Abstract

In this paper models for claim frequency and claim size in non-life insurance are considered. Both covariates and spatial random effects are included allowing the modelling of a spatial dependency pattern. We assume a Poisson model for the number of claims, while claim size is modelled using a Gamma distribution. However, in contrast to the usual compound Poisson model going back to Lundberg (1903), we allow for dependencies between claim size and claim frequency. Both models for the individual and average claim sizes of a policyholder are considered. A fully Bayesian approach is followed, parameters are estimated using Markov Chain Monte Carlo (MCMC). The issue of model comparison is thoroughly addressed. Besides the deviance information criterion suggested by Spiegelhalter et al. (2002), the predictive model choice criterion (Gelfand and Ghosh (1998)) and proper scoring rules (Gneiting and Raftery (2005)) based on the posterior predictive distribution are investigated. We give an application to a comprehensive data set from a German car insurance company. The inclusion of spatial effects significantly improves the models for both claim frequency and claim size and also leads to more accurate predictions of the total claim sizes. Further we quantify the significant number of claims effects on claim size.

Key words: Bayesian inference, compound Poisson model, non-life insurance, proper scoring rules, spatial regression models,

1 Introduction

In this paper statistical models for the number of claims and claim size in non-life insurance are discussed in a Bayesian context. Based on these models the total claim size can be simulated which is fundamental for premium calculation. In particular we consider regression models for spatially indexed data and allow for an underlying spatial dependency pattern by the inclusion of correlated spatial random effects. One important contribution of this paper is that we further allow for dependencies between the number of claims and claim size. This is in contrast to the classical compound Poisson model going back to Lundberg (1903), where independence of claim frequency and claim size is assumed. We give an application to a comprehensive data set from a German car insurance company and quantify the impact of number of claims effects on claim size. Further the issue of model comparison is thoroughly addressed.

In the classical Poisson-Gamma model the number of claims is assumed to follow a Poisson distribution and to be independent of the claim sizes which are modelled Gamma distributed. The use of GLMs in actuarial science has been discussed by Haberman and Renshaw (1996) who give several applications, including premium rating in non-life insurance based on models for claim frequency and average claim size. A more detailed study of GLMs for claim frequency and average claim sizes taking covariate information into account is given in Renshaw (1994). Taylor (1989) and Boskov and Verrall (1994) analyse household contents insurance data incorporating geographic information. Whereas Taylor (1989) uses spline functions, Boskov and Verrall (1994) assume a spatial Bayesian model based on Besag et al. (1991). However, instead of performing a separate modelling of claim frequency and claim size, in both papers adjusted loss ratios are fitted.

Another approach, which also does not perform a separate analysis of claim size and frequency is given by Jørgensen and de Souza (1994) and Smyth and Jørgensen (2002). They use a compound Poisson model, which they call Tweedie's compound Poisson model due to its association to exponential dispersion models, for analysing car insurance data. Based on the joint distribution of the number of claims and the total claim sizes, they model the claim rate, defined by the total costs per exposure unit, directly. The problem of premium rating taking latent structures into account and using separate models for claim frequency and claim size has been addressed by Dimakos and Frigessi (2002). Based on a spatial Poisson regression model and a spatial Gamma regression model for the average claim size, they determine premiums by the product of the expected claim frequency and the expected claim size. This approach relies on the independence assumption of claim frequency and claim size. Here the spatial structure is modelled via an improper Markov Random Field following Besag et al. (1991).

This paper extends the approach by Dimakos and Frigessi (2002) in several ways. We also assume a spatial Poisson regression model for claim frequency. However, whereas Dimakos and Frigessi (2002) consider only models for the average claim size per policyholder, we alternatively assume models for the individual claim sizes of each policyholder and investigate whether this leads to improved predictions of the total claim sizes. Further we allow for dependencies between

the number of claims and claim size. In particular, claim size is modelled conditionally on the number of claims which allows us to include the observed number of claims as covariate.

We follow a fully Bayesian approach, since this allows to adjust for parameter uncertainty by assuming the parameters to be random. Panjer and Willmot (1983) state in this context: "The operational actuarial interpretation is that the risk is first selected from the whole set of risks in accordance with the risk distribution, and the performance of the selected risk is then monitored. The statistical interpretation is essentially Bayesian." Markov Chain Monte Carlo (MCMC) is used for parameter estimation and thus facilitates the desired Bayesian inference.

In this paper spatial dependencies are modelled using a Gaussian conditional autoregressive (CAR) prior introduced by Pettitt et al. (2002) for the spatial effects. CAR models are based on the assumption that the effects of adjacent sites are similar, leading to a spatially smoothed dependency pattern. In contrast to the widely used intrinsic CAR model introduced by Besag and Kooperberg (1995) the spatial prior used in this paper leads to a proper joint distribution of the spatial effects. Other proper modifications of the intrinsic CAR model have been proposed by Sun et al. (1999) and Czado and Prokopenko (2004).

Based on the MCMC output of the models for claim frequency and the average and individual claim sizes, respectively, we approximate the posterior predictive distribution of the total claim sizes using simulation. We would like to emphasize again, that independence of claim size and claim frequency is not necessary here.

Using the discussed models, we analyse a large data set from a German car insurance company. In particular we consider policyholders with full comprehensive car insurance and claims caused by traffic accidents. One of our main interests is to investigate whether, after adjusting for covariate information, models are improved by additionally including spatial random effects. Further, we study the impact of the observed number of claims as additional covariate for the claim size models and quantify these effects on the expected claim sizes. Finally, we are interested, if there is a gain in using models for individual claim sizes in contrast to models for average claim sizes, where information is aggregated.

Models are compared using several criteria. Next to the well known deviance information criterion (DIC) suggested by Spiegelhalter et al. (2002), the predictive model choice criterion (PMCC), see for example Gelfand and Ghosh (1998), is used for comparing model fit and complexity of the considered models. Further, proper scoring rules (Gneiting and Raftery (2005)) based on the posterior predictive distribution are investigated. The inclusion of spatial effects leads to a significantly improved model fit both for claim frequency and claim size, more accurate predictions of the total claim sizes are obtained. When spatial effects are neglected the posterior predictive means of the total claim sizes in some regions with particular high (low) observed total claims are estimated considerably lower (higher) than based on the spatial models. Further, effects for the number of claims turn out to be significant for the claim size models, for an increasing number of claims, both average and individual claim sizes tend to decrease. The results for the average and individual claim sizes are very similar, therefore modelling of average claim sizes seems to be sufficient.

The paper is organized as follows. In Section 2 the models for claim frequency and claim size are discussed, information on the assumed prior distributions and the developed MCMC algorithms is given. The criteria used for model comparison are presented in Section 3, the application to German car insurance data using and comparing several models is given in Section 4. Finally, we give a summary of the results and draw conclusions.

2 Spatial regression models for claim frequency and claim size

Premiums in insurance are based on the expected total claim size which is determined both by the number of claims as well as by the individual or average claim sizes. We will consider spatial regression models for these quantities in the following.

2.1 Models for claim frequency

We choose a Poisson regression model including spatial effects for modelling claim frequency. In particular, we assume for the number of claims $N_i, i = 1, \dots, n$, observed at J regions

$$N_i \sim \text{Poisson}(\mu_i^N),$$

where the mean μ_i^N is given by

$$\mu_i^N = t_i \exp(\mathbf{x}_i^{N'} \boldsymbol{\beta}^N + \gamma_{R(i)}^N).$$

Here, t_i denotes the exposure time of policyholder i , the covariate vector for the i -th observation including an intercept is given by $\mathbf{x}_i^N = (1, x_{i1}^N, \dots, x_{ik}^N)'$, $\boldsymbol{\beta}^N = (\beta_0^N, \beta_1^N, \dots, \beta_k^N)'$ denotes the vector of unknown regression parameters. Spatial dependencies are modelled by introducing a random effect $\gamma_j, j = 1, \dots, J$ for each region. The random vector of spatial effects for J regions is given by $\boldsymbol{\gamma}^N = (\gamma_1^N, \dots, \gamma_J^N)'$ with $R(i) \in \{1, \dots, J\}$ denoting the region where the i -th policyholder is living in. The model is completed with the following prior assumptions. For the regression parameters $\boldsymbol{\beta}^N$ a normal prior with large standard deviation, in particular,

$$\boldsymbol{\beta}^N \sim N_{k+1}(0, \tau^2 I_{k+1}) \quad \text{with} \quad \tau^2 = 100$$

is considered, since we have little prior information. Here I_{k+1} denotes the $k + 1$ -dimensional identity matrix. For the spatial effects the proper conditional autoregressive prior with hyper-parameters σ^2 and ψ

$$\boldsymbol{\gamma} | \sigma^2, \psi \sim N(\mathbf{0}, \sigma^2 Q^{-1}) \tag{2.1}$$

based on Pettitt et al. (2002) is chosen. The (i, j) -th element of the spatial precision matrix Q is specified by

$$Q_{ij} = \begin{cases} 1 + |\psi| \cdot N_i & i = j \\ -\psi & i \neq j, i \sim j \\ 0 & \text{otherwise} \end{cases} \quad \forall i, j = 1, \dots, J$$

where $i \sim j$ denotes adjacent regions. We define regions to be neighbours if they share a common border. The parameter ψ determines the degree of spatial dependence, for $\psi = 0$ the spatial effects are independent, for increasing values of ψ an increasing spatial dependency is obtained. For the spatial hyperparameters σ^2 and ψ proper priors are assumed, in particular we choose for σ^2 the noninformative prior

$$\sigma^2 \sim IGamma(a, b) \quad \text{with} \quad a = 1 \quad \text{and} \quad b = 0.005$$

which is a common parameter choice for vague Gamma priors and for ψ the prior $\psi \sim \frac{1}{(1+\psi)^2}$ which is concentrated on small values for ψ close to 0. Only the hyperparameter $\frac{1}{\sigma^2}$ can be sampled directly from a Gamma distribution, for the remaining parameters a single component Metropolis Hastings algorithm is implemented. We choose an independence proposal for the spatial effects, in particular a t-distribution with 20 degrees of freedom having the same mode and inverse curvature at the mode as the target distribution. As investigated in Gschlöbl and Czado (2005a) this proposal distribution leads to very good mixing samplers with low Monte Carlo standard errors. For the regression parameters β and the spatial hyperparameter ψ symmetric random walk proposal distributions are taken.

2.2 Models for claim size

It is natural for the analysis of claim size to take only observations with positive claim size into account. We will consider both models for the individual claim sizes and the average claim size of a policyholder. Since we aim to allow for the modelling of dependencies between the number and the size of the claims, we consider models for the claim sizes conditionally on the number of claims. Prior specifications will be given at the end of this section.

2.2.1 Modelling individual claim sizes

For policyholder $i = 1, \dots, n$ let $S_{ik}, k = 1, \dots, N_i$, denote the individual claim sizes for the N_i observed claims. In this paper we are interested in modelling claim sizes resulting from traffic accidents in car insurance, not including IBNR (incurred but not reported) losses. These kind of data typically have a skewed distribution, but do not contain extremely high claims which would require the use of heavy tailed distributions like for example the Pareto distribution, see for example Mikosch (2004). Therefore we assume a Gamma model in this paper. In particular, we assume the individual claim sizes to be independent Gamma distributed conditionally on N_i

$$S_{ik}|N_i \sim Gamma(\mu_i^{SI}, v), \quad k = 1, \dots, N_i, \quad i = 1, \dots, n \quad (2.2)$$

with mean and variance given by

$$E(S_{ik}|N_i) = \mu_i^{SI} \quad \text{and} \quad Var(S_{ik}|N_i) = \frac{(\mu_i^{SI})^2}{v}.$$

For the parameterisation used here, the density of the Gamma distribution is given by

$$f(s_{ik}|\mu_i^S, v) = \frac{v}{\mu_i^{SI}\Gamma(v)} \left(\frac{vs_{ik}}{\mu_i^{SI}}\right)^{v-1} \exp\left(-\frac{vs_{ik}}{\mu_i^{SI}}\right).$$

We consider a regression on the mean μ_i^{SI} including covariates \mathbf{w}_i and spatial effects ζ^I for the J geographical regions. By choosing a log link we obtain

$$\mu_i^{SI} = \exp(\mathbf{w}_i' \boldsymbol{\alpha}^I + \zeta_{R(i)}^I), k = 1, \dots, N_i, i = 1, \dots, n. \quad (2.3)$$

Here $\mathbf{w}_i = (1, w_{i1}, \dots, w_{ip})'$ denotes the vector of covariates for the i -th observation including an intercept, $\boldsymbol{\alpha}^I = (\alpha_0^I, \alpha_1^I, \dots, \alpha_p^I)'$ the vector of unknown regression parameters and $\zeta^I = (\zeta_1^I, \dots, \zeta_J^I)$ the vector of spatial effects which are modelled by a CAR prior based on Pettitt et al. (2002) like in the Poisson model for claim frequency. Since we consider a model for the individual claim sizes conditionally on the number of claims, the observed number of claims N_i may be introduced as a covariate as well. The number of claims per policyholder observed in car insurance data typically is very low, therefore we include N_i as a factor covariate with reference level $N_i = 1$. Hence, including number of claims effects denoted by $\alpha_{N_i=k}^I, k = 2, \dots, \max_i N_i$, the mean μ_i^{SI} reads as follows

$$\begin{aligned} \mu_i^{SI} &= \exp(\mathbf{w}_i' \boldsymbol{\alpha}^I + \zeta_{R(i)}^I) \\ &= \exp\left(\sum_{k=0}^p w_{ik} \alpha_k^I + \sum_{k=2}^{\max_i N_i} n_{ki} \alpha_{N_i=k}^I + \zeta_{R(i)}^I\right), k = 1, \dots, N_i, i = 1, \dots, n, \end{aligned} \quad (2.4)$$

where $n_{ki} = \begin{cases} 1, & N_i = k \\ 0, & \text{otherwise} \end{cases}$.

Additional variability between policyholders might be modelled by replacing, the number of claims effects $\alpha_{N_i=k}^I, k = 1, \dots, \max_i N_i$ in (2.4) with normal distributed policyholder specific random effects $c_i | N_i \sim N(\alpha_{N_i=k}^I, \sigma_{N_i=k}^2)$ centered at $\alpha_{N_i=k}^I$ and variance $\sigma_{N_i=k}^2$ depending on the number of observed claims. However, this model extension did not improve the model fit for the data considered in the application presented in Section 4 and therefore will not be further persecuted.

2.2.2 Modelling average claim sizes

Alternatively, the average claim sizes $S_i, i = 1, \dots, n$ can be modelled. The average claim size S_i for policyholder i is given by

$$S_i := \sum_{k=1}^{N_i} \frac{S_{ik}}{N_i}.$$

Since we assume the $S_{ik} | N_i, k = 1, \dots, N_i$ to be independent and identically distributed, the average claim size S_i given the observed number of claims N_i is again Gamma distributed with mean $E(S_i | N_i) = \mu_i^{SA} = \mu_i^{SI}$ and variance $Var(S_i | N_i) = \frac{(\mu_i^{SA})^2}{N_i v}$, that is we have

$$S_i | N_i \sim Gamma(\mu_i^{SA}, N_i v). \quad (2.5)$$

Again a regression is performed on the mean μ_i^{SA} , both covariates and spatial effects are taken into account. Note, that the covariates $\tilde{\mathbf{w}} = (1, \tilde{w}_1, \dots, \tilde{w}_{\tilde{p}})$ do not necessarily have to be the same

ones as for the individual claim sizes and that the estimated regression parameters and spatial effects for the average claim size will differ from the ones for the individual claim sizes. To point this out, we use the index A for the mean μ_i^{SA} , the regression parameters $\boldsymbol{\alpha}^A$ and the spatial effects $\boldsymbol{\zeta}^A$ in the model for average claim sizes. With a log link we obtain the following model

$$\mu_i^{SA} = \exp(\tilde{\mathbf{w}}_i' \boldsymbol{\alpha}^A + \zeta_{R(i)}^A).$$

Here again, number of claims effects $\alpha_{N_i=k}^A$, $k = 1, \dots, \max_i N_i$, can be included leading to

$$\begin{aligned} \mu_i^{SA} &= \exp(\tilde{\mathbf{w}}_i' \boldsymbol{\alpha}^A + \zeta_{R(i)}^A) \\ &= \exp\left(\sum_{k=0}^{\tilde{p}} \tilde{w}_{ik} \alpha_k^A + \sum_{k=2}^{\max_i N_i} n_{ki} \alpha_{N_i=k}^A + \zeta_{R(i)}^A\right), k = 1, \dots, N_i, i = 1, \dots, n, \end{aligned} \quad (2.6)$$

with n_{ki} defined as in the previous section.

Prior distributions for claim size models

Similar to the Poisson model for the number of claims we have little prior knowledge on the regression parameters $\boldsymbol{\alpha}^I$ and $\boldsymbol{\alpha}^A$ in the models for individual and average claim sizes, respectively. Therefore we assume a normal prior with large standard deviation, in particular,

$$\boldsymbol{\alpha}^I \sim N_{p+\max_i N_i}(\mathbf{0}, \tau^2 \mathbf{I}_{p+\max_i N_i}), \quad \boldsymbol{\alpha}^A \sim N_{\tilde{p}+\max_i N_i}(\mathbf{0}, \tau^2 \mathbf{I}_{\tilde{p}+\max_i N_i})$$

with $\tau^2 = 100$ which is a common choice. For the scale parameter v the gamma prior $v|a, b \sim \text{Gamma}(a, b)$, i.e. $\pi(v|a, b) = \frac{b^a}{\Gamma(a)} v^{a-1} \exp(-vb)$ with $a = 1$ is assumed, resulting in the conditional mean and variance given by $E(v|a = 1, b) = \frac{1}{b}$ and $\text{Var}(v|a = 1, b) = \frac{1}{b^2}$. Following a fully Bayesian approach we also assign a noninformative gamma prior to the hyperparameter b , in particular $b|c, d \sim \text{Gamma}(c, d)$, i.e. $\pi(b|c, d) = \frac{d^c}{\Gamma(c)} b^{c-1} \exp(-bd)$ with $c = 1$ and $d = 0.005$, resulting in $E(b|c, d) = 200$ and $\text{Var}(b|c, d) = 40000$. However, the models turn out to be very robust with respect to the prior on b , a very similar estimated posterior mean of v is obtained when b is fixed to 0.005, which is a popular choice for a flat gamma prior.

The spatial effects are modeled using the conditional autoregressive prior (2.1), i.e.

$$\boldsymbol{\zeta}^l | \sigma^2, \boldsymbol{\psi} \sim N_J(\mathbf{0}, \sigma^2 \mathbf{Q}^{-1}), \quad l = I, A,$$

assuming the same prior distributions for the hyperparameters σ^2 and $\boldsymbol{\psi}$ as in Section 2.1. The hyperparameter b can be sampled directly from a gamma distribution, for the regression parameters, the spatial effects and spatial hyperparameters a single component Metropolis Hastings algorithm with the same proposal distributions as in the Poisson model given in Section 2.1 is used. For the scale parameter v a symmetric random walk proposal distribution is taken.

3 Model comparison

For complex hierarchical models like those considered in this paper, the computation of Bayes factors often used for model comparison, see for example Kass and Raftery (1995), requires

substantial efforts, see Han and Carlin (2001). Therefore, we consider model choice criteria and scoring rules which can be easily computed using the available MCMC output here. In this paper only nested models are compared, however, the criteria presented in this section also can be used for comparing non nested models.

3.1 Deviance Information Criterion (DIC) and Predictive Model Choice Criterion (PMCC)

The deviance information criterion (DIC), suggested by Spiegelhalter et al. (2002), for a probability model $p(\mathbf{y}|\boldsymbol{\theta})$ with observed data $\mathbf{y} = (y_1, \dots, y_n)$ is defined by

$$DIC := E[D(\boldsymbol{\theta}|\mathbf{y})] + p_D.$$

It considers both model fit as well as model complexity. The goodness-of-fit is measured by the posterior mean of the Bayesian deviance $D(\boldsymbol{\theta})$ defined as

$$D(\boldsymbol{\theta}) = -2 \log p(\mathbf{y}|\boldsymbol{\theta}) + 2 \log f(\mathbf{y})$$

where $f(\mathbf{y})$ is some fully specified standardizing term. Model complexity is measured by the effective number of parameters p_D defined by

$$p_D := E[D(\boldsymbol{\theta}|\mathbf{y})] - D(E[\boldsymbol{\theta}|\mathbf{y}]).$$

According to this criterion the model with the smallest DIC is to be preferred. Using the available MCMC output both p_D and DIC are easily computed by taking the posterior mean of the deviance $E[D(\boldsymbol{\theta}|\mathbf{y})]$ and the plug-in estimate of the deviance $D(E[\boldsymbol{\theta}|\mathbf{y}])$. We will compute the DIC with the standardizing term $f(\mathbf{y})$ set equal to zero. An information theoretic discussion of the DIC as criterion for posterior predictive model comparison is given in van der Linde (2005). A related approach for model comparison is given by the predictive model choice criterion (PMCC) considered by Laud and Ibrahim (1995) and Gelfand and Ghosh (1998). It is based on the posterior predictive distribution given by $p(\mathbf{y}_{rep}|\mathbf{y}) = \int p(\mathbf{y}_{rep}|\boldsymbol{\theta})p(\boldsymbol{\theta}|\mathbf{y})d\boldsymbol{\theta}$ where $\mathbf{y}_{rep} = (y_{rep,1}, \dots, y_{rep,n})$ denotes a new, replicated data set. Here \mathbf{y}_{rep} and \mathbf{y} are assumed to be independent given $\boldsymbol{\theta}$. The posterior predictive distribution can be estimated by $\hat{p}(\mathbf{y}_{rep}|\mathbf{y}) := \frac{1}{R} \sum_{j=1}^R p(\mathbf{y}|\hat{\boldsymbol{\theta}}^j)$ where $\hat{\boldsymbol{\theta}}^j, j = 1, \dots, R$ denotes the j -th MCMC iterate of $\boldsymbol{\theta}$ after burnin. The PMCC is defined by

$$PMCC := \sum_{i=1}^n (\mu_i - y_i)^2 + \sum_{i=1}^n \sigma_i^2, \tag{3.7}$$

where $\mu_i := E(y_{rep,i}|\mathbf{y})$ and $\sigma_i^2 := Var(y_{rep,i}|\mathbf{y})$ denote the expected value and the variance of a replicate $y_{rep,i}$ of the posterior predictive distribution. Similar to the DIC, models with a smaller value of the PMCC are preferred. While the first term $\sum_{i=1}^n (\mu_i - y_i)^2$ gives a goodness-of-fit measure which will decrease with increasing model complexity, the second term $\sum_{i=1}^n \sigma_i^2$ can be considered as penalty term which will tend to be large both for poor and overfitted models, see

Gelfand and Ghosh (1998). The quantities μ_i and σ_i^2 can be estimated based on the MCMC output $\hat{\boldsymbol{\theta}}^j, j = 1, \dots, R$ by $\hat{\mu}_i := \frac{1}{R} \sum_{j=1}^R \mu_i(\hat{\boldsymbol{\theta}}^j)$ and $\hat{\sigma}_i^2 := \frac{1}{R} \sum_{j=1}^R \sigma_i^2(\hat{\boldsymbol{\theta}}^j)$, where $\mu_i(\boldsymbol{\theta})$ and $\sigma_i^2(\boldsymbol{\theta})$ denote the mean and the variance of the underlying model $p(\mathbf{y}|\boldsymbol{\theta})$ depending on the parameters $\boldsymbol{\theta}$. When the mean $\mu_i(\boldsymbol{\theta})$ and the variance $\sigma_i^2(\boldsymbol{\theta})$ of the model are not explicitly available, the PMCC can be alternatively evaluated using simulation. For every MCMC iteration $j = 1, \dots, R$ after burnin, a replicated data set $\mathbf{y}_{rep}^j = (y_{rep,1}^j, \dots, y_{rep,n}^j)$ can be simulated from $p(\mathbf{y}|\hat{\boldsymbol{\theta}}^j)$. The mean μ_i and the variance σ_i^2 can then be estimated by the empirical counterparts $\hat{\mu}_i := \frac{1}{R} \sum_{j=1}^R y_{rep,i}^j$ and $\hat{\sigma}_i^S := \frac{1}{R-1} \sum_{j=1}^R (y_{rep,i}^j - \hat{\mu}_i)^2$. In the application given in Section 4 we will use the PMCC for comparing models for individual, average and total claim sizes. Since the mean $\mu_i(\boldsymbol{\theta})$ and the variance $\sigma_i^2(\boldsymbol{\theta})$ are explicitly given in the models for the number of claims and for the individual and average claim sizes, we will compute the PMCC directly using the MCMC output for these models. The distribution of the total claim sizes however, is not available in an analytically closed form, therefore here, the PMCC will be evaluated using simulation as described above.

3.2 Scoring rules for continuous variables

Gneiting and Raftery (2005) consider scoring rules for assessing the quality of probabilistic forecasts. A scoring rule assigns a numerical score based on the forecast of the predictive distribution of a specific model and the value that was observed and can be used for comparing the predictive distribution of several models. Ideally, both calibration and sharpness of the predictive distribution are taken into account.

Gneiting and Raftery (2005) also use scoring rules in estimation problems for assessing the optimal score estimator for the unknown model parameters. Assume a parametric model $P_\theta := p(\mathbf{y}|\boldsymbol{\theta})$ with parameters $\boldsymbol{\theta}$ based on the sample $\mathbf{y} = (y_1, \dots, y_n)$. Then, the mean score

$$S_n(\boldsymbol{\theta}) = \frac{1}{n} \sum_{i=1}^n S(P_\theta, y_i)$$

can be taken as a goodness-of-fit measure, where S is a strictly proper scoring rule, i.e. the highest score is obtained for the true model. For details on strictly proper and proper scoring rules see Gneiting and Raftery (2005). Since for the true parameter vector $\boldsymbol{\theta}_0$, see Gneiting and Raftery (2005),

$$\operatorname{argmax}_{\boldsymbol{\theta}} S_n(\boldsymbol{\theta}) \rightarrow \boldsymbol{\theta}_0, n \rightarrow \infty,$$

the optimum score estimator based on scoring rule S is given by $\hat{\boldsymbol{\theta}}_n = \operatorname{argmax}_{\boldsymbol{\theta}} S_n(\boldsymbol{\theta})$. We will use scoring rules in a Bayesian context as measures for comparing models based on their posterior predictive distribution. Gneiting and Raftery (2005) provide and discuss several scoring rules, we will present some of the proper scoring rules for continuous variables here. In particular we consider the logarithmic score (LS), the continuous ranked probability score (CRPS), the interval score (IS) and a score for quantiles which we will denote as quantile score (QS). All these scores are positively oriented, i.e. the model with the highest mean score $S_n(\boldsymbol{\theta})$ is favoured.

The logarithmic score LS is given by

$$LS(P_\theta, y_i) := \log p(y_{rep} = y_i | \mathbf{y}),$$

where $p(y_{rep} = y_i | \mathbf{y})$ denotes the posterior predictive density at $y_{rep} = y_i$ of the model under consideration. When a sample of MCMC iterates $\hat{\theta}^j, j = 1, \dots, R$ after burnin is available, an approximation of $\log p(y_{rep} = y_i | \mathbf{y})$ for the i -th observation is straightforward, i.e.

$$\hat{\log} p(y_{rep} = y_i | \mathbf{y}) := \frac{1}{R} \sum_{j=1}^R \log p(y_i | \hat{\theta}^j),$$

where $p(y | \hat{\theta}^j)$ denotes the density at the observed value y based on the j -th MCMC iterates. In contrast to the logarithmic score which only considers the posterior predictive density evaluated at the observed value, the following scoring rules take both calibration and sharpness into account.

The continuous ranked probability score CRPS for a parametric model P_θ with posterior predictive cumulative density function (cdf) $F(x) := \int_{-\infty}^x p(\tilde{y} | \mathbf{y}) d\tilde{y}$ is defined by

$$CRPS(P_\theta, y_i) = - \int_{-\infty}^{\infty} (F(x) - 1\{x \geq y_i\})^2 dx,$$

where $1\{x \geq y\}$ takes the value 1 if $x \geq y$ and 0 otherwise. Hence, the CRPS can be interpreted as the integrated squared difference between the predictive and the empirical cdf based on the single observation y_i . A graphical illustration of the CRPS is presented in Figure 3.2 when P_θ is a normal distribution with mean θ_1 and variance θ_2 . Here the pdf of a normal distribution

Figure 1: Pdf (left column with $y = 0, 2$ indicated as dashed lines) and cdf of a normal distribution with mean 0 and standard deviation 1 (first row) and 4 (second row), respectively. The differences between the cdf and the empirical cdf for two observations $y = 0$ (middle) and $y = 2$ (right) are indicated as dashed regions.

with mean 0 and standard deviation 1 (left panel in first row) and 4 (left panel in second row)

respectively is plotted. The difference between the corresponding cdf and the empirical cdf for two observations $y = 0$ and $y = 2$ is indicated in the middle and right plot of each row as dashed regions. These plots show that the CRPS rewards sharp distributions, but also takes into account if the observation y is close to the center or rather in the tails of the distribution. According to Székely (2003) the CRPS can be expressed as

$$CRPS(P_\theta, y_i) = \frac{1}{2}E|y_{rep,i} - \tilde{y}_{rep,i}| - E|y_{rep,i} - y_i|. \quad (3.8)$$

Here $y_{rep,i}, \tilde{y}_{rep,i}$ are independent replicates from the posterior predictive distribution $p(\cdot|\mathbf{y})$ and the expectation is taken with respect to $p(\cdot|\mathbf{y})$. Estimation of the CRPS is again straightforward using the available MCMC output: for $j = 1, \dots, R$ simulate independently two replicated data sets $\mathbf{y}_{rep}^j = (y_{rep,1}^j, \dots, y_{rep,n}^j), \tilde{\mathbf{y}}_{rep}^j = (\tilde{y}_{rep,1}^j, \dots, \tilde{y}_{rep,n}^j)$ based on the distribution $p(\mathbf{y}|\hat{\theta}^j)$ and estimate the mean formula in (3.8) by $\hat{E}|y_{rep,i} - \tilde{y}_{rep,i}| := \frac{1}{R} \sum_{j=1}^R |y_{rep,i}^j - \tilde{y}_{rep,i}^j|$ and $\hat{E}|y_{rep,i} - y_i| := \frac{1}{R} \sum_{j=1}^R |y_{rep,i}^j - y_i|$.

The interval score IS_α is based on the $(1 - \alpha)$ 100 % posterior prediction interval defined by $I = [l_i, u_i]$ where l_i and u_i denote the $\frac{\alpha}{2}$ and $1 - \frac{\alpha}{2}$ quantile of the posterior predictive distribution for the i -th observation. It rewards narrow prediction intervals and assigns a penalty for observations which are not covered by the interval. The interval score is defined by

$$IS_\alpha(l_i, u_i, y_i) = \begin{cases} -2\alpha(u_i - l_i) - 4(l_i - y_i) & \text{if } y_i \leq l_i \\ -2\alpha(u_i - l_i) & \text{if } l_i \leq y_i \leq u_i \\ -2\alpha(u_i - l_i) - 4(y_i - u_i) & \text{if } y_i \geq u_i \end{cases} .$$

Using the available MCMC output, replicated data sets $\mathbf{y}_{rep}^j = (y_{rep,1}^j, \dots, y_{rep,n}^j), j = 1, \dots, R$, can be simulated from which l_i and $u_i, i = 1, \dots, n$ can be determined. In order to compare models based on prediction intervals with both moderate and large coverage, we will use $\alpha = 0.1$ and $\alpha = 0.5$, respectively.

As will be seen in the application, the posterior predictive distribution of the total claim size in car insurance typically has most of its mass at zero. In particular, zero will in general be included in the posterior prediction intervals and the interval score will not be appropriate for model comparison. Here one sided scores might be more interesting to investigate. Gneiting and Raftery (2005) propose a proper scoring rule based on the quantiles $r_{\alpha,i}$ at level $\alpha \in (0, 1)$ of the predictive distribution for the i -th observation given by

$$S(r_{\alpha,i}, y_i) = \alpha s(r_{\alpha,i}) + (s(y_i) - s(r_{\alpha,i}))1\{y_i \leq r_{\alpha,i}\} + h(y_i)$$

for a nondecreasing function s and h arbitrary. We will use this score with the special choice $s(x) = x$ and $h(x) = -\alpha x$ and refer to the resulting scoring rule as quantile score QS_α which is given by

$$QS_\alpha(r_{\alpha,i}, y_i) = (y_i - r_{\alpha,i})[1_{\{y_i \leq r_{\alpha,i}\}} - \alpha].$$

Analogous to the interval score, the α -quantile $r_{\alpha,i}$ of the posterior predictive distribution can be computed based on the MCMC output and evaluation of the quantile score is straightforward.

The predictive model choice criterion PMCC discussed in the previous section, can be expressed as a scoring rule as well. The corresponding positively oriented score function is defined by

$$S(P_\theta, y_i) = -(E(y_{rep,i}|\mathbf{y}) - y_i)^2 - Var(y_{rep,i}|\mathbf{y}).$$

However, this is not a proper scoring rule, see Gneiting and Raftery (2005) and should be used with care.

4 Application

The models described in the previous section will now be used to analyse a data set from a German car insurance company. Our main questions of interest for this application are the followings: does the inclusion of spatial effects, after having adjusted for covariate information, improve the models and can we observe a spatial pattern for the expected number of claims and the expected claim sizes? Do the individual and average claim sizes of a policyholder depend on the number of observed claims, i.e. are there significant number of claims effects for the models for claim size? Based on the models for the number of claims and claim size, we finally approximate the posterior predictive distribution of the total claim sizes. Here again, we are interested, to what extent the inclusion of spatial and claim number effects influences the total claim sizes. Should we prefer models for the individual or the average claim sizes?

4.1 Data description

The data set contains information about policyholders in Germany with full comprehensive car insurance within the year 2000. Not all policyholders were insured during the whole year, however the exposure time t_i of each policyholder is known. Several covariates like age and gender of the policyholder, kilometers driven per year, type of car and age of car are given in the data. The deductible which differs between policyholders will also be included as covariate. Germany is divided into 440 regions, for each policyholder the region he is living in is known. We analyse a subset of these data, in particular we only consider traffic accident data for policyholders with three types of midsized cars. The resulting data set contains about 350000 observations. There is a very large amount of observations with no claim in the data set and the maximum number of observed claims is only 4, see Table 1.

The histogram of the observed positive individual claim sizes in DM given in Figure 4.1 reveals that the distribution of the claim sizes is highly skewed. The average individual claim size is given by DM 5371.0, the largest observed claim size takes the value DM 49339.1 which is less than 0.01 % of the sum of all individual claim sizes. Therefore, the use of a Gamma model seems to be justified.

For an increasing number of observed claims, the average individual claim sizes decrease, see Table 2, indicating a negative correlation between claim size and the number of claims.

number of claims	percentage of observations
0	0.960
1	0.039
2	$6.9 \cdot 10^{-4}$
3	$1.7 \cdot 10^{-5}$
4	$2.8 \cdot 10^{-6}$

Table 1: Summary of the observed claim frequencies in the data

Figure 2: Histogram of the observed positive individual claim sizes.

4.2 Modelling claim frequency

We first address the modelling of claim frequency. In order to identify significant covariates and interactions, the data set is analysed in Splus first using a Poisson model without spatial effects. The obtained covariates specification is then used as a starting specification for our MCMC algorithms. An intercept, seventeen covariates like age, gender of the policyholders or mileage and interactions were found to be significant for explaining claim frequency. However, for reasons of confidentiality no details about these covariates and their effects will be reported. In order to obtain low correlations between covariates, we use centered and standardized covariates throughout the whole application. Since Germany is divided into 440 irregular spaced regions, 440 spatial effects are introduced for the MCMC analysis. We are interested in spatial effects after adjusting for population effects, therefore the population density in each region is included as covariate as well. In particular the population density is considered on a logarithmic scale which turned out to give the best fit in the initial Splus analysis.

The MCMC algorithm for the spatial Poisson regression model introduced in Section 2.1, is run

	all observations	$N_i = 1$	$N_i = 2$	$N_i = 3$	$N_i = 4$
mean	5371.0	5389.9	4403.8	3204.2	330.5

Table 2: Mean of the observed individual claim sizes taken over all observations and over observations with $N_i = k, k = 1, 2, 3, 4$ observed claims separately.

for 10000 iterations, a burnin of 1000 iterations is found to be sufficient after investigation of the MCMC trace plots. We assume both a model including and without spatial effects, both containing the same covariates, and compare them using the DIC and the PMCC. Although the effective number of parameters p_D increases from 16.0 to 98.2, the improvement in the goodness-of-fit expressed by the posterior mean of the deviance $E[D(\boldsymbol{\theta}|\mathbf{y})]$, leads to a lower value of the DIC when spatial effects are included (see Table 3). This shows that, after taking the information given by the covariates into account, there is still some unexplained spatial heterogeneity present in the data which is captured by the spatial effects. Although the inclusion of the population density in each region allows for geographic differences already, spatial random effects still have a significant influence on explaining the expected number of claims. The PMCC given in the Table 3 as well confirms these results.

γ	DIC	$E[D(\boldsymbol{\theta} \mathbf{y})]$	p_D	PMCC	$\sum_{i=1}^n (\mu_i - y_i)^2$	$\sum_{i=1}^n \sigma_i^2$
no	122372	122356	16.0	28624	14297	14328
yes	122143	122045	98.2	28613	14280	14334

Table 3: DIC, posterior mean of the deviance $D(\boldsymbol{\theta}|\mathbf{y})$, effective number of parameters p_D and PMCC, split in its two components, for the Poisson models for claim frequency with and without spatial effects γ .

The left panel in the top row in Figure 3 shows a map of the estimated posterior means of the spatial effects, ranging from -0.441 to 0.285. The corresponding posterior means of the risk factors $\exp(\gamma_i)$ for the minimum and maximum spatial effects are given by 0.65 and 1.34. A trend from the east to the west of Germany is visible for the spatial effects, the risk for claims tends to be lower in the east and increases towards the south western regions. A map of the 80 % credible intervals for the spatial effects is given by the right panel. For the eastern and south western regions significant spatial effects are present, whereas the spatial effects for the regions in the middle of Germany do not significantly differ from zero.

4.3 Modelling the average claim size

In this section the average claim sizes $S_i := \sum_{k=1}^{N_i} S_{ik}$ are analysed using the spatial Gamma regression Model (2.5), i.e. $S_i|N_i \sim \text{Gamma}(\mu_i^{SA}, N_i v)$ with mean specification (2.6). Considering only observations with a positive number of claims, altogether 14066 observations are obtained. Again, significant covariates and interactions are identified by analysing the data in Splus first, assuming a Gamma model without spatial effects. An intercept and fourteen covariates including gender, type and age of car as well as the population density in each region, modelled as polynomial of order four, have been found to have significant influence. Further, the observed number of claims N_i is included as covariate. Since the highest number of claims is four, the number of claims is treated as a factor with three levels where $N_i = 1$ is taken as reference level. These covariates will be taken into account when analysing the data set using MCMC.

number of claims

average claim size

individual claim size

Figure 3: Map of the estimated posterior means (left) together with map of the 80 % credible intervals (right) for the spatial effects in the Poisson (top row), average (middle row) and individual (bottom row) claim size regression model. For grey regions, zero is included in the credible interval, black regions indicate strictly positive, white regions strictly negative credible intervals.

Therefore, including spatial and number of claims effects the mean μ_i^{SA} is specified by

$$\mu_i^{SA} = \exp(\tilde{\mathbf{w}}_i' \boldsymbol{\alpha}^A + \zeta_{R(i)}^A) = \exp\left(\sum_{k=1}^{15} \tilde{w}_{ik} \alpha_k^A + n_{2i} \alpha_{N_i=2}^A + n_{3i} \alpha_{N_i=3}^A + n_{4i} \alpha_{N_i=4}^A + \zeta_{R(i)}^A\right)$$

where $n_{ki} = \begin{cases} 1, & N_i = k \\ 0, & \text{otherwise} \end{cases}$. We consider both models with and without number of claims effects $\alpha_{N_i=k}^A, k = 2, 3, 4$ in the following, to quantify the influence of these effects. The MCMC sampler for Model (2.5) including and without spatial effects and the observed number of claims is run for 10000 iterations. Again a burnin of 1000 is found to be sufficiently large. Models are compared using the DIC, the PMCC and some of the scoring rules given in Section 3. The lowest value of the DIC is obtained for the model both including N_i and spatial effects (see Table 4). Although the increase of the estimated effective number of parameters is very small when the number of claims is included as covariate, the values of the posterior mean of the deviance decreases by 28 and 40 in the model with and without spatial effects respectively, indicating a significant improvement. The results for the scoring rules and the PMCC, divided into its two components, see (3.7), are reported in Table 4 as well. The computation of the DIC, the PMCC and the scores is based on 5000 iterations of the MCMC output, the first 5000 iterations are neglected. Note, that the computation of the interval score IS_α and the continuous ranked probability score CRPS is based on simulated data, whereas the logarithmic score LS and the PMCC are calculated directly using the MCMC output. For the logarithmic score LS, the interval score IS_α and the CRPS the highest mean score $S_n(\boldsymbol{\theta})$ is obtained for the model including spatial effects and number of claims effects. This confirms the significance of spatial and number of claims effects. According to the negatively oriented PMCC the spatial models also are to be preferred to the non-spatial ones. However, lower values of the PMCC are obtained for the models without number of claims effects which is mainly caused by the second term of the PMCC. Here it should be kept in mind, that the PMCC is not a proper scoring rule as noted in Section 3.2.

A map of the posterior means and the 80 % credible intervals of the spatial effects for the model both including spatial effects and N_i is given in the middle row in Figure 3. Similar results are obtained for the model without N_i . The estimated posterior means of the risk factors $\exp(\gamma_i)$ for the minimum and maximum spatial effects range from 0.81 to 1.13. Contrary to the estimated spatial effects for claim frequency, the average claim size tends to be higher for some regions in the east of Germany, whereas for regions in the south western part lower claim sizes are to be expected. Again, according to the 80 % credible intervals, the spatial effects are only significant for some regions in the east and the south west of Germany.

The estimated posterior means together with 95 % credible intervals of the number of claims effects $\alpha_{N_i=k}^A, k = 2, 3, 4$ are reported in Table 5. For an easier interpretation of the results we also give the estimated posterior means of the factors $\exp(\alpha_{N_i=k}^A), k = 2, 3, 4$ which quantify the relative risk in contrast to observations with the same covariates but only one observed claim. Compared to a policyholder with one observed claim, the expected average claim size for an

Table 4: DIC, posterior mean of the deviance $D(\boldsymbol{\theta}|\mathbf{y})$, effective number of parameters p_D and mean score $S_n(\boldsymbol{\theta})$ for scoring rules LS, IS_α ($\alpha = 0.5, 0.1$), CRPS and PMCC, split in its two components, for the models including and without spatial and claim number effects. In the top tables results for the average claim size models, in the lower tables results for the individual claim size models are given.

observation with two observed claims decreases by about 25 %. If three or four claims have been reported, the expected average claim size even decreases by about 75 % and 92 %, respectively.

4.4 Modelling individual claim sizes

Now, the individual claim sizes $S_{ik}, k = 1, \dots, N_i, i = 1, \dots, n$ will be analysed directly using Model (2.2), i.e. $S_{ik}|N_i \sim \text{Gamma}(\mu_i^{SI}, v)$. This time we do not consider the data aggregated for each policyholder like in Section 4.3, but deal with N_i positive claims for every person, resulting in

Table 5: Estimated posterior means of the number of claims effects and the risk factors $\exp(\alpha_{N(i)=k}^l)$, $l = I, A$ in the Gamma model for average (top) and individual (bottom) claim sizes including spatial effects, with the 95 % credible intervals given in brackets.

14325 observations altogether. The data have again been analysed in Splus first using a Gamma model without taking spatial effects into account. Altogether an intercept and sixteen covariates, the same ones as for the average claim size and two additional interaction terms, turned out to be significant for explaining the individual claim sizes. Again, we assume both models with and without the observed number of claims N_i as a factor covariate and including and without spatial effects. When both spatial and claim number effects are included, the mean μ_i^{SI} reads

$$\mu_i^{SI} = \exp(\mathbf{w}'_i \boldsymbol{\alpha}^I + \zeta_{R(i)}^I) = \exp\left(\sum_{k=1}^{17} w_{ik} \alpha_k^I + n_{2i} \alpha_{N_i=2}^I + n_{3i} \alpha_{N_i=3}^I + n_{4i} \alpha_{N_i=4}^I + \zeta_{R(i)}^I\right).$$

10000 iterations of the MCMC algorithm are performed and a burnin of 1000 is taken. According to the DIC values for these models given in Table 4, the model fit is significantly improved by including the number of claims as covariate. Taking spatial effects into account additionally gives a better model fit. The results for the scoring rules and the PMCC are also given in Table 4. Confirming the results of the DIC, the highest mean score of scoring rules LS, IS_α and CRPS and the lowest value of the PMCC is obtained for the model both including spatial effects and number of claims effects. The estimated posterior means of the spatial effects for the model including N_i together with the 80 % credible intervals are given in the bottom row in Figure 3. The results are very similar to the findings for the average claim size in the previous section, here the minimum

and maximum posterior means of the risk factors $\exp(\gamma_i)$ are given by 0.82 and 1.14, respectively. In Table 5 the estimated posterior means together with 95% credible intervals are reported for the number of claims effects $\alpha_{N_i=k}^I$ and the relative risk factors $\exp(\alpha_{N_i=k}^I)$, $k = 2, 3, 4$, in the model including spatial effects. The effects are significant for all levels, indicating a decrease of the expected individual claim sizes for an increasing number of claims. Note, that in comparison to the results for the average claim size where the factor $\exp(\alpha_{N_i=3}^A)$ for observations with three claims was estimated by 0.146, the factor $\exp(\alpha_{N_i=3}^I)$ for the individual claim sizes is estimated by 0.575, resulting in a considerably lower decrease of the expected individual claim sizes. A direct comparison of the models for average and individual claim sizes based on the DIC, the PMCC or the scoring rules is not possible, since the average claim size models are based on aggregated data resulting in less observations. However, qualitatively the findings are very similar, in both approaches the best model fit is obtained when both spatial and claim number effects are taken into account.

4.5 Posterior predictive distribution of the total claim size

The distribution of the total claim sizes is not available analytically, but can be determined numerically using recursion formulas going back to Panjer (1981) when independence of claim size and claim frequency is assumed. In our approach the independence assumption is violated, however, based on the MCMC output of the models for the number of claims and claim size the posterior predictive distribution of the total claim size can be approximated. For this independence of claim size and the number of claims is not required. In the following we describe how the total claim size $S_i^T = \sum_{k=1}^{N_i} S_{ik}$ for policyholder $i = 1, \dots, n$ can be simulated based on the MCMC output. Let $\hat{\beta}^{Nj}$, $\hat{\gamma}^{Nj}$, $\hat{\alpha}^{Aj}$, $\hat{\zeta}^{Aj}$, $\hat{\alpha}^{Ij}$, $\hat{\zeta}^{Ij}$, $j = 1, \dots, R$ denote the MCMC draws after burnin for the regression parameters and spatial effects of the claim frequency and claim size models, respectively. The quantities \hat{v}^{Aj} and \hat{v}^{Ij} denote the MCMC draws of v in the Gamma model for average and individual claim sizes, respectively. Then, for models based on the average claim sizes, proceed as follows. For $j = 1, \dots, R$

- simulate $N_i^j \sim \text{Poisson}(\hat{\mu}_i^{Nj})$ where $\hat{\mu}_i^{Nj} := t_i \exp(\mathbf{x}_i^{Nj} \hat{\beta}^{Nj} + \hat{\gamma}_{R(i)}^{Nj})$
- if $N_i^j = 0$ set $S_i^{Tj} = 0$
- otherwise simulate:
 $S_i^j \sim \text{Gamma}(\hat{\mu}_i^{SAj}, \hat{v}^{Aj} N_i^j)$ where $\hat{\mu}_i^{SAj} := \exp(\tilde{\mathbf{w}}_i' \hat{\alpha}^{Aj} + \hat{\zeta}_{R(i)}^{Aj})$ and set $S_i^{Tj} := N_i^j \cdot S_i^j$

Based on the models for individual claim sizes, the simulation of the total claim size changes to: for $j = 1, \dots, R$

- simulate $N_i^j \sim \text{Poisson}(\hat{\mu}_i^{Nj})$ where $\hat{\mu}_i^{Nj} := t_i \exp(\mathbf{x}_i^{Nj} \hat{\beta}^{Nj} + \hat{\gamma}_{R(i)}^{Nj})$
- if $N_i^j = 0$ set $S_i^{Tj} = 0$

- otherwise simulate for $k = 1, \dots, N_i^j$:

$$S_{ik}^j \sim \text{Gamma}(\hat{\mu}_i^{SIj}, \hat{v}^{Sj}) \text{ where } \hat{\mu}_i^{SIj} := \exp(\mathbf{w}'_i \hat{\boldsymbol{\alpha}}^{Ij} + \hat{\zeta}_{R(i)}^{Ij}) \text{ and set } S_i^{Tj} := \sum_{k=1}^{N_i^j} S_{ik}^j$$

Thus, a sample $S_i^{Tj}, j = 1, \dots, R$ of the total claim size S_i^T is obtained by which the posterior predictive distribution of S_i^T can be approximated. In order to compare the simulated total claim sizes S_i^T based on the different models for claim size and claim frequency, we compute the continuous ranked probability score CRPS and the predictive model choice criterion PMCC. The DIC and the logarithmic score cannot be computed here, since they are based on the explicit form of the total claim size distribution which is not available. The interval score will also be omitted out of the following reasons: Due to the large amount of observations with zero claims in our data set, the percentage of simulations with total claim size equal to zero is also very high. Zero will be included in the $(1 - \alpha)$ 100 % posterior predictive intervals of the total claim sizes for $\alpha = 0.5, 0.1$ for almost all observations. Therefore only observations falling above the upper quantiles of the prediction intervals would be considered as outliers and be penalized. Hence, the use of the interval score will not be appropriate any more. Instead we consider one-sided quantities here like the quantiles r_α at level $\alpha = 0.95, 0.99$ and the number of observations falling above these quantiles and compute the quantile score QS_α described in Section 3.2 for $\alpha = 0.95, 0.99$. Both the scores as well as the PMCC are computed using 5000 simulations of the total claim sizes S_i^T .

The results for the simulations based on models for the average and the individual claim sizes, reported in Tables 6 and 7, are qualitatively the same.

The PMCC favours the simulations based on the models including spatial effects for the number of claims only, further better results are achieved when number of claims effects are taken into account. This is caused especially by the second term of the PMCC, representing the model variances, which are considerably lower when the number of claims is included as covariate in the claim size models.

The mean scores for the CRPS and the quantile scores $QS_\alpha, \alpha = 0.95, 0.99$, are very close for all models, in general slightly higher scores are obtained for simulations based on a spatial Poisson model for the number of claims. Further, the simulations based on a spatial model for both claim frequency and claim size and including number of claims effects tend to achieve the highest score. The size of the quantiles seems to be mainly determined by the inclusion or neglect of spatial effects in the Poisson model for the number of claims. The quantiles at level $\alpha = 0.95$ are higher when spatial effects are included on the number of claims, reflecting a higher model complexity. The percentage of observations falling above the 95 % quantile ranges from 3.60 % to 3.65 %, lying below the expected 5 %. This might be caused by the fact noted already above. Since for some observations even the 95 % quantile will be only zero, a zero observation will not be regarded as an outlier. This might be overcome by randomizing zero observations, i.e. considering zero observations as outliers with a certain probability when the 95 % quantile takes the value zero. The 99% quantiles in contrast, are slightly higher when no spatial Poisson models are assumed, the percentage of outliers is close to the expected 1 %. Comparing the

Table 6: In the upper table the PMCC, split in its two components is given for several models for the simulated total claim sizes S_i^T , based on models for average claim sizes. In the lower table the mean score $S_n(\boldsymbol{\theta})$ for the CRPS, the 95 and 99 % quantiles, the percentage of observations lying above these quantiles and the corresponding quantile mean scores QS_α , $\alpha = 0.95, 0.99$, are given.

results in Tables 6 and 7, no significant difference is observed for the CRPS and the quantile scores between the simulations based on average and individual claim sizes, respectively. When number of claims effects are included, better values of the PMCC are obtained when models for the average claim sizes are assumed. Without number of claims effects in contrast, the PMCC gives a slight preference to simulations based on individual claim sizes. Hence, although more detailed data information is available for the individual claim size models, this additional knowledge has no significant influence on the prediction of the total claim sizes, at least when number of claims effects are taken into account.

Table 7: In the upper table the PMCC, split in its two components is given for several models for the simulated total claim sizes S_i^T , based on models for individual claim sizes. In the lower table the mean score $S_n(\boldsymbol{\theta})$ for the CRPS, the 95 and 99 % quantiles, the percentage of observations lying above these quantiles and the corresponding quantile mean scores QS_α , $\alpha = 0.95, 0.99$, are given.

$\frac{1}{R} \sum_{j=1}^R S_i^{Tj}$ of the simulated total claim sizes, averaged over each region, are given. Since we only consider the posterior predictive mean of the simulated total claim sizes, it is natural that the map displaying the true total claim sizes shows more extreme values. Hence, for a better visual comparison of the maps, we have built six classes for the total claim size in these plots, assuming equal length for the four middle classes, but summarizing extremely small or high values in broader classes. The simulations are based on the models for average claim sizes with the number of claims included as covariate. The plots look very similar for the simulations based on the models for the individual claim sizes. When spatial effects are included in the Poisson model (middle row), an increasing trend from the east to the west is observable for

the simulated total claim sizes. The additional inclusion of spatial effects for the average claim size leads to small changes in the very eastern and south western parts of Germany. The rough spatial structure of the observed total claim sizes (top) is represented reasonable well for these two models. However, if spatial effects are only included for the average claim sizes, the regions with high observed total claim sizes in the middle and south western parts of Germany are not detected. The same holds for the simulations based on the models without any spatial effects. For regions in the east of Germany with rather low true total claim sizes for example, the mean of the total claim sizes is estimated up to 1.27 times as high when no spatial effects at all are taken into account compared to a spatial modelling of claim frequency and claim size. For one south western region with large observed total claims in contrast, the posterior mean of the simulated total claim size based on non spatial models is only estimated 0.69 times as large compared to the simulations based on spatial models for claim frequency and claim size.

The estimated probabilities for the total claim sizes being equal to zero as well as density estimates of the positive simulated total claim sizes of the policyholders in the two regions Hannover and Lörnbach are given in Figure 5. For Hannover which is located in the northern middle part of Germany the largest posterior mean of the spatial effect in the average claim size model was estimated ($\hat{\zeta}^A = 0.12$), while in Lörnbach which is situated in the south west of Germany the smallest effect $\hat{\zeta}^A = -0.22$ was observed. The true total claim size, averaged over all policyholders in the region, is given by DM 335.0 in Hannover and DM 220.0 in Lörnbach. The estimated posterior means of the spatial effects in the Poisson model for the number of claims are given by $\hat{\gamma} = -0.10$ in Hannover and $\hat{\gamma} = 0.29$ in Lörnbach. Figure 5 shows that the estimated probability for zero total claim sizes and the density estimates of the positive total claim sizes notably change when spatial effects are included to the models for claim frequency and average claim size. In Hannover, the inclusion of spatial effects to the models for claim frequency and the average claim size leads to a higher estimated probability of zero total claim sizes and heavier tails for the estimated density of the positive total claim sizes. The posterior predictive mean of the total claim sizes, averaged over all policyholders in Hannover, takes the value 254.3 when spatial effects are included which is closer to the true total claim size than without spatial effects where the posterior predictive mean takes the value 252.3. In Lörnbach in contrast, the estimated probability for zero total claim sizes decreases and more mass is given to small positive total claim sizes when spatial effects are added. Here again the posterior predictive mean of the total claim sizes, averaged over all policyholders in Lörnbach, is closer to the true total claim size when spatial effects are taken into account (218.4) compared to simulations based on the non spatial models where the posterior predictive mean is estimated as 201.9. Ideally, when the predictive quality of models is of interest, the data should not be used twice, i.e. parameter estimation should be based on part of the data only and predictions should be done for the remaining data. Since in this section model comparison rather than prediction was focussed, all data were used for parameter estimation and simulation of the total claim sizes. However, for the sake of completeness, we also fitted the Poisson models for claim frequency and the Gamma models for the average claim size based on 75 % of the data only and simulated the

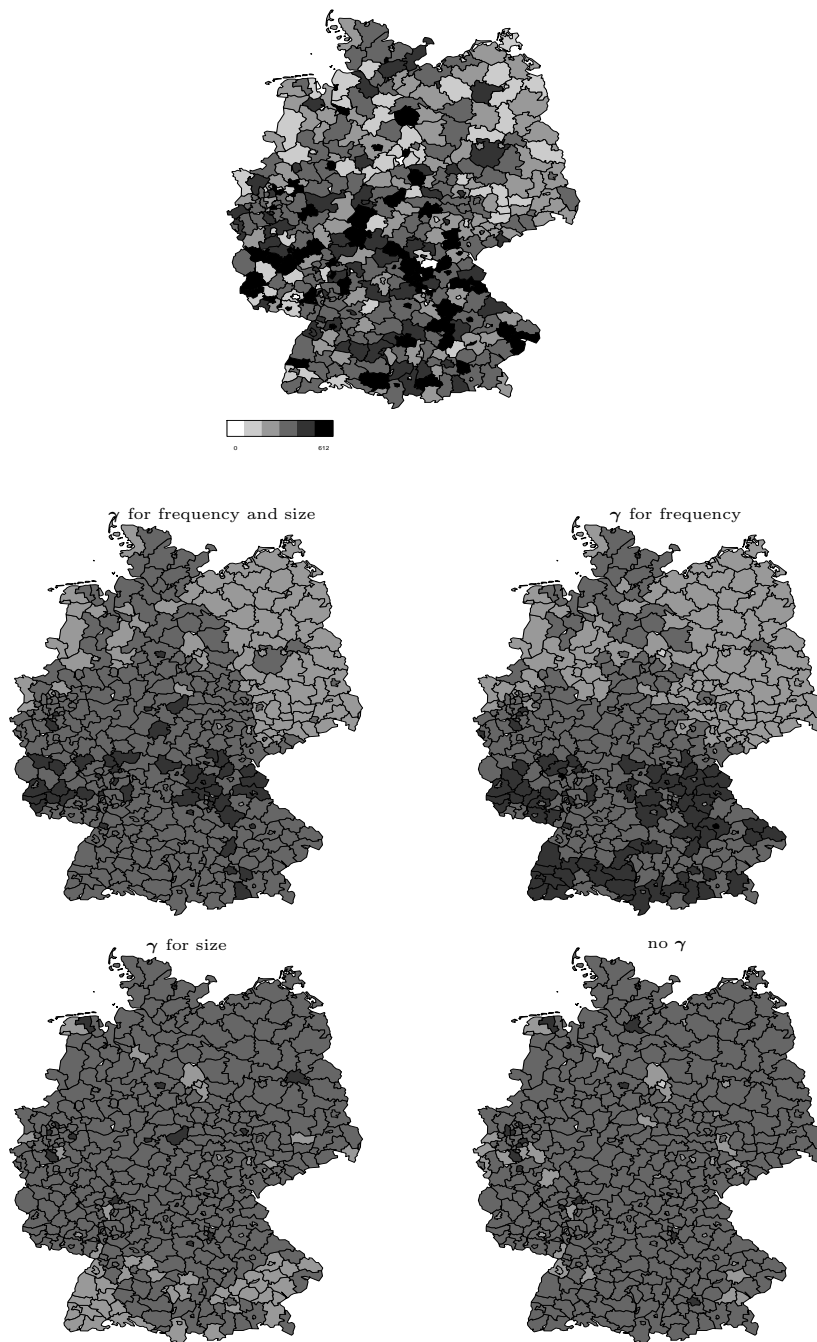

Figure 4: Observed total claim sizes (top) and posterior predictive means of the simulated total claim sizes based on Poisson and Gamma models for average claim sizes with and without spatial effects. grey level classification: $[0, 100)$, $[100, 150)$, $[150, 200)$, $[200, 250)$, $[250, 300)$, $[300, \infty)$

Figure 5: Estimated probabilities for zero total claim sizes (left panel) and density estimates of the positive total claim sizes (right panel) of the policyholders in the regions Hannover and Lörnbach based on spatial (solid lines) and non spatial (dashed lines) models for both claim frequency and average claim size.

total claim sizes for the remaining 25 % of the data. Results for the PMCC, the CRPS and the quantile scores, reported in Table 8, are qualitatively the same as observed before. The mean scores are very close for all models, the quantile scores give a slight preference to simulations based on a spatial Poisson model. Note, that the mean scores take lower values now compared to the simulations based on all data. Further, about 9 % of the observations exceed the 95 % quantile, about 2.9 % fall above the 99 % quantile. This shows, that prediction of the true total claim sizes is worse here. However, this is to be expected, since the information given in these 25 % of the data has not been accounted for in parameter estimation.

5 Summary and conclusions

We have presented a Bayesian approach for modelling claim frequency and claim size taking both covariates as well as spatial effects into account. In contrast to the common approach where independence of the number of claims and claim size is assumed, we do not need this assumption. Instead, we have shown, that by including the observed number of claims as covariate for claim size, models for claim sizes are significantly improved. If for example a policyholder caused two or three claims, the expected average claim size decreases by about 25 and 75 %, respectively, compared to a policyholder with only one claim.

We have considered models for both individual and average claim sizes, both models gave very similar results in our application to car insurance data. Based on the models for claim frequency and individual and average claim sizes, respectively, we finally approximated the posterior predictive distribution of the total claim sizes using simulation. According to several scoring rules

Table 8: PMCC, split in its two components, mean score $S_n(\boldsymbol{\theta})$ for the CRPS, the 95 and 99 % quantiles, the percentage of observations lying above these quantiles and the corresponding quantile mean scores QS_α , $\alpha = 0.95, 0.99$, for several models for the simulated total claim sizes S_i^T , based on models for average claim sizes. Parameter estimation is based on 75 % of the data, total claim sizes are simulated for remaining 25 % of the data.

and the PMCC, especially the inclusion of spatial effects in the model for claim frequency leads to improved predictions of the total claim sizes. However, the inclusion of number of claims effects in the claim size models hardly affects the total claim sizes according to the scoring rules. This can be explained by the fact, that very rarely more than one claim is simulated and therefore number of claims effects have almost no impact.

Further, the additional information available when the non-aggregated data for individual claim sizes are analysed, does not lead to better predictions of the total claim size. The modelling of average claim sizes turned out to be sufficient.

The number of claims might also be modelled using more flexible models allowing for overdis-

person like for example the negative binomial distribution, the generalized Poisson distribution introduced by Consul and Jain (1973) or zero inflated models, see Gschlößl and Czado (2005b) for more details. However, for the data set analysed in this paper, the Poisson distribution turned out to give a sufficient model fit.
