirler vane angles of 30° and 40° produce almost same combustion temperature. Meanwhile, swirler vane angles of 50° and 60° produce about the same temperature in the flame front. Swirler vane angle of 60° shows lowest combustion temperature at the flame tail. Meanwhile, swirler vane angle of 30° shows highest combustion temperature at the flame tail.

Meanwhile, from the flame observation, swirler vane angle of 60° produces wider and shorter flame length compared to the other swirler vane angles. Swirler vane angle of 30° produces most narrow and longest flame length. All the swirler vane angles produce yellow flame except the swirler vane angle of 30° which produces yellow reddish flame. Yellow flame rather than yellow reddish flame indicates better fuel and air mixing. Stable flame was produced where the movement of the flame is minimized. The flame is also shorter and wider compared to the two earlier orifice plate configurations.

### 6.3.10 Temperature Profile for Various Swirlers Using Orifice Plate of 30mm with Downstream Injection at Equivalence Ratio of 0.803

**Figure 6.49:** Combustion Temperature vs. Axial Distance from Swirler Exit for Various Swirler Using Orifice Plate of 30mm with Downstream Injection at Equivalence Ratio of 0.803

Figure 6.49 shows combustion temperature as a functional of the axial distance from swirler exit. The figure shows relationship of combustion temperature between swirler vane angles of 30°, 40°, 50° and 60° using orifice plate of 30mm with downstream injection. Temperature of less than 1000°C was exhibited in this figure for all swirler vane angles indicating that thermal NO mechanism for NO<sub>x</sub> formation was prevented. Swirler vane angle of 30° produces highest temperature along the chamber. This is followed by swirler vane angles of 40° and 50° at the flame front. At the flame front, lowest temperature was exhibited by swirler vane angle of 60°. Meanwhile, swirler vane angle of 40° shows lowest temperature at the combustor exit. The highest temperature point for all swirler vane angles is shifted to the distance of about 350mm from the swirler exit using downstream injection configuration. The circumstances of these phenomena were explained in section 6.4.3. However, for swirler vane angles of 50° and 60°, highest temperature was exhibited at the distance of about 400mm from the swirler exit.

Meanwhile, from the flame observation, once again swirler vane angle of  $60^\circ$  produces better flame shape. Even though swirler vane angle of  $30^\circ$  produces longer flame, but this flame is shorter compared to that for upstream injection. A yellow flame was observed during experimental testing showing that the mixing of fuel and air was better compared to the setting with upstream injection. The flame from swirler vane angle of  $50^\circ$  shows better shape compared to flame with swirler vane angle of  $40^\circ$ . A yellow bluish flame was observed for swirler vane angles of  $50^\circ$  and  $60^\circ$ .

### 6.3.11 Temperature Profile for Various Swirlers Using Orifice Plate of 25mm with Downstream Injection at Equivalence Ratio of 0.803

**Figure 6.50:** Combustion Temperature vs. Axial Distance from Swirler Exit for Various Swirler Using Orifice Plate of 25mm with Downstream Injection at Equivalence Ratio of 0.803

Figure 6.50 shows temperature profile for swirler vane angles of  $30^\circ$ ,  $40^\circ$ ,  $50^\circ$  and  $60^\circ$  using orifice plate of 25mm with downstream injection at equivalence ratio of 0.803. Temperature of about  $400^\circ\text{C}$  was produced near the swirler exit for swirler vane angle of  $60^\circ$ . The temperature gradient is very steep for this setting where

within the next 200mm from the swirler exit, the temperature rises to 800°C. The highest temperature is exhibited at distance of 345mm from the swirler exit which is 998.8°C for swirler vane angle of 60°. The lowest temperature at the combustor exit was produced by swirler vane angle of 30° which is 816.8°C. However, the difference is small between the highest and lowest temperature at this point that is 21.7°C. Swirler vane angle of 30° produces lowest temperature along the combustion chamber except at the distance of about 350mm to 400mm from the swirler exit, where the temperature for this swirler is slightly higher than swirler vane angles of 40° and 50°. Lowest temperature was shown by swirler vane angle of 40° at this distance.

Meanwhile, from the flame observation, swirler vane angle of 30° produces short and wide flame. However, a shorter flame was produced by other swirler vane angles in this setting. Swirler vane angle of 60° produces shortest and widest flame followed by swirler vane angles of 50° and 40°. A bluish flame was observed during the experimental testing.

### 6.3.12 Temperature Profile for Various Swirlers Using Orifice Plate of 20mm with Downstream Injection at Equivalence Ratio of 0.803

**Figure 6.51:** Combustion Temperature vs. Axial Distance from Swirler Exit for Various Swirler Using Orifice Plate of 20mm with Downstream Injection at Equivalence Ratio of 0.803

For this setting, swirler vane angle of  $60^\circ$  shows lowest combustion temperature along the combustion chamber except at the distance of 10mm from the swirler exit, where swirler vane angle of  $30^\circ$  produces lowest temperature. Producing lower temperature was good in term of preventing the risk of thermal  $\text{NO}_x$  formation. However, low temperature also could be because of less homogeneous mixing of fuel and air. However, in present situation, the lower temperature was caused by uniform distribution of air and fuel mixing which reduces the flame speed at highest temperature point. This is because less homogeneous mixing of air and fuel would generate high CO emission which is contradictory with these experimental results. At the flame front, swirler vane angle of  $30^\circ$  produces lower temperature compared to swirler vane angle of  $50^\circ$ . Meanwhile, swirler vane angle of  $40^\circ$  shows highest temperature at the flame front. About 300mm from the combustor exit, temperature for swirler vane angles of  $30^\circ$  and  $40^\circ$  shifted place where swirler vane angle of  $30^\circ$  produces highest temperature among all other swirler vane angles. Once again the

highest temperature for all swirler vane angles located at distance of 345mm from swirler exit.

Meanwhile, from the flame observation, swirler vane angle of  $60^\circ$  produces the shortest and widest flame. It could be concluded that, the flame for swirler vane angle of  $60^\circ$  using orifice plate of 20mm with downstream injection was the shortest and widest compared to all other settings. Swirler vane angle of  $30^\circ$  produces longer and narrower flame in this setting. However, the flame is much shorter compared to the other settings that were discussed before. The flame was also blue in colour indicating that the best fuel and air mixing was produced by swirler vane angle of  $60^\circ$  using orifice plate of 20mm with downstream injection. Swirler vane angle of  $50^\circ$  produces shorter and wider flame compared to swirler vane angle of  $40^\circ$ .

#### **6.4 Discussion on Combustion Temperature Profile**

As shown previously, combustion temperature was highest at the middle section of the combustion chamber. Generally for swirler vane angle of  $30^\circ$ , the highest temperature point exist further downstream of the combustion chamber compared to the other swirler vane angles for all setting. This is followed by swirler vane angles of  $40^\circ$ ,  $50^\circ$  and  $60^\circ$ , respectively. The highest peak temperature for swirler vane angle of  $60^\circ$  was the nearest to the swirler exit. This shows that swirler vane angle of  $60^\circ$  produces shortest flame amongst all, meanwhile swirler vane angle of  $30^\circ$  produces longest flame amongst all. This is due to better mixing of fuel and air produced in higher swirler vane angle. Higher swirler vane angle generates bigger reverse flow zone and widen the flame angle which in turn reduce the flame length (Morcos, V.H. and Abdel-Rahim, Y.M., 1999). Besides that, swirler vane angle of  $60^\circ$  produces lowest discharge temperature compared to other swirler vane angles. This is followed by swirler vane angles of  $50^\circ$ ,  $40^\circ$  and  $30^\circ$ . This shows that bigger swirler vane angles do reduce the overall flame temperature.

Orifice plate insertion does not show any significant different on the flame length even though smaller orifice plate exhibit shorter and wider flame due to bigger

swirler pressure drop at the swirler outlet phase which maximizes the swirler outlet shear layer turbulence (Escott, N.H., 1993). However, smaller orifice plate configuration did reduce the peak temperature of the flame. Even though this does not apply for all settings, it does apply for most of the settings. Orifice plate of 30mm with upstream injection exhibit high peak temperature exceeding 1000°C for all swirler vane angles except for swirler vane angle of 60° which produces highest peak temperature of 950.1°C. Meanwhile, for upstream injection, other orifice plate configurations produce flame temperature of less than 1000°C for all swirler vane angles except for swirler vane angle of 60° with orifice plate of 25mm which shows highest peak temperature of 1010.5°C. For downstream injection, all swirler vane angles with orifice plate of 20mm and 25mm produce flame temperature of less than 1000°C. Flame temperature of more than 1000°C was exhibited for swirler vane angle of 60° with orifice plate of 25mm and 30mm. Smaller orifice plates exhibit higher flame temperature compared to the bigger ones. This was aligned with Kim's (1995) suggestion. However, in upstream injection, orifice plate of 20mm shows lower temperature than orifice plate of 25mm.

Beside these two aspects, equivalence ratio does play the key role on the flame length characteristic. Even though the peak temperature was almost the same for all equivalence ratios for a particular setting, but fuel lean equivalence ratios produce shorter flame length. This could be because of more air is present in the chamber which completes the combustion earlier compared to fuel rich equivalence ratios. Fuel rich equivalence ratios produce longest flame length because more fuel and less air exist in the combustion chamber forces the flame to increase its length to complete its combustion outside the chamber. At fuel lean equivalence ratio below 0.8, the flame was short and narrow. The flame then gets wider with gradual increase in flame length with the increase of equivalence ratio. Once the flame reaches its peak temperature limit, further increase of equivalence ratio shows decrease of flame angle and rapid increase in flame length.

Besides that, downstream injection also shows shorter flame length compared to upstream injection. Downstream injection exhibit lower peak temperature compared to upstream injection. More complete combustion was exhibited with downstream injection rather than upstream injection as the flame produced was blue

in colour shows fuel was burned completely. Yellow and reddish flame as exhibited in upstream injection indicated that there are some fuel was left unburned. Wider flame was also exhibited with downstream injection. This might be because of downstream injection provides steeper boundary of velocity gradients and higher intensity turbulence between the forward flow and the reverse flow zone that promotes high entrainment rates and rapid mixing between the fuel and air.

However, all variation that has been studied does share the same factor to improve both fuel atomization process and mixing between fuel and air, causing intensive combustion with short flame.

## **6.5 Comparison on Varying Orifice Plate Diameter and Injection Position**

Orifice plate of 20mm with downstream injection produces lowest emissions compared to the other settings. The  $\text{NO}_x$  emission was reduced about 17 percent for orifice plate of 20mm with upstream injection compared to orifice plate of 25mm with same injection position. Orifice plate of 30mm with upstream injection exhibit lower  $\text{NO}_x$  emission compared to orifice plate of 25mm with upstream injection at equivalence ratio of 0.803. However, this result does not reflect the overall comparison.  $\text{NO}_x$  emission was higher with orifice plate of 30mm compared to the orifice plate 25mm for all of the equivalence ratios except at equivalence ratios of 0.803 and 0.888.  $\text{NO}_x$  emission at equivalence ratio of 0.888 was the same for both orifice plates.

CO emission was reduced about 23 percent and 29 percent for orifice plates of 25mm and 20mm with upstream injection respectively compared to orifice plate of 30mm with upstream injection. The CO emission reduction of less than 10ppm was obtained between orifice plate of 25mm and 20mm with upstream injection.

Same pattern of emission results was shown in  $\text{SO}_2$  emission where orifice plate of 30mm exhibits highest emission while orifice plate of 20mm exhibits lowest emission in upstream injection position. Orifice plate of 30mm with upstream

injection produces 71 ppm of SO<sub>2</sub> emission, which was reduced to 66 ppm when orifice plate of 25mm with upstream injection was used. The emission was further reduced about 24 percent when replaced with orifice plate of 20mm at the same injection point.

In downstream injection, NO<sub>x</sub> emission was reduced about 24 percent for orifice plate of 25mm compared to orifice plate of 30mm. Meanwhile, NO<sub>x</sub> emission reduction about 59 percent was achieved for orifice plate of 20mm compared to orifice plate of 30mm. Lowest NO<sub>x</sub> emission was achieved by this setting that is 7 ppm.

CO emission also shows emission improvement when smaller orifice plate was used. CO emission of less than 100 ppm was obtained using orifice plates of 25mm and 20mm for both injection positions. CO emission decreased about 33 percent for orifice plate of 25mm with downstream injection compared to orifice plate of 30mm with downstream injection. Further decrease in orifice plate diameter to 20mm reduced CO emission to 66 ppm.

Meanwhile, SO<sub>2</sub> emission in downstream injection shows 2 ppm rise in emission for orifice plate of 25mm compared to orifice plate of 30mm at equivalence ratio of 0.803. This was apparent for all equivalence ratios. Further decrease in orifice plate diameter increases the SO<sub>2</sub> emission. In downstream injection, highest SO<sub>2</sub> emission was shown by orifice plate of 20mm that is 22 ppm.

Meanwhile from the point of injection position, for orifice plate of 30mm, CO emission and SO<sub>2</sub> emission show reduction in emission results while NO<sub>x</sub> emission shows rise in emission results. When using orifice plate of 30mm, CO emission and SO<sub>2</sub> decrease about 16 percent and 89 percent respectively for downstream injection compared to upstream injection. The NO<sub>x</sub> emission rise was 4 ppm for orifice plate of 30mm with downstream injection compared to orifice plate of 30mm with upstream injection. However, NO<sub>x</sub> emission actually decreases for all other equivalence ratios for orifice plate of 30mm with downstream injection compared to orifice plate of 30mm with upstream injection except for equivalence ratio of 0.803.

NO<sub>x</sub> emission was also reduced about 28 percent for orifice plate of 25mm with downstream injection compared to orifice plate of 25mm with upstream injection. The CO emission for this orifice plate was almost the same where upstream injection configuration shows CO emission of 90 ppm while downstream injection configuration shows higher 7 ppm at 97 ppm of CO emission. At equivalence ratios from 0.649 to 0.803, orifice plate of 25mm with upstream injection produces lower CO emission compared to orifice plate of 25mm with downstream injection. Meanwhile SO<sub>2</sub> emission dropped about 85 percent for orifice plate of 25mm with downstream injection compared to orifice plate of 25mm with upstream injection. The SO<sub>2</sub> emission different between these two settings was 56 ppm.

Downstream injection configuration shows lower NO<sub>x</sub> emission compared to upstream injection configuration for orifice plate of 20mm. NO<sub>x</sub> emission was reduced about 53 percent for orifice plate of 20mm with downstream injection compared to the upstream injection. CO emission was reduced to 66 ppm from 88 ppm, which is about 25 percent reduction for downstream injection compared to upstream injection for orifice plate of 20mm. Meanwhile, SO<sub>2</sub> emission was reduced about 56 percent for orifice plate of 20mm downstream injection compared to orifice plate of 20mm with upstream injection.

## **CHAPTER VII**

### **CONCLUSION AND RECOMMENDATION FOR FUTURE WORK**

#### **7.1 General Conclusions**

Swirler could support combustion over a wide range of operating conditions through the generation of central recirculation zone that is formed when the vortex breakdown occur. Turbulence effect in the combustion chamber also could be generated by increasing the blockage or pressure drop of the swirler (Kim, M.N., 1995). Swirlers produce rapid fuel and air mixing which also creates turbulence effect in the combustion chamber. Swirling flow induces a highly turbulent recirculation zone which stabilizes the flame resulting in better mixing and combustion. Another effect of swirl is to decrease the velocity gradient at the exit of burner thus causing a faster decay of the velocities in the flow field with increase the swirl flow (Kim, M.N., 1995). Besides that, swirl reduces both flame lengths and flame attachment lengths and consequently shortens the combustion chamber length necessary for complete combustion. Swirl also promotes high combustion efficiency, easy ignition, reactant recirculation zone residence time, pollutant optimisation potential, widened stability and blow off (Escott, N.H. 1993). Besides that, recirculation vortex produced by swirl acts as a heat source forcing combustion product to move upstream and mix with the partially premixed reactant. This increases the amount of contact between fuel, air and hot combustion products.

Orifice plate, on the other hand, reduces the pressure at the swirler outlet phase, so that the swirler outlet shear layer turbulence was maximized to assist in mixing of fuel and air. Outlet orifice or swirler shroud also creates the flow pressure loss at the outlet plane rather than in the vane passage which maximizes the shear layer turbulence. Orifice plate insertion also increases the total pressure loss and thus for a specific orifice plate the airflow was reduced with decreasing orifice diameter. Smaller orifice sizes enhance better mixing due to improved upstream mixing. Beside that, orifice plate insertion helps to prevent fuel from entraining into the corner recirculation zone that will create local rich zone thus generates lower  $\text{NO}_x$  emission by eliminating locally rich region (Al-Kabie, H.S., 1989). Locally rich region tends to generate locally high  $\text{NO}_x$  emission that contributes to overall high  $\text{NO}_x$  emission. Smaller orifice plates outlet do increase the velocity of the air and fuel at the swirler shroud thus reduce the risk of flashback. However, this velocity should not be too high as lift off could occur and cause blow off of combustion. The increase in velocity also would increase the Reynolds number which increases the strength of turbulence effect and thus reduces the combustions residence time. Other than that, from the aerodynamic factor, air and fuel mixing rate increases as the pressure drop in the swirler outlet increases (Escott, N.H., 1993).

Meanwhile, proper injection positions assist in more complete combustion. Better mixing of fuel and air was enhanced in the downstream injection as the fuel, which enters the combustor, was in turbulence flow. Meanwhile in upstream injection, the fuel goes through a laminar flow before changing to turbulence flow. Downstream injection provide steeper boundary of velocity gradients and higher intensity turbulence between the forward flow and the reverse flow zone, that promotes high entrainment rates and rapid mixing between the fuel and air. Due to high entrainment and increased mixedness of the jets, flame length was reduced while increasing the diameter of the flame. This resulted in a more complete combustion (Escott, N.H., 1993).

## 7.2 Conclusion on Combustion Performance

From the results obtained, orifice plate of 20mm produced best emission results compared to orifice plates of 25mm and 30mm. This proved that orifice plate does help to create the swirler pressure loss at the swirler outlet so that the swirler outlet shear layer turbulence was maximized to assist in mixing of fuel and air. Smaller orifice plate produces better emission results compared to the larger one. Larger orifice plates produces higher local rich region near the fuel injector outlet, which in turn generate more emissions. Smaller orifice helps to prevent fuel from entraining into the corner recirculation zone that will create local rich zone (Kim, M. N., 1995). Small orifice plate size enhances better mixing than the larger ones due to improved upstream mixing. This once again could be attributed to good mixing resulted from the smaller area that generates higher turbulence due to increased swirling of the fuel and air mixture prior to combustion.

Besides the orifice plate effects, varying swirler vane angle also does helps in mixing the fuel and air thoroughly prior to ignition and hence reduces emissions. Swirler vane angle of  $60^\circ$  exhibit better emission results compared to other swirler vane angles. Increasing the swirler vane angles increases the swirl intensity that helps in promoting the mixing of fuel and air. Besides that, it also increases the reverse flow of hot burned gases back into the burner. The high temperature of this product serves as an energy source for preheating and ignition assistance for the incoming fresh combustible mixture (Al-Kabie, H.S., 1989). The process goes into a cycle and this keep the flame from extinguishing or having to ignite continuously. Varying swirler vane angle does vary its swirl strength which was expressed in terms of swirl number. One way of increasing the swirl number is by increasing the vane angle of the swirler. Increasing swirler vane angle from  $30^\circ$  to  $60^\circ$  would increase the swirl number from 0.706 to 2.534 hence increases the swirl intensity of the flow which increases the recirculation zone length and diameter. Longer recirculation zone provides flame stability and reduction in emissions. Yet, once the recirculation zone achieved a certain length, further increased in swirl number will not have much effect on the length of recirculation zone. At this point it is considered that the central recirculation zone has been well established. However, most of the plotted

graphs do agree with Alkabi's (1989) view stating that there is no significant effect on  $\text{NO}_x$  emissions by varying the vane angle from  $20^\circ$  to  $60^\circ$ .

Swirl has several important effects on combustion system. Swirler increases the blockage or pressure drop in the combustion chamber. This pressure drop generates turbulence, which supply rapid fuel and air mixing to promote the mixing. Turbulence energy is created from pressure energy dissipated downstream of the stabilizer. The most important effect of swirl in combustion process is that it improves flame stability and extends flammability limit. From the results, higher pressure drop was created by swirler vane angle of  $60^\circ$  which gives most stable flame. This is followed by swirler vane angles of  $50^\circ$ ,  $40^\circ$  and  $30^\circ$ . Swirler vane angle of  $30^\circ$  has bigger vane opening which reduces its swirl velocity. Low swirl velocity generates less swirler pressure drop in the chamber (Kim, M.N., 1995).

When air is tangentially introduced into the combustion chamber, it is forced to change its path, which contributes to the formation of swirling flow. Low pressure in the core centre of the swirling flow is retrieving the jet flow in the combustion chamber and thus, produces the not-so-good slope of axial pressure. Meanwhile at the optimum swirler angle, the swirl finds its own direction and as a result, swirl vortex is formed (Nazri, 1997).

The downstream injection shows better emissions results compared to the upstream injection. This is because better mixing of fuel and air was enhanced in the downstream injection as the fuel, which enters the combustor, were in turbulence flow. Meanwhile in upstream injection, the fuel goes through a laminar flow before changing to turbulence flow. Downstream injection provide steeper boundary of velocity gradients and higher intensity turbulence between the forward flow and the reverse flow zone that promotes high entrainment rates and rapid mixing between the fuel and air. Due to high entrainment and increased homogeneous mixing of the jets, flame length was reduced while increasing the diameter of the flame. This resulted in a more complete combustion.

In low fuel lean region, the content of carbon monoxide emission decreases with the increase of equivalence ratio meanwhile the  $\text{NO}_x$  emission rise with the

increase of equivalence ratio. This was anticipated due to the fact that any measure of decreasing  $\text{NO}_x$  will tend to increase CO since both emissions were on the different side of the balance.

As for conclusion, swirler vane angle of  $60^\circ$  using orifice plate of 20mm with downstream injection produces the lowest emissions results compared to other settings in this project. Meanwhile, swirler vane angle of  $30^\circ$  using orifice plate of 30mm with upstream injection produces the highest emission results. Higher swirler vane angles with smaller orifice plate configurations show lower emission results. Meanwhile the downstream injection produces lower emission compared to the upstream injection setting.

### **7.3 Conclusions on Emission Results**

Even though three pollutants i.e.  $\text{NO}_x$ , CO and  $\text{SO}_2$  were studied in this project,  $\text{NO}_x$  emission was the main pollutant that needs to be reduced. CO emission could be minimized by homogeneous mixing of the fuel and air.

The relation between the combustion performance to the swirlers, orifice plates and injection positions has been studied in the present work. All other operating parameters were kept constant such as fuel pressure, swirling air pressure, injection air pressure, injection air flow rate and fuel flow rate. Only swirling air flow rate was varied.

Even though  $\text{NO}_x$  emission shown by swirler vane angle of  $30^\circ$  using orifice plate of 30mm with upstream injection was low at equivalence ratio of 0.803, for overall, this swirler vane angle produces highest emissions compared to the other setting in the present work. Highest  $\text{NO}_x$  emissions shown by this setting is 61 ppm at equivalence ratio of 0.603. Lowest  $\text{NO}_x$  emission was shown by swirler vane angle of  $60^\circ$  using orifice plate of 20mm with downstream injection. As mentioned earlier, higher swirler vane angle with smaller orifice plate size exhibit better emission

results. Meanwhile downstream injection produces lower emission results compared to upstream injection.

#### **7.4 Conclusions on Temperature Profiles**

The base emissions formation in the present work is Prompt NO. Thermal NO was prevented as the combustion temperature is below 1300°C. Fuel NO formation is also prevented as the fuel used in this study is not nitrogen bound fuel.

Higher swirler vane angles with smaller orifice plates produce shorter and wider flame. Higher swirler vane angle with smaller orifice plate reduces flame length that is necessary for complete combustion and generates bigger reverse flow zone which widens the flame diameter (Morcos, V.H. and Abdel-Rahim, Y.M., 1999). Meanwhile smaller orifice, due to improved upstream injection and maximized shear layer turbulence, widens the flame diameter. Wider flame was also exhibited with downstream injection. This is because downstream injection provides steeper boundary of velocity gradients and higher intensity turbulence between the forward flow and the reverse flow zone that promotes high entrainment rates and rapid mixing between the fuel and air. Upstream injection configuration produces yellowish flames indicating that there is some fuel left unburned and incomplete combustion. Meanwhile downstream injection configuration produces bluish flames indicating more complete combustion occurs in this phase. The highest temperature point or peak temperature occurs further downstream of combustion chamber for orifice plate of 30° compared to other swirler vane angles. Peak temperature for swirler vane angle of 60° was the nearest to swirler outlet. Smaller orifice plate also does reduce the peak temperature thus reduce the NO<sub>x</sub> emission. NO<sub>x</sub> emission increases parallel with temperature rise.

## 7.5 Recommendation for Future Work

The present work shows higher swirler vane angle produces better emission results. However, past researchers do agree that there is an optimum swirler vane setting where further increase in swirler vane angle increases the emissions. More swirler vane angles should be studied to investigate this optimum setting such as  $70^\circ$  and  $80^\circ$ . Besides that, more precise swirler vane angle degree should take into consideration. Rather than studies between swirler angle of  $50^\circ$  and  $60^\circ$ , swirler vane angles of  $51^\circ$ ,  $52^\circ$ ,  $58^\circ$ ,  $59^\circ$  should also be considered to produce optimum swirler vane setting. Besides that, varying the swirler vane depth would also provide some extra advantages on emission reduction.

Meanwhile, from the injection mode, present work employs a single 1mm hole. Smaller diameter holes should also be considered to produce smaller fuel droplet and atomization of fuel could easily be established. Besides that, comparison between single and multiple injector holes could also be studied. Wall injection and vane passage injection may also be considered in the future work.

The measurement of local velocity profiles and the turbulent intensities of the combustor flow field especially that near the swirler outlet will add crucial information to the present experimental and theoretical results.

## Appendix S Combustion Calculation

### Basic Combustion Chemical Formulation

where:

$a_1, b_1, c_1, d_1$  = molar coefficients

$a, b, c, d$  = fuel components

### Combustion Calculation of Fuel Air Equivalence Ratio for Diesel Fuel

Stoichiometric fuel to air can be calculated with:

$$FAR_{\text{stoi}} = 1 \text{ mole of fuel} / a_1(O_2 + 3.76N_2)$$

### Flow Rate

1 CFM (Cubic Foot per Minute) = 28.317 LPM (Liter per Minute)

$$V_a = V_{\text{as}} + V_{\text{ai}}$$

$$m_a = \rho_a V_a$$

$$m_f = \rho_f V_f$$

**Appendix S**  
**Combustion Calculation (cont'd)**

**Air Fuel Ratio (AFR) & Fuel Air Ratio (FAR)**

$$\text{AFR}_{\text{act}} = m_a / m_f$$

$$\text{FAR}_{\text{act}} = m_f / m_a$$

$$\text{AFR}_{\text{stoi}} = 14.5$$

$$\text{FAR}_{\text{stoi}} = 0.0689$$

**Equivalence Ratio Based on Fuel Air Ratio ( $\Phi$ -FAR)**

$$\Phi\text{-FAR} = \text{FAR}_{\text{act}} / \text{FAR}_{\text{stoi}}$$

Air Fuel Ratios for Various Fuels

Fuel	Chemical Formula	HHV [kJ/kg] [kg air/kg fuel]	Air/Fuel Ratio Stoichiometric	Fuel/Air Stoichiometric
Methane	CH <sub>4</sub>	55,500	17.2	0.05814
Propane	C <sub>3</sub> H <sub>8</sub>	50,300	15.6	0.06410
Octane	C <sub>8</sub> H <sub>18</sub>	47,900	15.1	0.06623
Methanol	CH <sub>3</sub> OH	22,700	6.5	0.15385
Ethanol	C <sub>2</sub> H <sub>5</sub> OH	29,700	8.99	0.11123
Hydrogen	H <sub>2</sub>	141,600	27.2	0.03677
Gasoline	C <sub>8</sub> H <sub>15</sub>	47,300	14.6	0.06849
Diesel	C <sub>12.5</sub> H <sub>22.2</sub>	44,800	14.5	0.06897

**Appendix S**  
**Combustion Calculation (cont'd)**

**Equivalence Ratio Calculation (Example:  $\phi = 0.703$ )**

$$\dot{v}_f = 50 \text{ ml} / \text{min}$$

$$\dot{v}_f = 0.000833 \text{ l} / \text{s}$$

$$\dot{v}_f = \underline{\underline{0.000000833 \text{ kg} / \text{s}}}$$

$$\dot{v}_a = \dot{v}_{as} + \dot{v}_{ai}$$

$$\dot{v}_a = (509.706 + 170) \text{ l} / \text{min}$$

$$\dot{v}_a = (679.706 / 60) \text{ l} / \text{s}$$

$$\dot{v}_a = 11.328433 \text{ l} / \text{s}$$

$$\dot{v}_a = \underline{\underline{0.011328433 \text{ m}^3 / \text{s}}}$$

$$\rho_f = \frac{\dot{m}_f}{\dot{v}_f}$$

$$\dot{m}_f = \rho_f \dot{v}_f$$

$$\dot{m}_f = (810)(8.333 \times 10^{-7}) \text{ kg} / \text{s}$$

$$\dot{m}_f = 0.000675 \text{ kg} / \text{s}$$

$$\dot{m}_f = \underline{\underline{6.75 \times 10^{-4} \text{ kg} / \text{s}}}$$

$$\rho_a = \frac{\dot{m}_a}{\dot{v}_a}$$

$$\dot{m}_a = \rho_a \dot{v}_a$$

$$\dot{m}_a = (1.229)(0.011328433) \text{ kg} / \text{s}$$

$$\dot{m}_a = \underline{\underline{0.013923 \text{ kg} / \text{s}}}$$

$$AFR_{act} = \frac{\dot{m}_a}{\dot{m}_f} = \frac{0.013923 \text{ kg} / \text{s}}{6.75 \times 10^{-4} \text{ kg} / \text{s}} = \underline{\underline{20.626}}$$

$$AFR_{stoi} = 14.5$$

$$FAR_{stoi} = \frac{1}{14.5} = \underline{\underline{0.06897}}$$

$$FAR_{act} = \frac{1}{AFR} = \frac{1}{20.626} = \underline{\underline{0.04848}}$$

$$\phi = \frac{FAR_{act}}{FAR_{stoi}} = \frac{0.04848}{0.06897} = \underline{\underline{0.703}}$$
