

## CHAPTER 1

### INTRODUCTION

#### 1.1 Overview

There are many methods used in pumping process. Basically, for gas laser or semiconductor laser it used electrical injection as pumping method. Most solid state lasers are pumped with optical sources (Noriah, 2002). The goal in designing optical pumps for solid state laser is to match the output spectrum of the optical pump with that of laser pump bands. Optical pump sources can be divided into two broad categories. One category is black and greybody radiators, of which filament lamps are the best example. The other category is pump sources with line emission spectra, of which semiconductor lasers are the best example (Kuhn, 1998). Noble gas discharge lamps are compromised between blackbody radiators and line sources. They have significant blackbody component generated by recombination radiation from gas ions capturing electrons into bound states (free-bound) and from Bremstahlung radiation. Noble gas discharge lamps are typically designed so that the plasma completely fills the lamp.

Flashlamp excitation is an attractive method to initiate laser of lasing media (Winstanley, 1997). The first demonstration of laser action by Maiman was achieved in 1960 by using ruby laser, a crystalline solid system where flashlamp was used as

pumping source (Hecht, 1991). The flashlamp-pumped solid-state laser is now by far the most common pulsed laser system in the world with neodymium ions either in crystal or in glass as the preferred lasing medium (Shaw, 1997).

Pulsed flashlamps, particularly xenon filled flashlamps are used in variety of application. Besides used as pumping sources in laser application, there are many others application of flashlamp. These include light source for flash photography (Elloumi *et al*, 2004), copying, optical detection and optical ranging applications, in cosmetology, dermatology and other medical applications (Inochkin *et al*, 2004).

Ultraviolet light (UV) emitted by medium and high power flashlamp has been very useful tool for drinking-water treatment. Intense peak power associated with microsecond pulses of ultraviolet light generated by inert gas (xenon, krypton) flashlamps appears effective tool, against a broad range of pathogens, including *Cryptosporidium and Giardia* (Ganesh *et al*, 2003).

For the past few years, revolutionary new techniques in medical and aesthetic applications have been developed and they are taking the industry by storm. These techniques referred to as Intense Pulsed Light (IPL<sup>TM\*</sup>), Variable Pulsed Light (VPL), Controlled Pulsed Light (CPL), or Intense Flash Light (IFL) are essentially the same. The systems harness the energy from a pulsed flashlamp and deliver it directly to the skin. Thousands of systems are currently operating in Japan and Europe, and the Federal Drug Administration (FDA) has cleared them for use in the USA. This technique is providing highly effective in several treatment area (Attwood and Mehlmann, 2004). These include hair removal, skin rejuvenation, medical skin treatment and acne treatment.

## 1.2 Flashlamp Driver Circuit

Studies of triggering flashlamp as pumping sources have been investigated by many previous researchers. Thus, various methods and patterns of xenon flashlamp drivers have been designed.

Several generations of discharge circuit exists for driving flashlamp. The original discharge circuits used an in-line trigger transformer or a trigger coil on the lamp to initiate conduction. A series capacitor-inductor discharge would then occur to deliver the energy into the lamp. This circuits whilst very simple. Furthermore, has relatively high jitter between trigger and laser pulse and also reduces lamp lifetime. However, it is still used today for limited low repetition rate applications.

In order to improve the driver, the second generation of discharge circuits use an active simmer supply, which triggers lamp into conduction and keeps the lamp in conduction with a few hundred milli-ampere current flows through it. A semiconductor-switching device, such as a thyristor, can then be used to control the discharge into the lamp. This enables repetitive pulsed operation of the lamp. Jitter and lifetime are much improved and the circuit works well for most application.

The latest and third generation for discharge technologies is the use of an opening and closing switch, such as an IGBT in combination with a large capacitor bank. The energy storage must be greater than that to be delivered into the lamp. This gives a highly flexible technology, where both the pulse energy and pulse length can be controlled independently. Repetition rates of many kilohertz are possible and many different applications can be tackled by the same circuit implementation (Greenwood and Miler, 1999 )

Study of the designing single mesh circuit for driving xenon flashlamp was presented by Markiewicz and Emmet (1966). This single mesh circuit has been found accurate and useful. Pettifer *et al* (1975) reported a reliable 60 kV flashlamp triggering system. The triggering system has proved to be an efficient and reliable unit for simultaneously triggering a pair of heavy walled, water cooled quartz flashlamp. Recently, in 1998 a zero-current switching resonant converter as a power supply of a pulsed Nd:YAG laser was adopted to control the laser power density. This power supply was designed and fabricated suitable for the high frequency range and to reduce switching loss and noises (Kim *et al*, 1998). A new method of sequential charge and discharge circuit (SCADC) was proposed by Hong *et al* (1999). The power supply is composed of low frequency capacitors instead of very expensive high frequency capacitors. This method have been designed and fabricated based on a cheap and simple power supply.

Kim *et al* (2001) have proposed a new power supply for pulsed Nd:YAG laser adopting zero crossing control (ZCC) method which is simple and compact in design. In this power supply, SCR was turned on at zero point of input AC voltage by the method of zero crossing control (ZCC). In 2002, a new real time multi-discharge method (RTMD) was reported. This method uses real-time one-chip microcomputer that can turn on the flashlamp with a precision of up to  $1\mu\text{s}$  and thus can create diverse pulse shapes and strength, in addition to longer pulse (Hong *et al*, 2002).

A flashlamp driver for medical laser system was reported by McCarthy *et al* (2003). This driver circuit was employed IGBT device for power switching and use microprocessor in order to control laser pulse width. In 2004, Inochikin *et al* reported a power supply or driver circuit for a pulsed flashlamp. A high-speed semiconductor switch was employed in order to turn on and off of the flashlamp by a suitable control. DC simmer current source was connected across flashlamp to maintain discharge in the flashlamp.

### 1.3 Comparison of Rare-Gas Flashlamp

Rare gas is also known as noble gas. This noble gas is in Group 8A in the periodic list table. They include neon, argon, krypton, xenon and radon (David, 1982). It was found that in the past few years there has been increased interest in rare gas flashlamp, particularly with respect to their application in solid-state laser pumping and in high intensity illumination for photographic work. Substantially programs by a number of people have been carried out to investigate the characteristics of flashlamp.

Oliver and Barnes (1969) presented data on the spectral emission characteristics of xenon, krypton, argon and neon in the region where the emission line spectra make up a substantial portion of energy. From the spectra data in terms of both output power and emitted quanta, it was show that xenon is the most efficient of all the rare gases, a fact which has been reported previously by Barnes (1964).

Study of rare gas pumping efficiencies for Neodymium laser was reported in 1969 by Oliver and Barnes. The investigation was presented on the comparative pumping efficiencies of xenon, argon and krypton flashlamp. The results obtained confirm that krypton can be more efficient than xenon for driving Neodymium laser when run at low current density. Nevertheless, at high drive levels, xenon is superior to all the rare gases.

Fountain *et al* (1970) presented a study of comparison of Krypton and Xenon flashlamp for Nd:YAG laser. As demonstrated previously by Oliver and Barnes (1969), Krypton lamp was found generally superior to xenon for pumping Nd:YAG laser except at high current densities.

## **1.4 Problem Statement**

A flashlamp driver is the most important part in a solid state laser system. It is used as a pump source for laser material. This study is the initial stage to develop a flashlamp driver circuit for optical pumping. Hence, this driver can or will be used as a reference to develop a driver circuit that can be used as a pump source in the future.

## **1.5 Objective**

The main objective of this study is to develop a xenon flashlamp driver using PIC16F84A microcontroller and characterize the xenon flashlamp output. The use of PIC16F84A microcontroller is as a control element.

## **1.6 Scope**

In this study, a programmable flashlamp driver circuit was developed. Programmability is provided by a PIC16F84 microcontroller. The flashlamp driver used a series injection trigger mode as a triggering circuit. The current setup allows the flashlamp to operate in single shot. A Rogowski coil was used to detect the pulse current waveform. Xenon flashlight output is then recorded using a CCD laser beam profile and analyzed by using imaging software. A photodiode was employed to detect the output of the flash light.

## 1.7 Thesis Outline

This thesis is divided into eight chapters. In the first chapter, it reviews some of previous research on the development of flashlamp driver, and the application of the xenon flashlamp in various field of research.

Chapter 2 reviews the characteristics of the xenon flashlamp including the lamp design, optical and electrical characteristics of the lamp. Besides, the basic of the flashlamp driver, this chapter also discusses and the mode of triggering the mechanism of breakdown in gaseous.

Chapter 3 explains about the experimental methods and the techniques used in development flashlamp driver. This includes a series injection triggering technique and image processing software. A Rogowski coil is used to detect the current curve during the discharge. The calibration of a high voltage power supply that is employed in the system is described in Chapter 4.

The development of pulse generator using PIC16f84A microcontroller, which is interfaced to the personal computer using RS232 lines driver is discussed in chapter 5. This generator acts like a control element for the flashlamp driver. The development of flashlamp driver circuit is covered in Chapter 6. Series injection triggering mode was employed to trigger a U-shape xenon flashlamp. The pulse current during the discharge time was measured. The relation of the pulse current and peak power during the discharge time due to the capacitance value or input energy is also discussed.

The characteristic of flashlamp output is enlightened in chapter 7. The bandwidth of the flashlamp pulse at FWHM was measured using the IPL10050 photodiode. Plasma spectral gradient induced by xenon flashlamp was recorded with the aid of CCD Laser Profiler.

Finally, the conclusions of the project are noted in Chapter 8. These provide with the summarization of the whole project and also problems arisen during the period of study. Finally, a few proposal are suggested for future study.
