

Reduced adsorption of caesium on clay minerals caused by various humic substances

C. Dumat, S. Staunton*

U.F.R. de Science du Sol, I.N.R.A., 2 place Viala, 34060 Montpellier Cedex, France

Abstract

The effect of the addition of various humic substances on the adsorption of caesium on two mineral clays has been studied. All measurements were carried out in dilute suspension under controlled conditions of temperature and ionic strength. Only a small proportion of the humic substance was adsorbed on the clays (<10%). In general, the affinity of the clay-humic complexes for caesium was less than that of the bare clay. The decrease was greater for illite than for montmorillonite, and greatest at trace concentrations of caesium and increased with increasing concentration of each humic substance. However, no correlation was found between the amount of humic substance adsorbed and the decrease in Cs adsorption when all complexes were considered. Neither size nor the origin of the humic substances could explain the extent of the adsorption decrease. Since neither steric hindrance nor decrease in the number of adsorption sites was the driving force behind this phenomenon, it is hypothesized that the affinity of the clay surface is modified by the organic macromolecules. The highly selective frayed edge sites of illite are particularly sensitive to the adsorption of polyanions because of their proximity to anion adsorption sites. The observed decrease in Cs adsorption may contribute to the unexpectedly high bioavailability of Cs in organic soils. © 1999 Elsevier Science Ltd. All rights reserved.

1. Introduction

The radioisotopes of caesium, ^{137}Cs and ^{134}Cs , with half-lives of 30.4 and 2.1 years, respectively, have been introduced into the environment by various events, notably fallout from the atmospheric weapons testing in the 1950s and 1960s and accidents such as the one at the Chernobyl nuclear power plant in 1986. The environmental and radioecological problems posed by caesium contamination of soils are long term, and

accurate prediction is required. Adsorption of caesium on soil constituents is one of the factors which determines the availability of radiocaesium to biological systems. It is well known that caesium is strongly adsorbed on clay minerals (Sawhney, 1972; Maes & Cremers, 1986; Cornell, 1993). This adsorption is highly specific, particularly on illitic materials which are thought to contain a small proportion of sites, frayed edge sites (FES), which have a very strong affinity for caesium (Brouwer, Baeyens, Maes & Cremers, 1983). In contrast, the adsorption of caesium on organic matter is non-specific, and depends on the cation exchange capacity (CEC) of the organic matter and the relative proportions of caesium and other cations present. Indeed other cations may be preferentially associated with organic matter in soils and sediments. The formation of complexes between Cs and organic ligands is negligible.

Nevertheless, some observations on the fate of radiocaesium in soils lead us to suspect that organic matter does play some role in the extent and strength of adsorption. It is widely observed that radiocaesium is more easily available to biological systems in soils with high organic matter contents (Barber, 1964; van Bergeijk, Noordijk, Lembrechts & Frissel, 1992), and therefore, by implication, less strongly adsorbed. A simple explanation for this would be that organic soils and peats do not contain sufficient quantities of clay materials, particularly illites, to effectively immobilise caesium. However, recent studies have shown that even peats contain trace amounts of illite (Hird, Rimmer & Livens, 1995), which should be more than sufficient to adsorb the trace amount of caesium present even in the most highly contaminated soils. For example, an OECD report (OCDE, 1987) gives the greatest recorded contamination of ^{137}Cs due to the accident at Chernobyl in a member country as 190 kBq m^{-2} in Sweden. As little as $1 \text{ mg illite kg}^{-1}$ soil (assuming the cation exchange capacity of illite to be $0.1 \text{ mol}_c \text{ kg}^{-1}$ and the proportion of highly selective sites to be 1%) would have sufficient capacity to adsorb this amount of Cs. It is possible that the presence of organic matter reduces the affinity of clay minerals for Cs. Other possible explanations of the ongoing bioavailability of Cs in highly organic upland soils depend on plant physiology, and are beyond the scope of this study.

A small number of studies have suggested that the presence of humic substances does decrease the adsorption of Cs (Bunzl & Schultz, 1985; Maguire, Pulford, Cook & Mackenzie, 1992; Hsu & Chang, 1995). We consider that the generality of this effect should be tested. In a previous study, we have shown that the removal of organic matter from a soil clay increases its affinity for caesium (Dumat, Cheshire, Fraser, Shand & Staunton, 1997). For the present study, the effect of the addition of humic acid and fulvic acid from three different origins to two reference clays, a montmorillonite and an illite is studied. We have chosen to investigate humic substances because they constitute a large proportion of soil organic matter. The amount of adsorbed humic substance in the complexes studied is far less than the organic matter content of the organic upland soils in which Cs bioavailability is a particular problem. However, if soil organic matter modifies the affinity of minerals for Cs, only the small proportion directly associated with clay minerals could play a role.

The effect was studied at two initial caesium concentrations at varying ratios of clay to humic substance. A short exchange period was used (2 h) to ensure that only true ion exchange was measured, with no interference from either long term weathering

effects of the humic substances on the clays or the slow adsorption of Cs characteristic of illites. The clays were chosen for their differing affinity for caesium, resulting from different adsorption mechanisms. Similarly, a comparison of the phenomenon at two concentrations of caesium, when different adsorption sites may dominate adsorption, allows us to clarify the origin of the observed effect. At trace additions of Cs the adsorption on illites is dominated by highly selective sites which account for a small proportion of the cation exchange capacity. At larger Cs concentrations the affinity may be determined by the regular exchange sites, which are external planar sites and are very similar to those of montmorillonite. This point will be considered in greater detail in the Discussion. Even the trace Cs concentration used in this study is in excess of levels found in contaminated soil, however, since the extent of the decrease in Cs adsorption increases with decreasing Cs loading, the effect of organic matter should be at least as great in situ.

2. Materials and methods

Two reference clays were investigated, a Wyoming montmorillonite (M) and an illite from Le Puy (I), France. Their principal characteristics are given in Table 1. The clay-sized fraction ($< 2 \mu\text{m}$) was extracted from both minerals by sedimentation, saturated in Ca by repeated suspension in 1 M CaCl_2 and dialysed until salt free and the concentration adjusted to 20 g dm^{-3} . The humic substances (HS) were isolated from three different sources; Suwannee River, Peat and a Nordic Aquatic system. They were obtained from the International Humic Substance Society (IHSS) and used without further purification. The composition of the humic substances is presented in Table 2. After dissolving the fulvic acids in water, and the humic acids in 0.1 M NaOH, the solutions were then adjusted to pH 7 with NaOH or HCl. ^{137}Cs was obtained from Amersham International as an aqueous solution containing trace amounts of stable carrier Cs.

The Cs adsorption was carried out as follows. Triplicate suspensions of clay were prepared in polypropylene tubes by mixing appropriate volumes of clay suspension and solutions of Cs, humic substance and CaCl_2 used as a background electrolyte. The concentrations of the various components was as follows: CaCl_2 3.33 mM (ionic strength 10^{-2} M; clay 1 g dm^{-3} ; humic substance 0, 0.05, 0.1 or 0.25 g dm^{-3} ; CsCl 0 or 10^{-5} M; ^{137}Cs 1 or 2 MBq dm^{-3} , equivalent to 6.7 and 13.4 nM Cs (the higher ^{137}Cs

level for the systems containing illite which has a greater Cs adsorption capacity). The final pH of the suspensions was 7 ± 0.3 . The sodium present in the solutions of humic substance led to a Na concentration in the suspension of about 10^{-4} M. The presence of this amount of sodium did not change the Cs adsorption properties of the clays. These suspensions were shaken in a reciprocal shaker for 2 h at 20°C then centrifuged at 19 000 *g* for 30 min. Preliminary experiments have shown that these conditions are adequate to ensure complete separation of the aqueous and solid phases. Triplicate aliquots of the supernatant solution were taken, added to scintillation liquid and the β radiation was measured in a Beckman LS 5801 counter.

The distribution coefficient, K_d is defined as follows,

$$K_d = x_{Cs}/[Cs], \quad (1)$$

where x_{Cs} is the amount of Cs adsorbed on unit mass of clay (mol kg^{-1}) and $[Cs]$ (M) is the final concentration in solution. The value of K_d was calculated from the depletion of ^{137}Cs from solution, by comparison with a blank solution to which no clay had been added.

A small proportion of humic substance is adsorbed, it is therefore not possible to determine the amount adsorbed by measuring the loss from solution. The amount of humic substance adsorbed on the clays was therefore interpolated from the C content clay-humic substance complexes obtained as follows. Suspensions containing 50 g clay and 5 g humic substance were shaken overnight then centrifuged at 19 000 *g* for 30 min. The supernatant solution was decanted off, and the remaining solution removed by gently rinsing with water. The resulting plug was freeze dried and the C content measured using a Carlo Erba 1500. The amount of humic substance adsorbed was calculated from the known C content of the humic substance, supplied by the IHSS, and the C content of the bare clay obtained by the same method. The results of this analysis are given in Table 3. Table 4 gives the calculated values of $x_{HS}/[HS]$ and x_{HS} for each clay + humic substance complex where x_{HS} is the amount of humic substance adsorbed per unit mass of clay and $[HS]$ the final solution concentration. The adsorption isotherm of humic substances on clay is assumed to be linear (Theng and Scharpenseel, 1975). This assumption was confirmed by preliminary experiments with illite and a different fulvic acid and so these values were used to

calculate the amount of each humic substance adsorbed when the initial solution concentration was 0.25 g dm⁻³, which is used in Figs. 4 and 5.

3. Results

Fig. 1 shows the effect of increasing amounts of each of the humic substances (HS) on the K_d value of illite with two initial C_s concentrations in solution. Fig. 2 gives the equivalent data obtained with montmorillonite. The standard deviation of the

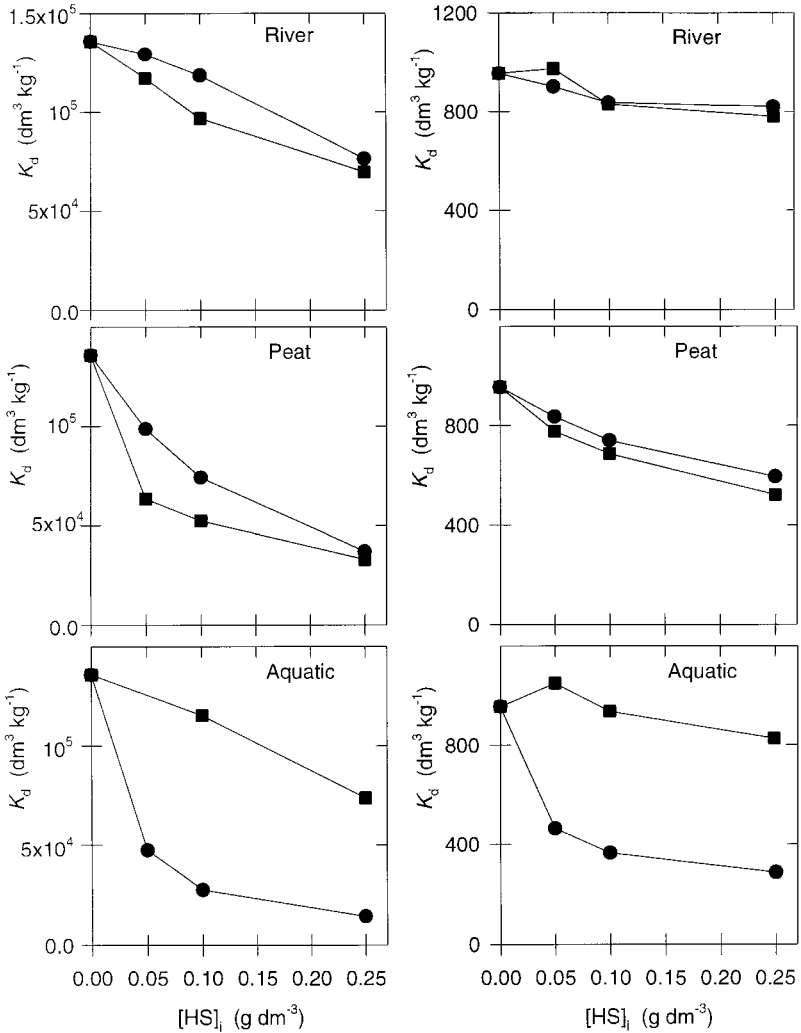

Fig. 1. Value of the distribution coefficient, K_d , on illite as a function of initial concentration of humic substance in solution. Two initial Cs concentrations in solution were studied; 13.4 nM or trace (left column) and 10 μM (right column) for the fulvic and humic acids of Suwannee River, Peat and Nordic Aquatic system (from top to bottom). (■) Fulvic acid; (●) Humic acid.

K_d values was about 5% and never exceeded 8%. The K_d values for the bare clays illustrate the well-known fact that there is greater adsorption on illite than on montmorillonite and that adsorption is highly concentration dependent, as indicated by the smaller value of K_d at the higher Cs concentration. The concentration dependence is more marked for illite than for montmorillonite. The addition of humic substance leads in general to a decrease in the value of K_d , with adsorption being less

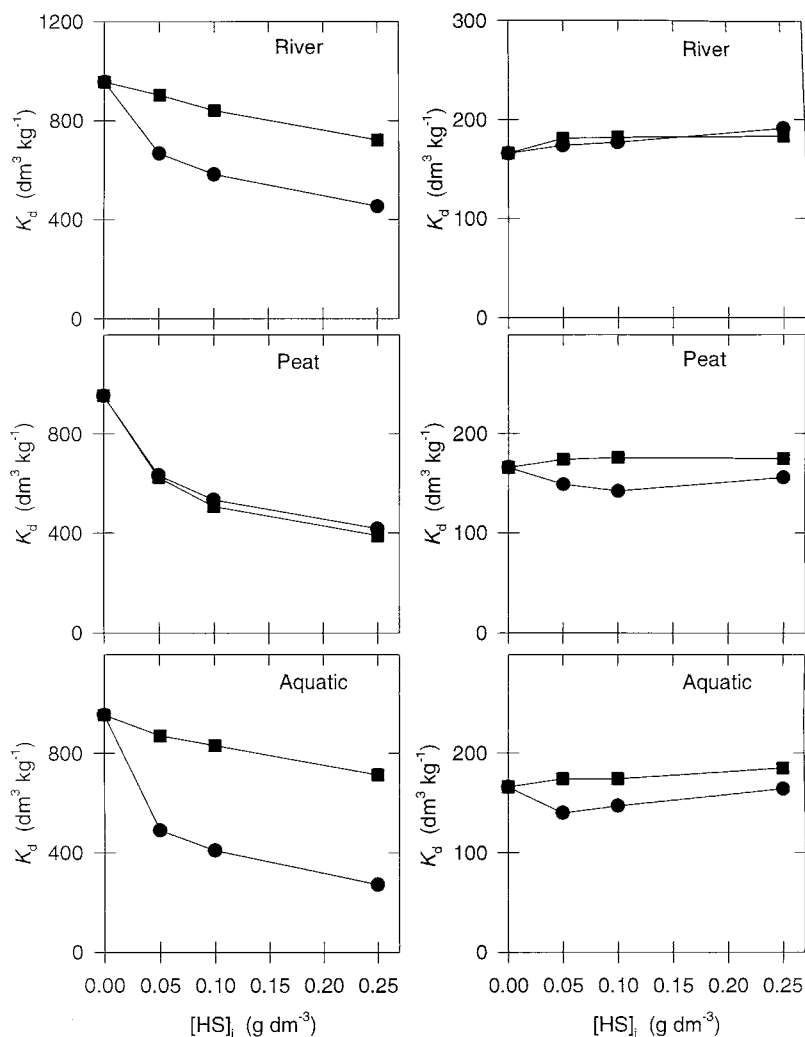

Fig. 2. Value of the distribution coefficient, K_d , on montmorillonite as a function of initial concentration of humic substance in solution. Two initial Cs concentrations in solution were studied; 6.7 nM or trace (left column) and 10 μ M (right column) for the fulvic and humic acids of Suwannee River, Peat and Nordic Aquatic system (from top to bottom). affected in the case of montmorillonite than illite. A more marked effect at trace levels of Cs than at the higher initial Cs concentration is observed. There is no significant decrease in K_d with HS addition for montmorillonite when the initial Cs concentration is 10 μ M.

Fig. 3 resumes the effect of the highest addition of humic substance on (a) illite and (b) montmorillonite for the two initial Cs concentrations. The value of K_d relative to that on the bare clay, denoted by $*K_d$, has been calculated for each clay + humic

Fig. 3. Value of K_d for the clay-humic complexes at the greatest addition of humic substance relative to that of the bare clay, $*K_d$, for each of the humic substances at each of the initial concentrations of Cs (trace level and 10 μ M) for (a) illite and (b) montmorillonite. White bars, trace Cs; Hatched bars, 10 μ M Cs.

substance couple. The trend mentioned above is more clearly demonstrated, namely a greater effect on illite than on montmorillonite and at trace levels of Cs. There is no clear trend linking the nature and origin of the humic substances and the reduction in Cs adsorption.

Fig. 4 shows the relative K_d value, $*K_d$, for the highest HS loading as a function of x_{HS} , the amount of HS calculated to be adsorbed (as described in Materials and Methods) for both clays at trace additions of Cs. About 10 times more humic substance is adsorbed on illite than on montmorillonite, with an average of 33 and

Fig. 4. Relative K_d value, $*K_d$, (as explained for Fig. 3) for each clay–humic complex at trace levels of Cs as a function of the amount of each humic substance calculated to be adsorbed x_{HS} . (▲) Illite; (■) Montmorillonite.

3 g kg^{-1} , respectively. The average value of $*K_d$ is lower for the illite complexes (0.38 ± 0.20) than that of the montmorillonite complexes (0.53 ± 0.13), but the difference is not significant. Fig. 5 relates the ratio of the relative K_d value of each illite complex, $*K_{d,I}$, to that of montmorillonite, $*K_{d,M}$, at the maximum humic substance concentration and at trace levels of Cs to the relative amounts of humic substance adsorbed on each clay. There is a 10-fold difference in the relative amount of HS adsorbed, $x_{HS,I}/x_{HS,M}$, and only a three-fold difference in the ratio of relative values of K_d , denoted by $*K_d$, on the two clays. There is no correlation between the two parameters, therefore the contrasting effect of humic substance on the affinity of the two clays for Cs is not simply a result of differing amounts of humic substance adsorbed.

4. Discussion

Preliminary studies (Staunton & Roubaud, 1997) indicated that the presence of humic substance decreased the adsorption of caesium on mineral clays. The data presented in Figs. 1 and 2 confirm that this is a general phenomenon. Furthermore, the decrease induced by a given HS is generally enhanced as its concentration is increased. Were this effect observed for an actinide or a transition metal, the likely explanation would be that the solubility of the cation was increased by the formation of complexes in solution. This explanation is highly improbable for caesium, which

Fig. 5. Ratio of the relative K_d value for each illite complex denoted by $*K_{d,I}$, as presented in Fig. 3a to that of montmorillonite, $*K_{d,M}$ (Fig. 3b) at trace levels of Cs, as a function of the amount of each humic substance calculated to be adsorbed on illite, $x_{HS,I}$, relative to that adsorbed on montmorillonite, $x_{HS,M}$.

has a limited tendency to form complexes. There may be some association between caesium and the polyanion in solution because of the cation exchange capacity of the latter, which has, however, a preference for the divalent calcium, present at a much greater concentration (0.33×10^{-2} M). In addition, the strong affinity of clay minerals for caesium would completely outweigh any tendency to complex formation in solution.

If it is accepted that the decrease in Cs adsorption is not due to complex formation in solution, it must result from a change in the affinity of the clay for caesium. Three hypotheses may be proposed to explain the change in affinity. First, a steric effect; access to cation adsorption sites, in particular the sites of greatest affinity for caesium, is impeded by the presence of the humic substance on the clay surface. Secondly, a decrease in the number of cation adsorption sites. Thirdly, a decrease in the average affinity of the cation adsorption sites for caesium. Each of these hypotheses will be considered in turn.

4.1. Steric effect of adsorbed humic substances

Some support for the hypothesis that the observed effect arises from steric hindrance comes from the relation between decreased adsorption and increase in humic substance added, and hence an increase in the amount adsorbed. However, only a small proportion of the humic substance is adsorbed because of the repulsion

between the clay surface and the polyanion since both are negatively charged. There is no evidence of the adsorption of humic acids on internal sites of expanding clays such as montmorillonite. The coating of the clay surface by the humic substance is likely to be limited to positively charged edge sites caused by broken Al-OH groups. There is therefore no reason for the adsorption of humic substances on mineral surfaces to be related to the mineral CEC. Nor should adsorption depend on surface area, unless the same mineral with differing degrees of dispersion or grinding are compared. The positively charged edge sites are distinct from the electronegative frayed edge sites of illite (FES), with a very strong affinity for caesium, but they may be in close proximity. This proximity lends some support to the steric hindrance hypothesis. However, a steric effect should be related not only to the amount of humic substance adsorbed but also to its size. It is well-known that humic acids are larger than fulvic acids, although the difference may be less than was previously thought (Thurman, Wershaw, Malcolm & Pinckney, 1982; Beckett, Jue & Giddings, 1987). Therefore, if steric hindrance was an important factor in the reduction of Cs affinity, the effects of humic and fulvic acids should differ. No systematic difference was observed between the effect produced by humic acids and fulvic acids. In addition, although the decrease depended on the amount of HS adsorbed for a given substance, there is no correlation between x_{HS} and $*K_d$ when all the data are considered. There is therefore no strong evidence to suggest that caesium adsorption is sterically hindered by the presence of humic substances on the clay surface.

4.2. Decrease in number of adsorption sites

Hsu and Chang (1995) have interpreted a reduction in caesium adsorption on clay in the presence of organic matter as a reduction in the number of adsorption sites. Such a phenomenon could not arise because of competition between cationic caesium and a polyanion. Organic matter, however, stabilizes clays aggregate formation, a greater number of clay platelets being associated (Vincente & Robert, 1981; Gu & Doner, 1992). Nevertheless, there is no evidence that this association leads to a decrease in the cation exchange capacity. Charge compensating cations on both internal and external adsorption sites remain exchangeable. Further, since aggregate formation involves planar surfaces more than clay edges, the strongly selective FES of illite should be less affected than the regular exchange sites, the latter playing an increasing role in caesium adsorption at higher caesium concentrations and on montmorillonite type clays. We observe the opposite; a greater effect on illite than on montmorillonite, particularly at trace additions of Cs. It therefore seems unlikely that the observed decrease in Cs adsorption is caused by a pro rata decrease in the number of adsorption sites, although a small decrease in the number of FES, with no consequence on the CEC could considerably affect the Cs affinity.

4.3. Decrease in affinity for caesium

Both the clay minerals studied adsorb caesium selectively. For example the Gaines-Thomas selectivity coefficients of the clays in the absence of humic substance

and at trace levels of Cs are 7×10^8 and $4 \times 10^3 \text{ M}^{-1}$ for illite and montmorillonite, respectively. As briefly outlined in the Introduction, the strong affinity of illite for trace amounts of caesium is usually attributed to the presence of highly selective frayed edge sites, which account for a tiny proportion (ca 1%) of the cation exchange capacity. As the amount of caesium adsorbed increases, these FES become saturated and an increasing proportion of less highly selective sites participate in adsorption, leading to a decrease in the value of K_d . If the decrease in Cs adsorption is due to a modification of the affinity of the clay surface when humic substances are present, then our observation that the effect is greater on illite at trace concentrations of Cs is important. This suggests that FES are influenced to a greater extent than are regular, planar exchange sites. Either humic substances are preferentially adsorbed on or near FES, or the affinity of the FES is changed more than that of the planar sites where adsorption occurs *via* Ca bridges. As stated above, the polyanion, like anions such as phosphate and sulphate, is likely to be adsorbed on positively charged edge sites arising from broken Al-OH groups (Stevenson, 1982). It is probable that the concentration of adsorbed humic substance is greater near the FES than on the planar surfaces. Unfortunately, the humic substances are too light to be observed directly by electron microscopy and so it is impossible to obtain direct evidence for this theory.

The presence of humic substance may also influence the affinity of the FES for caesium. This has been suggested by Hird, Rimmer and Livens (1995, 1996). The strong affinity of FES for caesium is thought to arise because Cs has a small hydration energy and so loses its hydration shell, forming a strong interaction with both clay platelets thereby closing the FES (Sawhney, 1972; Cornell, 1993). The presence of a macromolecule within, or at the outer edge of, the FES would impede or limit its collapse and so decrease its affinity for Cs.

The affinity of montmorillonite for Cs may be enhanced by the presence of trace impurities of illite. However, it is well known that the affinity of montmorillonite for the alkali metals increases in the order $\text{Na} < \text{K} < \text{Rb} < \text{Cs}$. This trend has been interpreted using the Hard and Soft Acid-Base Theory (Xu & Harsh, 1990). It is therefore probable that anything that modifies the Misono softness parameter would influence selectivity. The free energy and the charge density of the clay surface are modified by the presence of the humic substance (Jouany, 1991). Indeed, since the clay systems studied were initially homo-ionic in calcium, the K_d is related to the selectivity coefficient, and hence to the thermodynamic exchange coefficient and the Gibb's free energy of the exchange reaction (Maes & Cremers, 1986). Some of the humic substance is adsorbed as bridging complexes *via* calcium on the exchange complex. It is probable that the selectivity of Cs-Ca exchange differs from that of exchange between Cs and the Ca-HS surface complex. This may also have some effect on the overall affinity of the surface for Cs. Overall the smaller effect on montmorillonite than on illite, and the smaller effect at larger concentrations of Cs for both clays, suggest that various mechanisms responsible for the decrease in affinity of planar sites are less important than those acting on the FES.

5. Conclusions

Clay–humic substance complexes adsorb less caesium than do uncoated clays minerals. This decrease appears to be a general effect. For a given humic substance the effect increases with increasing humic substance adsorbed, although only a small proportion of the macromolecule is adsorbed by the clay. However, when all data are considered there is no correlation between the amount of humic substance on the clay and the decrease in Cs adsorption. No trend is observed for the nature (humic or fulvic acid) or origin (river, peat, aquatic) of the humic substances. A comparison of the relative effects on illite and montmorillonite at two concentrations of caesium leads to the conclusion that the phenomenon arises from a change in the affinity of the clay surface for caesium. Highly selective caesium adsorption sites, the frayed edge sites of illite, are particularly influenced. Although the adsorption of caesium in soils and geological formations, and hence its mobility and availability, is largely determined by clay content and mineralogy, the presence of organic matter may lead to significant modifications.

Acknowledgements

This study received partial financial support from the Agence Nationale pour la Gestion des Déchets Radioactifs (ANDRA), France. Carbon analyses of the samples was carried out by the Laboratoire d'Analyse, Arras, INRA and characterisation of the humic substances supplied by the IHSS. The clay samples were gifts of D. Tessier, INRA, Versailles.
