26 **Abstract**

27 Stable isotope and fatty acid analyses were used to study carbon sources for animals in a  
28 submerged plant bed. Epiphytes growing on *Potamogeton perfoliatus*, sand microflora, and  
29 alder leaves were the most important carbon sources. The most abundant macrophyte, *P.*  
30 *perfoliatus* was unimportant as a food source. Modelling (IsoSource) showed that epiphytes  
31 were the most important food source for the most abundant benthic invertebrates, the isopod  
32 *Asellus aquaticus* (annual mean contribution 64%), the amphipod *Gammarus pulex* (66%),  
33 and the gastropod *Potamopyrgus antipodarum* (83%). The mean annual contributions of sand  
34 microflora were respectively 21, 19, and 9% and of alder leaves, 15, 15, and 8% for these  
35 three species. The relative importance of carbon sources varied seasonally. The relative  
36 contribution of epiphytes was lowest for all three grazer species in July: *A. aquaticus* 38%, *G.*  
37 *pulex* 43%, and *P. antipodarum* 42%. . A decline in epiphyte biomass in summer may have  
38 caused this switch to less attractive food sources. *P. perfoliatus* provided habitat and shelter  
39 for consumers, but food was mainly supplied indirectly by providing space for attached  
40 epiphytes, which are fast-growing and provide a highly nutritious food source.

52 **Introduction**

53 Shallow nutrient poor lakes dominated by aquatic plants are species-rich with complex  
54 structure and food webs (Jeppesen et al. 1997). In contrast to nutrient rich plankton-  
55 dominated lakes, nutrient poor lakes have a higher diversity of carbon sources for their fauna:  
56 the submerged plants, attached epiphytes, sand microflora, allochthonous material such as  
57 leaves, and phytoplankton. Under extreme nutrient conditions only one primary producer  
58 community – macrophytes or phytoplankton – is expected to dominate a lake ecosystem, but  
59 within a range of intermediate nutrient levels alternating stable states are possible (Peckham  
60 et al. 2006). Fauna associated with submerged plants includes isopods, amphipods, crayfish,  
61 gastropods, various insect larvae, and small or juvenile fishes (Jeppesen et al. 1997). The food  
62 web is often characterised by omnivory and a lack of dietary specialisation (Jones and  
63 Waldron 2003). The links among epiphytes, grazing invertebrates, and fish seem to be  
64 important in structuring these systems (Jones et al. 2002). Epiphytes on submerged plants  
65 provide food for grazing invertebrates, which, by removing dense accumulations of epiphytes,  
66 release macrophytes from competition for light and nutrients and facilitate their growth and  
67 survival (Brönmark 1994; Hughes et al. 2004; Jaschinski and Sommer 2008).

68 Our detailed knowledge of the effects of plant-associated invertebrates in lakes is, however,  
69 limited. Most studies of periphyton and grazing in freshwater systems have concentrated on  
70 periphyton growing on stones or sediment (see Feminella and Hawkins 1995 for review). The  
71 existing studies on epiphyte grazing suggest that grazing plant-associated invertebrate species  
72 can control epiphyte accumulation (Cattaneo and Kalff 1980; Jones et al. 2002).

73 Past research suggests that epiphytic algae (mostly small filamentous green algae and  
74 diatoms) may be important carbon sources in these communities (Underwood and Thomas  
75 1990; James et al. 2000a; Jones and Waldron 2003; Hadwen and Bunn 2005). Macrophytes  
76 make the greatest contribution to the organic carbon pool in the littoral zones of these lakes,  
77 but may not be direct food sources for animals (Keough et al. 1996; Hecky and Hesslein

78 1995). The importance of periphyton/benthic productivity compared to pelagic productivity  
79 depends on the size and shape of the lake and on nutrient and light availability (Vadeboncoeur  
80 et al. 2008). A review on 193 studies showed that benthic productivity constituted on average  
81 46% of whole-lake productivity, and that benthic and pelagic food webs can be strongly  
82 linked (Vadeboncoeur et al. 2002).

83 Analytical tools, such as stable carbon and nitrogen isotope, and fatty acid analyses, may add  
84 detail to these generalisations. (Desvillettes et al. 1997; James et al. 2000b; Jones and Waldron  
85 2003; Hadwen and Bunn; 2005; Jaschinski et al. 2008a). The fractionation of  $\delta^{13}\text{C}$  is though  
86 to be low – maximally 1‰ per trophic level – and  $\delta^{13}\text{C}$  is therefore useful to identify different  
87 carbon sources. The  $\delta^{15}\text{N}$  content is enriched by 3 to 4‰ per trophic level on average and can  
88 be used to construct food webs (Eggers and Jones 2000). Fatty acid analysis can trace food  
89 sources in aquatic food webs because specific fatty acids are conserved in structure (Lee et al.  
90 1971; Brett et al. 2006). “Indicator” fatty acids, specific to diatoms, dinoflagellates or aerobic  
91 and anaerobic bacteria can be used as markers (Viso and Marty 1993; Desvillettes et al. 1997).  
92 Fungi, which provide an important link between detritus and invertebrates, might be traced  
93 indirectly by 18:1 $\omega$ 9 and 18:2 $\omega$ 6. These fatty acids originate from plant detritus. The strong  
94 correlation with ergosterol (a proxy for fungal biomass) supports the use as indicator fatty  
95 acid for fungi (Arts and Wainman 1999; Frostegård and Bååth 1996, Wurzbacher et al. 2010).  
96 We tested the hypothesis that epiphytes growing on *Potamogeton perfoliatus* L.were the most  
97 important primary source of organic matter for animals in a lake and we used stable isotope  
98 and fatty acid analyses to do this.

99

101

102

103 **Methods**

104 Study site

105 The study was carried out from May to September 2003. Field work began when *P.*  
106 *perfoliatus* appeared in spring, and ended when the plants started to senescence. All samples  
107 were obtained from Schluensee in north Germany (54° 11' 24" N, 10° 28' 12" E). The lake is  
108 small (1.27 km<sup>2</sup>), mostly shallow with one deep depression (45 m) and is surrounded by alder  
109 and willow trees. *P. perfoliatus* is the dominant submerged macrophyte down to 5 m water  
110 depth. Water temperature was about 12 °C in May, 20 °C in June, 22 °C in July, 23 °C in  
111 August, and 18 °C in September. The mean conductivity was 420 µS\* cm<sup>-2</sup> and the mean pH  
112 was 8.6±0.1SD (n = 5) from May to September. All measurements were made around  
113 midday. The sediment was sandy with a low content of organic material.  
114 The nutrient supply was lowest in June and July with nitrate/nitrite concentrations of about  
115 2.5 µmol l<sup>-1</sup>, ammonium ~ 1µmol l<sup>-1</sup>, silicate ~ 1.8 µmol l<sup>-1</sup> and phosphate ~ 0.2 µmol l<sup>-1</sup>  
116 (Table 1).

117

118 Sample collection

119 Samples of alder leaves (*Alnus* sp.), *P. perfoliatus*, attached epiphytes, sand microflora, and  
120 the most common macrozoobenthic organisms and fish species were analysed in this study.  
121 Samples were collected at 1 m water depth in a small wind exposed bay every month from  
122 May to September. We collected 20 *P. perfoliatus* shoots and 10 alder leaves from inside the  
123 plant stand on each sampling date. We swept the submerged plants with a net (mesh size 1  
124 mm) to obtain invertebrate samples. At each sampling date we swept about six to ten times in  
125 a straight line from the shore to 1 m water depth (about 5 m distance) until we had at least 20  
126 individuals of the main potentially epiphyte grazing species *Asellus aquaticus* and *Gammarus*  
127 *pulex*. We tried to sample - if possible – at least 3 individuals of other species present. The  
128 lines were approximately 1 m apart. Fish were caught with a dip net. Additionally we sampled  
129 60 *Potamopyrgus antipodarum* from plants and sediment and 10 *Dreissena polymorpha* from

130 stones. All samples were placed in plastic containers with water from the collection site and  
131 transported to the laboratory for sorting and further processing. We took 15 sediment cores (1  
132 cm inner diameter) in plant-free patches within the macrophyte stand at each sampling date.  
133 The sediment cores were taken at 1 m water depth 1 m apart in a line parallel to the shore  
134 (distance from the shore about 3m). Additionally, we collected *Asellus aquaticus* (L.) from  
135 the alder leaves of a nearby unvegetated area.

136

#### 137 Sample processing

138 In the laboratory, the plant material (*Alnus* sp. leaves and *P. perfoliatus* with epiphytes) was  
139 rinsed in distilled water to remove fine detritus and attached animals. Epiphytes were  
140 carefully scraped from the *P. perfoliatus* leaves and transferred to small amounts of distilled  
141 water using a plastic scraper and filtered on precombusted (450 °C, 24 h) Whatmann GF/F  
142 filters. The sediment cores were deep-frozen, the top 0.5 cm was cut off, and 3 at a time were  
143 pooled to yield a single sample (n = 5). Sand microflora, which consisted mostly of small  
144 epipsammic diatoms and bacteria in our study, was measured as detritus-free sediment.  
145 Visible detritus was manually removed and the sediment samples were carefully rinsed with  
146 water, which was discarded. We used this method, because the removal of the fine detritus  
147 particles was more important in this study than to loose a small part of the epiphyte biomass  
148 in form of epipellic diatoms. Observations with a dissecting microscope before and after the  
149 cleaning procedure of epiphytes and sediment showed the successful removal of unwanted  
150 material. All samples for stable isotope analysis were dried to constant weight (60 °C, 24 h)  
151 and stored in a dessicator. All samples for fatty acid analysis were deep-frozen at -80 °C.  
152 All invertebrate species were kept alive overnight in lake water to clear their guts. Muscle  
153 tissue was analysed for all fish species, the invertebrate species were processed as whole  
154 organisms. Consumer and plant samples for stable isotope analysis were dried to constant  
155 weight (60 °C, 48 h). The samples were ground in an agate mortar with a pestle as fine as

156 possible and then stored in airtight plastic vials. The shells of the molluscs, apart from  
157 unavoidable small fragments were discarded before this procedure.  
158 .

159 Stable isotope analysis

160 *P. perfoliatus* and *Alnus sp.* leaf subsamples were transferred into tin cups. Consumer and  
161 sediment subsamples were transferred into silver cups, treated with 0.2 µl 10% HCl to remove  
162 carbonates and then dried again. The use of HCl to remove nondietary carbon in tissue used  
163 for stable isotope analysis has been questioned, because the  $\delta^{15}\text{N}$  values can be influenced  
164 too, but the elimination of carbonates is absolutely necessary for some organisms, especially  
165 small gastropods and crustaceans that could only be sampled by crushing their shell or  
166 carapace. Preliminary analyses showed no statistically significant differences of  $\delta^{15}\text{N}$  in acid  
167 or no-acid treatments (Jaschinski *et al.*, 2008a).

168 All consumer species were measured as individuals, except the small gastropod  
169 *Potamopyrgus antipodarum*, where 10 individuals were pooled in order to obtain sufficient  
170 material for analysis (n = 3). All samples were combusted in a CN-analyser (Fisons, 1500N)  
171 connected to a Finnigan Delta plus mass spectrometer.  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$  values were calculated  
172 as

173

174 
$$\delta X (\text{‰}) = [(R_{\text{sample}}/R_{\text{standard}})-1] \times 1000$$

175

176 where X =  $^{15}\text{N}$  or  $^{13}\text{C}$  and R =  $^{15}\text{N}/^{14}\text{N}$  or  $^{13}\text{C}/^{12}\text{C}$ . Pure  $\text{N}_2$  and  $\text{CO}_2$  gases were used as  
177 primary standards and calibrated against IAEA reference standards (N1, N2, N3, NBS22 and  
178 USGS24). Acetanilide was used as internal standard after every sixth sample. The overall  
179 analytical precision was  $\pm 0.1\text{‰}$  for  $\delta^{15}\text{N}$  and  $\delta^{13}\text{C}$ .

180 The model of Phillips and Gregg (2003), which provides a range of feasible source mixtures,  
181 was used to determine the carbon sources:

182

$$183 \quad \delta_M = f_A \delta_A + f_B \delta_B + f_C \delta_C$$

$$184 \quad 1 = f_A + f_B + f_C$$

185

186  $f_A$ ,  $f_B$  and  $f_C$  are the proportions of source isotopic signatures ( $\delta_A$ ,  $\delta_B$  and  $\delta_C$ ) which  
187 coincide with the observed signature for the mixture ( $\delta_M$ ). All possible combinations of  
188 primary producer contributions were analysed with an increment of 1%. These predicted  
189 mixture signatures were compared with the measured values in the animals. If they were  
190 within a tolerance of 0.01%, they were considered feasible solutions. We only used  $\delta^{13}\text{C}$   
191 values in the modelling because of the sensitivity of the model to fractionation corrections  
192 (Connolly *et al.*, 2005). The fractionation is much larger for  $^{15}\text{N}$  than for  $^{13}\text{C}$  and can vary  
193 considerably between different species. We chose 0.2‰ as average fractionation increase of  
194  $^{13}\text{C}$  for freshwater ecosystems (France and Peters, 1997). Calculations were carried out with  
195 IsoSource, a Visual Basic program, which is available for public use  
196 (<http://www.epa.gov/wed/pages/models.htm>). Epiphytes, *Alnus sp.* leaves and sand  
197 microflora were used as possible carbon sources for the most abundant consumers (*A.*  
198 *aquaticus*, *Gammarus pulex*, and *P. antipodarum*)

199

200 Fatty acid analysis

201 The plant and consumer samples were freeze-dried for 48 h, ground in an agate mortar with a  
202 pestle and weighed. Plants were processed as individuals, while consumers were pooled into  
203 three replicate samples, each containing three individuals, with the exception of *P.*  
204 *antipodarum* where 10 individuals were pooled to obtain sufficient material for analysis. Fatty  
205 acids were extracted with a mixture of  $\text{CH}_2\text{Cl}_2$  and MeOH (2:1) with the addition of butylated  
206 hydroxytoluene (BHT; Sigma) to avoid auto-oxidation of the unsaturated fatty acids and  
207 trans-esterified with 2 ml of 3%  $\text{H}_2\text{SO}_4$  in methanol for four hours at 70 °C following the

208 method of Wiltshire *et al.* (2000). The Fatty Acid Methyl Esters (FAMES) were analysed on  
209 a Hewlett Packard 5890 Series II gas chromatograph using the GC temperature settings of von  
210 Elert (2002). We used a JW Scientific column (30 m length, 0.25 mm I.D., and 0.25  $\mu\text{m}$  film  
211 thickness). To quantify the fatty acid content an internal standard of heptadecanoic (17:0) and  
212 tricosanoic fatty (23:0) acid methyl esters was used.

213

214 Epiphyte and *P. perfoliatus* biomass

215 Epiphyte biomass was measured as chlorophyll *a*. Ten *P. perfoliatus* shoots were randomly  
216 selected on each sampling date. Epiphytes were carefully scraped from the shoots into small  
217 amounts of filtered lake water. This suspension was filtered on precombusted (450 °C, 24 h)  
218 Whatmann GF/F filters. Chlorophyll *a* and phaeophytin concentrations were measured  
219 according to Lorenzen (1967). The cleaned *P. perfoliatus* shoots were dried to a constant  
220 weight for 48 h at 60 °C and subsequently combusted for 8 h at 540 °C to determine the ash-  
221 free dry mass (AFDM). The surface area was calculated using the formula surface ( $\text{mm}^2$ ) =  
222 AFDM (g) x 1362.4 ( $R^2=0.96$ ), determined by measuring and weighing 100 shoots. All  
223 epiphytic chlorophyll concentrations were normalized to unit *P. perfoliatus* surface area.

224

225 Statistics

226 Temporal variability of carbon sources and trophic position of consumers was analysed using  
227 third-order polynomial regressions to find the best correlation between time and changes in  
228 food sources and trophic position (Statistica).

229

230

231

## 232 **Results**

233 Isotopic composition of food sources and consumers

234 Possible carbon sources fell into three categories based on  $\delta^{13}\text{C}$  values during the main  
235 growing season: (1) an enriched source *P. perfoliatus*; (2) a source of intermediate value for  
236 epiphytes growing on *P. perfoliatus*; (3) depleted sources consisting of sand microflora and  
237 alder leaves (Fig. 1). Alder leaves always had the most depleted  $\delta^{15}\text{N}$  signature (annual mean  
238  $-0.9\text{‰}$ ), whilst  $\delta^{15}\text{N}$  values of epiphytes (annual mean  $4.8\text{‰}$ ) and *P. perfoliatus* (annual mean  
239  $4.5\text{‰}$ ) were the most enriched. Sand microflora had intermediate  $\delta^{15}\text{N}$  values (annual mean  
240  $2.2\text{‰}$ ).

241 Observations with the microscope showed that epiphytes mostly consisted of filamentous  
242 green algae with an increasing amount of diatoms as the season progressed. Cyanobacteria  
243 were found in very small amounts with an increase in autumn. Sand microflora consisted  
244 mostly of prostrate diatoms, but green algae and cyanobacteria were also present. The  
245 proportions of these two algae groups increased from May to September.

246 Table 2 shows the consumers found and analysed in submerged macrophytes at the  
247 Schluensee in the growing season of 2003. The stable isotope signatures found are shown in  
248 Fig. 1. The crustaceans *A. aquaticus* and *G. pulex*, the ephemeropterid larvae *Cleon dipterum*,  
249 *Ephemera danica*, *Paraleptophlebia. submarginata* and *Torleya major* and the gastropod *P.*  
250 *antipodarum* had relatively similar  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values suggesting herbivory with a mixed  
251 contribution of epiphytes, sand microflora and alder leaves. All other gastropods *Galba*  
252 *trunculata*, *Lymnea stagnalis*, *Radix ovata*, and *Theodoxus fluviatilis* had more positive  $\delta^{13}\text{C}$   
253 signals closer to that of *P. perfoliatus*. The  $\delta^{15}\text{N}$  values ranged from  $4.7\text{‰}$  in *G. trunculata* to  
254  $7.3\text{‰}$  for *T. fluviatilis*.

255 Predators were dragon fly larvae *Calopteryx virgo* and *Orthetrum cancellatus*, crayfish  
256 *Orconectes limosus*, fish including stone loach *Barbatula barbatula*, and three-spined  
257 stickleback *Gasterosteus aculeatus*, and juveniles of the European perch *Perca fluviatilis*.  
258 Their  $\delta^{13}\text{C}$  signals indicated a mixed nutrition based ultimately on epiphyte, sand microflora,

259 alder leaf, and *P. perfoliatus* carbon. The perch were probably still in their planktivorous  
260 phase. Small crayfish and perch had lower  $\delta^{15}\text{N}$  values than the larger ones.  
261

262 Seasonal change in nutrition of main consumer species

263 The most abundant macrozoobenthic organisms were *A. aquaticus*, *G. pulex* and *P.*  
264 *antipodarum* (Gohse-Reimann 2007). Modelling of feasible mixtures showed that epiphytes  
265 were the most likely carbon source for all three species, but the relative contributions varied  
266 with time and species. The relative contribution of epiphytes to the nutrition of *A. aquaticus*  
267 (Fig. 2a) was high in June (85%), decreased strongly in July (38%) and increased again in  
268 autumn (63-72%). Sand microflora and alder leaves inevitably had complementary  
269 contributions to *A. aquaticus* nutrition with the highest values in July (33% and 29%,  
270 respectively). In contrast, *A. aquaticus* collected in a nearby unvegetated area had  
271 significantly lower  $\delta^{13}\text{C}$  values (around -29‰), and alder leaves (93-100%) were the most  
272 likely contributors to their nutrition (Table 3).

273 The relative contributions of epiphytes, sand microflora, and alder leaves to the nutrition of *G.*  
274 *pulex* (Fig. 2b) showed essentially the same pattern as for *A. aquaticus* in summer and  
275 autumn, with high values for epiphyte contribution in June (91%), a decrease in July (43%),  
276 and an increase in autumn (60-75%). The relative contribution of these autotrophs was  
277 intermediate in May (63%).

278 The most likely contributor to *P. antipodarum* nutrition was again epiphytes (90-100%), with  
279 the exception of July (Fig. 2c). The other possible carbon sources sand microflora and alder  
280 leaves had a low likelihood of making a substantial contribution to the gastropod's nutrition,  
281 but in July the importance of epiphytes as carbon source for *P. antipodarum* was strongly  
282 reduced (42%).  
283  
284

285 Biomarker fatty acids in dominant consumers  
286 The biomarker fatty acid for *P. perfoliatus* 18:3 $\omega$ 3 (Rozentsvet et al. 2002) was present in all  
287 consumer species (Fig. 3a), but only in insignificant amounts ( $\leq 1.2\%$ ). Concentrations of  
288 20:5 $\omega$ 3, characteristic for diatoms (Viso and Marty 1993; Desvillettes et al. 1997) were low in  
289 all consumers (Fig. 3b). A specific unsaturated fatty acid for green algae was not found in the  
290 epiphyte samples. We found 18:1 $\omega$ 9, a fatty acid occurring in high amounts in *Alnus* leaf  
291 litter, and thought to be characteristic for angiosperm detritus (Arts and Wainman 1999), in all  
292 animal species. *A. aquaticus* living on *Alnus* leaves (18%) and *G. pulex* (33%) had the highest  
293 levels of this fatty acid (Fig. 3c). The *G. pulex* value was derived from only one sample taken  
294 in September. Another biomarker fatty acid for angiosperm detritus 18:2 $\omega$ 6 was found in  
295 lower amounts.

296

297 Epiphyte biomass and phaeophytin content

298 The biomass of epiphytes on *P. perfoliatus*, measured as chlorophyll *a* per surface area was  
299 highest in May, and then declined to approximately one third of the initial values in summer.  
300 Epiphyte biomass increased again in late summer/autumn (Fig. 4). The phaeophytin values  
301 were generally low and ranged from 1 to 5% of the chlorophyll *a* values.

302

### 303 **Discussion**

304 Plant beds in littoral zones provide a variety of allochthonous and autochthonous organic  
305 matter (Jeppesen et al. 1997). Our stable isotope and fatty acid analyses strongly argue in  
306 favour of a food web based mainly on epiphytic algae and to a lesser degree on sand  
307 microflora and alder leaves in Lake Schluensee from May to September. The negligible  
308 amount of the characteristic biomarker fatty acid for *P. perfoliatus* 18:3 $\omega$ 3 found in  
309 consumers strongly suggests that the macrophyte is of minor importance for the carbon flow  
310 in this food web. Feeding experiments with some of the dominant grazers in Lake Schluensee

311 support this assumption (Gohse-Reimann 2007). Unfortunately, we found no characteristic  
312 fatty acid for green algae in the epiphyte samples to further support the results of the stable  
313 isotope analyses. The use of fatty acid analyses seemed to be somewhat limited in freshwater  
314 macrophyte systems, although the fatty acid composition of green algae is species-specific  
315 and under other circumstances a biomarker fatty acid for epiphytic green algae might be  
316 found.

317 The question of the importance of fresh macrophytes as food source is still in debate.  
318 Originally, submerged vascular plants were supposed to be only relevant as substratum for  
319 epiphytes and refuge from predation, and many studies found a low degree of herbivory (e.g.  
320 Porter 1977; Otto and Svensson 1981). But reviews of the literature and additional studies  
321 revealed that herbivory might be more common than generally thought (Newman 1991;  
322 Lodge 1991; Lodge et al. 1994; Jacobsen and Sand-Jensen 2006).

323 Epiphytes were the most important contributors to the nutrition of the most abundant  
324 invertebrates in our study. *P. antipodarum* had  $\delta^{13}\text{C}$  values closest to those of epiphytes. *P.*  
325 *antipodarum* is indigenous to New Zealand and colonised freshwater and brackish habitats in  
326 Australia, Europe, and North America during the 19th and 20th centuries and can reach  
327 densities as high as 800.000 ind. m<sup>-2</sup> (Kerans et al. 2005). It is a generalist feeder (i.e., both  
328 grazing herbivore and detritivore) and can feed on sand microflora, periphyton, fungi,  
329 bacteria, and detritus (James et al. 2000b; Aberle et al. 2005). Our findings concerning *P.*  
330 *antipodarum* nutrition are consistent with another study in New Zealand, where stable isotope  
331 signatures and gut analyses indicated that epiphytes are the predominant carbon source for  
332 this species (James et al. 2000a).

333 The most important source of nutrition for the two major crustacean species *A. aquaticus* and  
334 *G. pulex* were also epiphytes. Traditionally, both species are considered detritivorous shredders  
335 mainly feeding on decaying allochthonous leave material and on attached fungi and bacteria  
336 (Graça et al. 1993), but some studies suggest microscopic algae and macrophytes as

337 additional food sources (Moore 1975; Marcus et al. 1978). In laboratory studies even  
338 predation and cannibalism occurred (Kelly et al. 2002; Gohse-Reimann, 2007). Our results  
339 imply that both grazers show a great plasticity in feeding habits in accordance with the food  
340 sources available to them (Moore 1975). *A. aquaticus* from a nearby unvegetated area had  
341  $\delta^{13}\text{C}$  values indicating alder leaves as ultimate carbon source. High content of 18:1 $\omega$ 9, a fatty  
342 acid found in high amounts in leaf litter supports this assumption.

343 The  $\delta^{15}\text{N}$  values of both crustaceans (about 6.7‰) indicated a mostly herbivorous lifestyle. In  
344 particular, it was not possible that chironomid larvae were a preferred food item, as found in  
345 feeding experiments (Gohse-Reimann 2007). The chironomid larvae had higher  $\delta^{15}\text{N}$  values  
346 (annual mean 7.9‰) than both crustacean species in the plant bed. In contrast, the *A.*  
347 *aquaticus* specimen from the unvegetated area showed unusually high  $\delta^{15}\text{N}$  values (annual  
348 mean 13.4‰). The trophic fractionation from detritus to fungi and bacteria may explain the  
349 high  $\delta^{15}\text{N}$  values of *A. aquaticus* as this species preferentially feeds on fungi and bacteria  
350 colonizing the leaves (Graça et al. 1993). Otherwise predation on chironomid larvae may be an  
351 option in this environment, where alder leaves with associated fungi and bacteria provided the  
352 main food source.

353 In July, the proportional contribution of epiphyte carbon to the nutrition of *P. antipodarum*, *A.*  
354 *aquaticus*, and *G. pulex* was reduced by half compared with all other months. The  
355 contributions of sand microflora and alder leaves increased accordingly. This drastic change  
356 in food sources occurred along with a strong decrease in epiphyte biomass. Reduction in the  
357 quantity of the preferred food seems to induce a switch in nutrition to less attractive food  
358 items. Furthermore, these results support the hypothesis that grazing invertebrates can control  
359 the density of epiphytes and, thus, the competition between epiphytes and macrophytes for  
360 light and nutrients (Jones et al. 2002). A strong increase in the abundances of main consumers  
361 in summer (Gohse-Reimann 2007) in combination with low nutrient levels probably reduced

362 epiphyte biomass and production until autumn, when early storms and a decrease in consumer  
363 abundance changed the situation.

364 Our epiphyte chlorophyll *a* values are in the range of values found for epiphytes growing on  
365 *P. perfoliatus* in brackish water in the Chesapeake Bay (Neundorfer and Kemp 1993). The  
366 same seasonal development and similar absolute chlorophyll *a* values were found in a  
367 phosphate limited temperate lake for epiphytes growing on *Scirpus subterminalis*  
368 (Burkholder and Wetzel 1989). The phaeophytin content, which might be used as an indirect  
369 indicator for bacteria in the epiphyte community, was about ten times higher than in our study  
370 indicating that bacteria play a minor role as food source at our study site.

371 Other gastropod species than *P. antipodarum* occurred only occasionally and in low densities.  
372 The stable carbon signatures of *R. ovata* and *T. fluviatilis* indicated a possible contribution of  
373 the macrophyte *P. perfoliatus* to their nutrition. May flies (*C. dipterum*, *E. danica*, *P.*  
374 *submarginata*, *T. major*) were only found in May and June and their  $\delta^{13}\text{C}$  values suggested a  
375 mixed diet of epiphytes, sand microflora, and alder leaves.

376 Stable isotope analyses indicated that the main predators, American crayfish (*O. limosus*),  
377 loach (*B. barbatula*) and three-spined stickleback (*G. aculeatus*) ultimately depend on  
378 epiphyte, sediment microflora, *Alnus* leaves and *P. perfoliatus* carbon in about equal  
379 proportions. Crayfish are considered omnivorous, though preferring aquatic invertebrates, but  
380 may take macrophytes and leaf litter, when more nutritious food is scarce (Nyström et al.  
381 1999; Dorn and Mittelbach 2004). Feeding experiments with *O. limosus* showed that this  
382 crayfish preferentially fed on animals, but small amounts of leaf litter and macrophyte tissue  
383 were also ingested (Gohse-Reimann 2007). The relatively low  $\delta^{15}\text{N}$  values (annual mean  
384 8.7‰) give further evidence for an omnivorous life style of this species.

385 The basic food of loach is dipteran larvae, mostly chironomids, while other insect larvae are  
386 fed upon only in spring, and benthic crustaceans, amphipods and isopods become more  
387 important in autumn (Michel and Oberdorff 1995). This is in good accordance with the  $\delta^{15}\text{N}$

388 content of the loach, which decreased from 12.1‰ in spring to 9.1‰ in autumn while the  
389  $\delta^{15}\text{N}$  of chironomid larvae decreased simultaneously from 9.7‰ to 6.5. The  $\delta^{13}\text{C}$  of the loach,  
390 however, suggested that chironomids are not the only food source.

391 Sticklebacks are the top predator in this macrophyte system showing the highest  $\delta^{15}\text{N}$  values  
392 (14‰). This fish species is a generalist, feeding on insect larvae, benthic crustaceans,  
393 copepods and fish eggs, which may explain its high trophic position. The perch in our study  
394 were probably still in their zooplanktivorous phase (Hargeby et al. 2005).

395 Our assumption that there is no strong direct link between living macrophytes and higher  
396 trophic levels is consistent with other stable isotope analyses in plant-dominated lake systems  
397 (Hecky and Hesslein 1995; James, et al. 2000b; Jones and Waldron 2003). In contrast to most  
398 other studies on freshwater macrophyte systems, Keough et al. (1996) found that  
399 phytoplankton was the dominant carbon source in the littoral zone of Lake Superior and  
400 epiphytes played only a minor role in invertebrate nutrition. In addition, Solomon et al. (2008)  
401 showed that the importance of periphyton is species-dependent for aquatic insect larvae in a  
402 whole-lake  $^{13}\text{C}$  addition experiment. In marine seagrass beds, similar analyses also supported  
403 the importance of epiphytic algae (Moncreiff and Sullivan 2001; Jaschinski et al. 2008b) and  
404 benthic microalgae can also be relevant in salt marsh food webs (Teal 1962; Sullivan and  
405 Moncreiff 1990).

406 Epiphytes on submerged plants in temperate regions are generally believed to have the  
407 potential to fix more carbon than the macrophytes they grow on (Cattaneo and Kalff 1980;  
408 Jaschinski et al. 2008b) despite their relatively low biomass and provide a more nutritious and  
409 less toxic or repellent food than most macrophytes. Epiphytes usually contain more nitrogen  
410 and phosphorus in relation to carbon compared to macrophytes and leaf litter, and the content  
411 of essential fatty acids ( $\omega 3$  and  $\omega 6$  groups) is higher than in *Alnus* leaves (Brepohl, unpubl.  
412 data). Both amount and nature of the food sources thus influence what animals eat.

413

414 **Acknowledgements**

415 We thank T. Hansen for the analysis of the stable isotope samples. We also thank N. Aberle-  
416 Malzahn for helpful comments on the manuscript. S. Flöder provided valuable assistance in  
417 the field. The Brazilian National Counsel of Technological and Scientific Development  
418 (CNPq) and the German Research Foundation supported this work (So 145/20).

627 **Table 3** Results of the IsoSource model for the most abundant consumers. Mean contributions  
 628 of primary producers to consumer nutrition and the 1 to 99 percentile ranges are given (in  
 629 parentheses).

Formatted: English (U.K.)

Month	Epiphytes	Alder leaves	Sand microflora
<i>A. aquaticus</i>			
June	85 (84-87)	6 (0-13)	9 (0-16)
July	38 (35-41)	29 (5-55)	33 (4-60)
August	63 (58-67)	16 (0-30)	22 (3-42)
September	72 (64-79)	11 (0-20)	18 (1-36)
<i>A. aquaticus</i> (unvegetated area)			
June	0	99 (99-100)	1 (0-1)
July	0	93 (88-98)	7 (1-12)
August	0	100	0
<i>G. pulex</i>			
May	63 (50-75)	13 (0-25)	25 (0-50)
June	91 (90-92)	4 (0-8)	5 (0-10)
July	43 (40-46)	28 (2-52)	28 (2-58)
August	60 (54-64)	18 (2-35)	23 (1-44)
September	75 (68-81)	11 (2-19)	15 (0-30)
<i>P. antipodarum</i>			
May	100	0	0
June	88 (87-89)	5 (0-9)	7 (2-13)
July	42 (39-45)	31 (5-55)	27 (0-56)
August	90 (89-91)	3 (0-7)	7 (2-11)
September	96 (95-96)	2 (1-2)	3 (2-4)
