## Abstract

Professional associations and other producer groups often complain that their reputation is damaged by other groups providing a similar but lower-quality service and that the latter should be regulated. We examine the conditions under which a common regulatory regime can induce Pareto-improvements by creating a common reputation for quality among heterogeneous producers, when the regulator cannot commit to a given quality. A common reputation can be created only if the groups are not too different and if marginal cost is declining. High cost groups and small groups benefit most from forming a common regime.

JEL: L43, L44

Keywords: Quality Regulation, Licensing, Collective Reputation, Reputational Externality

Note: Preliminary. We thank the Cowles Foundation at Yale University for financial support. Guinnane thanks the National Science Foundation and the German Marshall Fund of the United States for funding his related project on German credit cooperatives.

# 1 Introduction

Many professions are subject to occupational licensing and quality regulation, with, in many cases, the standards set by the professional groups themselves. A common, perhaps majority, view among economists is that such monopoly licensing arrangements are devices to increase the incomes of the producers at the expense of the consumers. An alternative view is that if there is asymmetric information between producer and consumer then setting minimum standards can bring about a Pareto-improvement by increasing the trust that the client has in the professional: consumers are more willing to buy the service if there is less risk that the provider is incompetent or fraudulent. Evidence that, historically, producer incomes rise when licensing is introduced (see Law and Kim (2005)) is consistent with both hypotheses. An alternative solution might be for producers to develop individual reputations for high quality, but this may be inadequate in the cases of occupations, such as those of physicians or realtors, whose service is purchased infrequently or for which there are serious consequences if something goes wrong.

This still does not establish a case for state-enforced licensing or regulation. Why should the professional groups not form voluntary associations which set standards for their members to adhere to and thereby establish collective reputations<sup>1</sup> for the chosen quality? This private solution allows for the possibility that, alongside a given professional group, other groups ('para-professions') might form parallel associations which establish their own reputations for a different standard of the same, or a similar, service. Why should such groups be denied entry?

One possible answer is that there is a reputational externality: the actions of one group may damage the reputation of another group, thereby reducing overall welfare. Partly on these grounds, in the UK, physicians have objected to allowing nurses to perform procedures previously reserved for doctors and lawyers have objected to

---

<sup>1</sup>An Office of Fair Trading report on the UK estate agency (realtor) market remarked: 'Effective codes, those that have high recognition among consumers and are well enforced, should also help to marginalise rogue traders within a sector. Whole sectors of business can suffer through the behaviour of the rogue element which can damage consumer confidence.' (OFT (2004), p.112).

allowing licensed conveyancers to sell house conveyancing (escrow?) services.

The above phenomenon is not limited to groups of professionals. An historical case study which is important in the development of state-sponsored auditing requirements is that of credit cooperatives in nineteenth century Germany (Guinnane (2003)). The German credit cooperatives were divided into a number of associations, the most important of which were a primarily urban group begun in the 1850s under the leadership of Hermann Schulze-Delitzsch and an overwhelmingly rural group begun in the 1860s and associated with Friedrich-Wilhelm Raiffeisen. Like many later cooperatives, they were all small banks funded by retained earnings, member capital contributions, and deposits, but there were important differences between the groups in size, member liability, staffing, lending practices, and relationships with other financial institutions. Schulze-Delitzsch and his followers argued that all German credit cooperatives were viewed by the public as similar to each other and distinct from other financial institutions such as commercial banks; moreover, bad news about one of Raiffeisen's cooperatives could harm those in Schulze-Delitzsch's group. From the 1860s and 1870s, some cooperative groups made regular audits a condition of group membership and the Schulze-Delitzsch group campaigned for a law requiring all cooperatives to be subject to regular audits. A law was duly passed in 1889 requiring an audit every two years (by one of the private auditing associations in most cases).<sup>2</sup> This law was an important precursor of the later laws on mandatory audits of joint-stock companies. However, even after the 1889 law, each group complained that it was being damaged because the other's standards were too low.<sup>3</sup>

In effect, each group of cooperatives complained that they would like to raise their standards, but that it was too hard, given the low standards of the other group

---

<sup>2</sup>Schulze-Delitzsch regarded it as important that it should be possible for the auditing to be conducted by the associations themselves, rather than government, partly because of a fear of state expropriation, but also because of a moral hazard argument, that state monitoring would be an inferior substitute for, and drive out, self-monitoring. See Guinnane (2003).

<sup>3</sup>Similar developments took place in the US in the nineteenth century. Buildings and Loans Associations (B&Ls), predecessors of the Savings and Loans, attempted with some success to persuade states to pass laws excluding "nationals", institutions offering similar savings and loan contracts, but differently organized and operating on much larger geographical scales. The B&Ls argued that problems in the nationals would hurt the reputation and business of the B&Ls. See Snowden (2003) and Brumbaugh (1988).

- perhaps because the reputational cost of cutting quality in one group does not all fall on that group but, through the reputational externality effect, partly on the other group. However, this begs a number of questions. Firstly, why should there be any collective reputation or reputational externality? After all, as long as consumers can observe the fact that you belong to association A, the actions of members of association B should be irrelevant to your reputation. Secondly, if all producers (and consumers) can benefit from the existence of a legally-mandated common quality standard, would they not also benefit from forming a merged professional body<sup>4</sup> which imposes a common standard on all its members? In that case, those producers who chose to remain outside would suffer because they did not belong to any certifying body, so that this solution should be credible and state involvement unnecessary.

However, this in turn begs the question whether, or under what conditions, it is possible for a group of heterogeneous producers to develop a common reputation through regulation, whether private or state. Consider two groups which are homogeneous internally, but different from each other, perhaps in their cost of achieving high quality. Suppose that they decide to join a single body for the purpose of standard-setting and auditing, but that consumers can still tell which group a consumer belongs to. Suppose further that (a) the auditor chooses standards to maximize the total profits of all the producers, and (b) the auditor cannot commit in advance to the standard which he will enforce. The latter assumption stems from the supposition that the auditor has no more commitment power than the producers, and that a producer cannot commit to a given quality before supplying a service (if he could there would be no problem of asymmetric information). In that case, under what conditions is it credible that the auditor would set (as opposed to merely announcing to the public) the same standard for both types of producer? Might it not be optimal for him, even if the public believes that there is a common standard, to set a lower standard where high quality is more expensive to achieve? The same considerations may apply in the case of state regulation, particularly where, as frequently happens, the regulation is carried out by industry insiders, or where, as in our model, social surplus coincides

---

<sup>4</sup>Indeed, in the 1920s the German cooperative associations did merge into a single body.

with producer profit because producers are price-discriminating local monopolists. Where reputational externality does not exist, and the conditions do not exist for common regulation to lead to a Pareto-improving common quality, the supposition must be that the purpose of monopoly licensing is to restrict competition.

We examine these questions in the context of a dynamic model, set out in Section 2, with the following features. In each period large numbers of new consumers arrive, each of whom will live for two periods, has unit demand in each period, and observes the quality only of her own purchases (and only *ex post*). There are large numbers of long-lived small producers each of whom is a local monopolist and is matched randomly with consumers; there is no entry of producers. Thus it is not possible to develop an individual reputation for quality and the anti-competitive motivation for quality regulation is absent. Each producer belongs to one of two groups, which are distinguished by their cost of achieving high quality,  $c^q$ ; the latter cost has to be paid in a given period for quality to be high in that period. As mentioned above, consumers can tell, before buying, which group a producer belongs to, even if there is a single auditor for both groups. They do not observe the values of  $c^q$ . The auditor(s) can choose and enforce quality but cannot commit (as far as the consumer is concerned) to a given quality in advance.

We find, in Section 3, that if the two groups are heterogeneous, in the sense that their costs of high quality ( $c^q$ ) are independent random variables, then no reputational externality exists when the two groups are separately audited and regulated - in any equilibrium, a change in the quality of one group has no effect on a consumer's belief about the other group. On the other hand, every equilibrium is inefficient because of the existence of two groups: if there were a single homogeneous group with a single auditor then full efficiency could be achieved. A reputational externality does exist if the groups are homogeneous (the cost of high quality is the same for both groups). Moreover, this gives rise to a worse equilibrium than in the independent costs case if, in addition, marginal production costs are declining over the relevant range. On the other hand, there is always an equilibrium in which, because of the reputational externality, quality and profits are *higher* than in the heterogeneous case;

furthermore, the bad reputational equilibrium does not exist if marginal production cost is constant. We conclude from this that reputational externality is not a strong argument for common regulation. Even in those cases where it may lead to more inefficiency, the problem could in principle be solved by co-ordinating on a better equilibrium.

In answer to the question whether it is possible for heterogeneous groups to develop, through common regulation, a common reputation for quality, we find, in Section 4, that it is possible (and, thus, a common auditing framework can bring about a Pareto-improvement) only if (a) the two groups are not too dissimilar, in the sense that the support of  $c^q$  is not too large, and (b) if marginal production costs are declining. Given these conditions, a collective reputation can be created. The reason that marginal production costs must be declining is that, for consumers to believe that, despite heterogeneous cost of quality, the quality is the same in both groups, quality in group  $A$  must, given this belief, be a strategic complement for quality in group  $B$ . If marginal cost is declining then the fact that quality is high this period in group  $A$ , and so, given the consumers' beliefs, demand at group  $B$  will be high next period, means that the marginal benefit of setting quality high at  $B$  this period (through repeat custom for  $B$ -producers) is greater than it would be if quality were low at  $A$ . Thus, in equilibrium, high quality at one group is associated with high quality at the other, and similarly in the case of low quality.

One case in which declining marginal cost may obtain, and so common regulation is more likely to be appropriate, is the case in which learning-by-doing is important. Suppose that, because of technological progress, producers need to upgrade their skills in every period and that this takes place partly through learning-by-doing. Then, within a given period, marginal cost of producing the first units will be higher than marginal cost of producing subsequent units, at least up to a point.

We also ask, in Section 5, which groups benefit most from common regulation, in the case where common regulation can credibly lead to common standards. Does a high quality (in the sense of lower average value of  $c^q$ ) group benefit more than a low quality group? Does a small group benefit more than a large group? We find that

in the uniform case a low-quality group benefits more than a high-quality group. We also find that a small group has a lower expected profit under common regulation than a large group (because, having less weight in determining the standard, the small group is more likely to have a standard which is excessively onerous for it) but that a small group benefits more from introducing common regulation, because it is even worse off without it.

The above results are relevant in any context in which the actions of one group of agents may possibly affect the reputation of another group. For example, chains of hotels, restaurants, etc., attempt to establish reputations for a common standard of service across the whole chain. Under what conditions is it credible that such a reputation can be established for outlets in, say, different geographical regions with different costs? To take other examples, securities exchanges monitor their members to prevent fraud, universities create organizations that certify their standards, and so on.

#### *Related Literature*

There is a small theoretical literature on professional regulation. Leland (1979) analyzed professional licensing as a policy response to a lemons problem. Shaked and Sutton (1981), in a similar model, analyzed the incentives to form para-professions. Shapiro (1986) studied a moral hazard model in which licensing is viewed as a requirement for prior investment which alters the incentives to produce high quality. This differs from our model in a number of ways; for example, sellers in the Shapiro model are able to build individual reputations. Lizzeri (1999) analyzed the incentives of private intermediaries who certify quality; the focus of his paper is on strategic manipulation of information. None of these papers is concerned with collective reputation. There are three types of theory of collective reputation in the literature. Firstly, there is a multiple equilibrium theory (e.g., Arrow (1973)). Secondly, some papers (e.g., Benabou and Gertner (1993)) derive collective reputation from the existence of a common trait. Both of these phenomena are present in our analysis below of the case in which the groups have a common value of  $c^q$ . Thirdly, Tirole (1996) has

a dynamic model, partly adverse selection and partly moral hazard, in which employers can observe an agent's actions only imperfectly and cannot distinguish him from earlier generations of agents. If past generations have been corrupt trust in the agent will be low; this in turn gives the agent the incentive to behave corruptly. In this way, a reputation for corruption can persist through generations. We are concerned here with a somewhat different question: how the reputations of identifiably different groups may interact, and how regulation may create collective reputation.

## 2 The Model

There are two groups,  $A$  and  $B$ , each consisting of a continuum of risk-neutral producers of unit measure. Each group is homogeneous internally but, as we will explain below, different from the other group in its cost structure. All producers produce the same good, regardless of their group. They are not, however, in direct competition with each other: we model each individual producer as a local monopolist who is able to practice perfect price discrimination. Each producer, in each period, has a continuum of customers, each of whom has inelastic unit demand. It will be convenient to normalize so that the measure of customers (for each firm) is 4. In each period, a typical producer first chooses its quality of production. Quality can be either high or low; low quality costs zero and high quality costs  $c_i^q \geq 0$  where  $i \in \{A, B\}$  is the index of the firm's group. The cost of achieving high quality is a fixed investment cost, independent of the scale of production, and it must be paid in each period in which quality is high. For each group  $i \in \{A, B\}$ ,  $c_i^q$  is drawn at the beginning of time 1 from an atomless distribution  $F$  on  $[0, a]$ ;  $c_i^q$  is then fixed forever. The only difference between the two groups is the value of  $c_i^q$ . Our assumption for most of the paper is that  $c_A^q$  and  $c_B^q$  are independent, but we also look, in subsection 3.2, at a model in which  $c_A^q$  and  $c_B^q$  are correlated. After selecting quality for the period, the firm produces and sells quantity  $y \leq 4$  of the good (storage is not possible, so there can be no value in producing quantity higher than 4). The cost function  $c(y)$ ,

common to all firms in both groups, is given by  $c(y) = c$  if  $y \leq \lambda'$  and  $c(y) = 0$  if  $y > \lambda'$ , where  $c > 0$  and  $\lambda' > 2$ . As we will see, it will turn out to be crucial whether  $\lambda'$  is above or below 4. If  $\lambda' \geq 4$  then we effectively have constant marginal cost of production; in the other case, where  $\lambda' < 4$ , marginal cost is decreasing in the relevant range - in particular, cost of production is lower for the second half of total potential production than it is for the first half. It is convenient to define  $\lambda = \min[\lambda', 4]$ . Then  $\lambda = \lambda'$  unless we have the constant marginal cost case, in which event  $\lambda = 4$ .

Time is discrete and infinite and labeled  $t = 1, 2, \dots$ . In each period a generation of new identical risk-neutral consumers is born (we model this generation as a continuum of measure 2 for each producer) and lives for two periods. In each of these two periods, a consumer is randomly assigned (with equal probabilities) to a producer; thus, she has equal probability in each period of meeting an  $A$ -producer and a  $B$ -producer. In each of the two periods she buys and consumes at most one unit of the good. Since arrival of consumers at firms is random, each firm will have, in any period  $t \geq 2$ , a measure 2 of new-born consumers, a measure 1 of old consumers who were assigned to an  $A$ -producer last period, and a measure 1 of old consumers who were assigned to a  $B$ -producer last period. Because of our assumption that producers are small the chance of a consumer repeat-purchasing from a given producer is zero. On the other hand, there is repeat purchasing as far as a particular group is concerned (i.e., a particular customer of an  $A$ -producer may meet another  $A$ -producer later). The formulation is intended to represent a situation in which the good is purchased in a lumpy and infrequent manner, so that repeat purchasing (looked at from the perspective of a group) is present but limited; furthermore there is potential for interaction between firms in one group and firms in the other, because consumers may buy from both groups at different times.

All consumers are identical and in each period they derive utility 0 from a low-quality good and utility  $v > 0$  from a high-quality one. We assume that  $v > c$ , which ensures that there is potentially a positive surplus in any match between a producer and a consumer. A consumer knows the group identity of a producer with whom she is matched, but, at the time of buying, she cannot observe the quality of the good

- she discovers this only when she consumes it. The quality (after the fact) of her first-period purchase, if any, and the group affiliation of the firm or firms with which she has been matched are the only pieces of information which the consumer has. She cannot observe qualities produced at any firm before she was born, or, after she is born, at firms with whom she is not matched. Nor can she observe the costs,  $c_A^q$  and  $c_B^q$ , of achieving high quality.

For simplicity, we assume, as noted above, that each firm is a perfect-price-discriminating local monopolist. This means that, after choosing quality, the firm observes a given consumer  $k$ 's willingness-to-pay  $v\pi_k$ , where  $\pi_k \in [0, 1]$  is the consumer's belief that the good will be of high quality. The firm's objective is to maximize the expected present value of its profit stream, discounted by the factor  $\delta \in [0, 1)$ . Since the firm will not meet its current customers again, it has no interest in charging  $k$  less than  $v\pi_k$ . Equally, it cannot charge more since  $k$  will get no surplus in the future, and hence can have no incentive to pay extra in order, say, to learn about quality in the firm's group. Whatever its chosen quality, the firm will therefore sell, at price  $v\pi_k$ , to any customer  $k$  for whom  $v\pi_k \geq c$ , since these trades are certainly profitable. Let the measure of these customers be  $y'$ . The cost of serving the remaining customers is  $C(y') = \max[(\lambda - y')c, 0]$ . The firm will therefore sell to the remaining customers, at their respective valuations, if and only if the resulting revenue is at least  $C(y')$ . In particular, it will sell to all the remaining customers if  $y' \geq \lambda$ , so that marginal cost at  $y'$  is zero, and to none of them if  $\lambda = 4$ , which would imply that marginal cost of serving all customers is  $c$ .

For a given producer at a given period, each of its current customers' beliefs about its quality is independent of the producer's past and current decisions, because it has not served any of these customers before. Therefore its profit is independent of its chosen quality, so it is clear that it will always choose low quality as long as  $c_i^q > 0$ . Obviously this outcome is inefficient, and inferior for the producers. A natural response would be for the group to appoint an auditor, or regulator, to maintain a quality standard for the group as a whole. We assume therefore that each group has such an auditor. Our main interest will be in whether heterogeneous groups benefit

by having a common regulatory regime, so we examine two cases: (a) the *separate auditors* case, in which each group has its own distinct auditor, and (b) the *single auditor* case in which the two groups have the same auditor. An auditor is able, in each period, to choose the quality level for the whole group. In the single auditor case, the auditor chooses two levels of quality - one for group  $A$  and one for group  $B$  - which may or may not be the same.<sup>5</sup>

In modeling the auditor in this way, what we have in mind is that he is able to announce to the members of the association what the required quality is and that he has the ability credibly, at zero cost, to enforce the announced standard, by, for example, random audits and adequate sanctions. There is an issue as to whether the auditor would have the incentive after the fact to carry out the announced punishment of a producer who has been found not to meet the required standard. In this paper, however, we side-step that issue by assuming, in effect, that the auditor has the ability to commit to the sanction in advance (as in Banerjee, Besley and Guinnane (1994)). This does not mean, though, that the auditor is able to commit publicly to choosing a particular quality standard - that is, if he announces to the consumers that the quality is high, he will nevertheless choose high quality only if it is in his (and the producers') interest to do so (in particular, if the cost of high quality is not too high).

The objective of the auditor is to maximize the unweighted sum of the utilities (i.e., long-run discounted profits) of the firms which he is auditing. Since consumers earn zero surplus this is the same objective as a utilitarian social planner would pursue. Like the producers, but unlike the consumers, the auditor of group  $i$  knows the cost  $c_i^q$  of high quality. An auditor does not observe the quality in a group which he is not auditing. Although the auditor controls the quality of output, he does not control pricing or production decisions. As a result an association does not act as if it were a single firm; in particular, a producer, as noted above, will not offer low introductory prices in order to allow customers to learn about the quality.

---

<sup>5</sup>In principle, the auditor might prefer to choose different qualities for different producers in a given group. As our analysis below will show, this will not be in his interest. For the moment, we make the assumption that the auditor chooses the same quality for all producers in the same group.

### *Strategies*

In the separate auditors case, a pure strategy  $\sigma_i$  for the auditor of group  $i$  specifies, for each possible cost  $c_i^q \in [0, a]$ , a function  $\sigma_i(c_i^q)$  which maps each history of the form  $(q_1^i, q_2^i, \dots, q_{t-1}^i)$  to a choice of quality at date  $t$ ,  $q_t^i \in \{h, l\}$ . In the single auditor case, a pure strategy  $\sigma$  of the auditor specifies, for each pair  $(c_A^q, c_B^q) \in [0, a]^2$ , a function  $\sigma(c_A^q, c_B^q)$  mapping each history  $(q_1^A, q_1^B; q_2^A, q_2^B; \dots, q_{t-1}^A, q_{t-1}^B)$  to a pair of date- $t$  qualities  $(q_t^A, q_t^B)$ .

### *Beliefs*

At the point when a customer has to make her first-period decision whether to buy, a consumer has two possible first-period histories, namely  $A$  and  $B$ , i.e., all she knows is the group identity of the producer. When she makes her second-period buying decision she has twelve possible second-period histories, denoted by  $(i, q; j)$  where  $i, j \in \{A, B\}$  and  $q \in \{h, l, \phi\}$ . For example,  $(A, h; B)$  refers to the history in which she meets an  $A$ -producer in her first period, buys a unit and discovers that its quality is high, and then meets a  $B$ -producer in her second period.  $(A, \phi; B)$  represents a history in which she meets an  $A$ -producer in the first period and a  $B$ -producer in the second period, and there is no sale in the first period. The beliefs of a consumer who is born in period  $t$  are denoted by  $\pi_t : \{A, B\} \rightarrow [0, 1]$  and  $\tilde{\pi}_t : H \rightarrow [0, 1]$  where  $H$  is the set of second-period histories.  $\pi_t(\cdot)$  and  $\tilde{\pi}_t(\cdot)$  give the probability, conditional on the observed history, that if she buys she will get a high quality good. We will focus below on steady-state beliefs, that is, beliefs which are not indexed by  $t$ , so that all generations have the same prior belief and the same updating rule.

### *Equilibrium*

We will examine pure-strategy, perfect Bayesian equilibria with steady-state beliefs. In the separate auditors case such an equilibrium is defined in the following way. Each generation of consumers has a common belief system  $(\pi(A), \pi(B); \tilde{\pi}(\cdot))$  and each auditor  $i \in \{A, B\}$  has a pure strategy  $\sigma_i$  such that

(i) for each  $i$ , each  $t$ , each history  $(q_1^A, q_1^B; q_2^A, q_2^B; \dots, q_{t-1}^A, q_{t-1}^B)$  and each  $c_i^q \in [0, a]$ , the continuation strategy defined by  $\sigma_i$  maximizes  $i$ 's expected continuation payoff, given  $\sigma_j$  ( $j \neq i$ ) and the belief system  $(\pi(A), \pi(B); \tilde{\pi}(\cdot))$ ; and

(ii) the belief system  $(\pi(A), \pi(B); \tilde{\pi}(\cdot))$  gives the true conditional probabilities of high quality if the auditors employ the strategy pair  $(\sigma_A, \sigma_B)$ .

Similarly, in the single auditor case, an equilibrium consists of a steady-state belief system and a pure strategy  $\sigma$  such that, firstly,  $\sigma$  is optimal for the auditor after every history given the beliefs and, secondly, the beliefs are correct given  $\sigma$ . In order to avoid complications associated with knife-edge cases, we assume that, if indifferent, the auditor always chooses high quality.

### 3 Equilibrium with Separate Auditors

#### 3.1 Independent Costs

Take an arbitrary pure steady-state equilibrium in the separate auditors case, with  $c_A^q$  and  $c_B^q$  independent, and consider the problem of the auditor of group  $i$  at an arbitrary date  $t$ . He has to decide, knowing  $c_i^q$ , whether or not to set high quality for this period. This decision has no effect on the prices paid this period by the current customers of producers in group  $i$  since they do not know the current quality at the time that they buy. Nor will it have any effect on any members of the generations born at date  $t + 1$  or later, since they do not observe anything dated before their birth. Thirdly, since any date- $t$  customer of group  $j$  will never observe the current quality in group  $i$ , the decision will have no effect on prices paid in the future by these consumers. The only effect will be on  $i$ 's repeat customers: those consumers born at date  $t$  who are customers of group  $i$  at date  $t$  and will again be customers of group  $i$  at date  $t + 1$ .

First, note that old customers of group  $i$  who were assigned to the other group ( $j$ ) in their first period do not believe that there is any correlation between quality at  $i$  this period and quality at  $j$  last period. This is because the auditor of group  $i$  at time

$t$  does not observe  $c_j^q$  or  $q_{t-1}^j$  and  $c_i^q$  is independent of  $c_j^q$ .<sup>6</sup> That is,  $\tilde{\pi}(j, h; i) = \pi(i)$  and  $\tilde{\pi}(j, l; i) = \pi(i)$ . There are two possibilities to consider: either (a)  $\tilde{\pi}(i, h; i) \leq \tilde{\pi}(i, l; i)$  or (b)  $\tilde{\pi}(i, h; i) > \tilde{\pi}(i, l; i)$ .

In case (a) the price paid at date  $t + 1$  by the repeat customers will be no higher if they get high quality at date  $t$  than if they get low quality at date  $t$ . Clearly, then, there can be no gain, and there will be a positive cost, from setting high quality at  $t$ . In that case auditor  $i$  will set low quality regardless of  $c_i^q$  (except possibly if  $c_i^q = 0$ ). Since the beliefs are the same for all generations, in this equilibrium group  $i$  always has low quality and no sale is ever made (since the customers always place value zero on the goods produced by  $i$ ). Even if there is a deviation and group  $i$  producers produce and sell high-quality goods, the repeat customers will still expect low quality next period, i.e.  $\tilde{\pi}(i, h; i) = \tilde{\pi}(i, l; i) = 0$ . It is easy to check that this is indeed an equilibrium.

In case (b) the auditor derives a benefit from the higher price paid by repeat customers next period if he sets high quality this period. He sets this benefit against the cost  $c_i^q$ . Clearly there will be a critical value  $c_i^* \geq 0$  such that he sets high quality if  $c_i^q < c_i^*$  and he sets low quality if  $c_i^q > c_i^*$ . Since the beliefs are stationary across generations the auditor faces the same problem each period, so the threshold value  $c_i^*$  is independent of history. The steady-state belief of new-borns must therefore be that the probability of high quality at group  $i$  is given by

$$\pi(i) = F(c_i^*).$$

If  $\pi(i)$  is such that there is no possibility of a profitable sale, i.e. if

$$vF(c_i^*) < c$$

then new customers will not buy and so there will be no repeat customers. In that case there will be no incentive to choose high quality and so  $c_i^* = 0$ . This is the same

---

<sup>6</sup>Even if he could observe willingness-to-pay of former  $j$ -customers (we have assumed that he cannot), the above argument would apply at date 2 if he has to choose quality before observing it. Therefore, by stationarity of beliefs, independence applies at all times.

as the equilibrium which we saw in case (a) above.

Suppose, on the other hand, that new customers do buy (so  $c_i^* > 0$ ). The same will be true of old customers who were assigned to the other group in their first period since, as we have seen, they have the same belief about  $i$  as new-borns. If a new-born customer observes high quality at  $i$  then she deduces that  $c_i^q < c_i^*$  and, by Bayes' rule, she must believe that she will again get high quality if assigned to  $i$  in her second period; similarly, if she observes low quality then she will expect low quality next period. That is,  $\tilde{\pi}(i, h; i) = 1$  and  $\tilde{\pi}(i, l; i) = 0$ .

Next period there will be a measure 3 of sales made at a representative firm (2 to new-borns and 1 to previous customers of the other group) regardless of this period's quality, and a measure 1 of additional repeat customers (paying  $v$ ) if and only if quality this period is high. Therefore the benefit of setting high quality is equal to  $\delta v$  if  $\lambda \leq 3$  and  $\delta(v - c(\lambda - 3))$  if  $\lambda > 3$ . In the first case marginal cost of production is zero, given the assured sales of 3, so the discounted marginal benefit is  $\delta v$  for each extra unit sold; in the second case, marginal cost is  $c$  until sales reach  $\lambda$ . The auditor's strategy in each period must be to set high quality if and only if  $c_i^q$  is less than or equal to the discounted marginal benefit. That is,

$$c_i^* = \min[\delta v, \delta(v - c(\lambda - 3))].$$

Since  $\lambda \leq 4$  and  $c < v$ ,  $c_i^* > 0$ . If this is to be an equilibrium it must be that new customers place value of at least  $c$  on the good. That is,

$$vF(\min[\delta v, \delta(v - c(\lambda - 3))]) \geq c. \quad (1)$$

There exist, therefore, two possibilities for each group: either there is zero probability of high quality and the market has collapsed because of low expectations, or else sales are made (at least to three-quarters of potential) and there is positive probability of high quality. In total, there are four possible equilibria since beliefs about the two groups may be asymmetric: e.g., group  $A$  may have low quality for sure while group  $B$  has positive probability of high quality. In the low-quality case the auditor achieves

nothing - the equilibrium is the same as if he did not exist. But, as long as (1) is satisfied, the auditor can improve matters. Our interest will be in equilibria in which both groups have strictly positive probability of high quality: we call these *positive-quality equilibria*.

To summarize, we have the following result.

**PROPOSITION 1:** *If there are separate auditors and independent costs, then a positive-quality equilibrium exists only if (1) is satisfied. In that case, there is a unique such equilibrium. In this equilibrium, in every period, quality in group  $i$  is high if and only if  $c_i^q \leq c_i^*$ .*

Clearly a zero-quality equilibrium is highly inefficient. The positive-quality equilibrium, however, will also be inefficient. In the first-best, high quality will be produced in steady-state as long as

$$4v - \lambda c > c_i^q \tag{2}$$

since the left side of this inequality is the total surplus (gross of  $c_i^q$ ) in the event of high quality, and there is zero surplus if low quality is produced. In equilibrium, there is high quality only if

$$\min[\delta v, \delta(v - c(\lambda - 3))] \geq c_i^q \tag{3}$$

The left side of (3) is lower than that of (2) for all  $\delta \in (0, 1]$  since  $v > c$ . Therefore quality is too low in equilibrium. Notice that this inefficiency is not caused by any reputational externality. Since the two groups are independent, and since the customers are able to distinguish one group from the other, a change in the actions of group  $A$ , say, has no effect on the payoffs of group  $B$ , since it has no effect on the beliefs of any customers about the quality of group  $B$ . If there is little discounting, the inefficiency is caused instead by the fact that only a proportion of customers of a given group will be repeat customers of that group: clearly, if there were a single group with a single auditor, the auditor would set high quality if and only if (2) is satisfied.

### 3.2 Common Costs

We assumed above that the cost of high quality in one group is independent of the cost in the other group and that an auditor does not observe quality in the other group. As a result there is no reputational externality. We suppose now that the two costs  $c_A^q$  and  $c_B^q$  are correlated and we ask two questions: (i) is there a reputational externality in this case (i.e., in equilibrium, would an increase in quality at one group increase the revenue at the other)? and (ii) if so, is such an equilibrium necessarily worse than the equilibrium in the independent costs case - in particular, can inefficiency in this model be traced to the reputational externality? In this case it is plausible that the externality would be present because observing quality at group  $A$  would tell you something about  $c_A^q$  which in turn would give you some information about  $c_B^q$  and so about likely quality at group  $B$ . See Benabou and Gertner (1993) for an application of this idea in macro-economics, and Meyer and Vickers (1997) for an application to relative performance evaluation.

The answer to (i) will be that there are indeed equilibria in which the externality is present. In particular, if marginal cost is decreasing, there is an equilibrium in which average quality is lower than in the positive-quality equilibrium in the independent case: each association has an incentive to lower quality, damaging the interest of the other group, and reducing the incentive of the other group to invest in high quality. This lends some plausibility to the claims, referred to in the Introduction, that considerations of reputation can cause inefficiency which needs to be tackled by enforcement of industry-wide standards. On the other hand, the answer to (ii) above is that the reputation effect is not intrinsically bad, because there is another equilibrium (also exhibiting a reputational externality) in which both groups use the same cut-off strategies as in the independent cost case. In that equilibrium, therefore, average quality is the same as it would be without any externality; moreover, profits are higher than in the independent cost case. Thus reputational externality is not the main issue.

For simplicity, we look at the polar case in which there is complete correlation,

i.e.,  $c_A^q = c_B^q = c^q$ . Again,  $c^q$  is assumed to be distributed according to  $F$  on  $[0, a]$ . We also assume that  $\lambda = 3$ , so that in the independent costs case the critical value  $c^* = \delta v$ . As before, we assume that an auditor cannot observe past quality at the other group, so that equilibria derived from repeated-game considerations (enforcing high quality by using punishments for low quality) are not feasible.<sup>7</sup>

PROPOSITION 2: *Suppose that there are separate auditors and common costs,  $\lambda = 3$  and*

$$vF(\delta(v - c)) \geq c. \tag{4}$$

*Then there are two positive-quality equilibria. In one equilibrium both groups use cut-off  $c^* = \delta v$  and in the other they use cut-off  $\delta(v - c)$ . The first equilibrium Pareto-dominates the second and also Pareto-dominates the positive-quality equilibrium in the independent costs case. If there are constant marginal costs ( $\lambda = 4$ ), or if (1) holds but not (4), then only the first of the two equilibria exists.*

Note that, since in this case (1) is  $vF(\delta v) \geq c$ , (4) implies (1).

First, we set out the Pareto-inferior equilibrium; in this equilibrium the reputation effect leads to low average quality. The strategy of each auditor is to set high quality if and only if  $c^q \leq \delta(v - c)$ . New born consumers all buy at price  $vF(\delta(v - c))$ . ((4) guarantees that it is profitable to sell to them). A consumer who observes high (low) quality at one group expects high (low) quality next period at both groups, hence is willing to pay  $v$  (0). Clearly the beliefs are correct given the strategies because in equilibrium each group always has the same quality as the other. If  $c^q \leq \delta(v - c)$  then  $i$  knows that next period his group will sell at least 3 units for  $c$  or more at a representative firm next period regardless of whether he sets high or low quality this period (2 to new-borns and 1 to previous  $j$ -customers). Marginal production cost will therefore be zero, so the benefit of high quality is  $\delta v$ , which exceeds  $c^q$ , hence it is optimal to set high quality. If, on the other hand,  $c^q > \delta(v - c)$  then  $i$  knows

---

<sup>7</sup>One might ask why the auditor cannot deduce what the other group's quality was by observing the willingness-to-pay of customers who have previously bought from that group. Our assumption is that only the producers, not the auditor, observe willingness-to-pay.

that  $j$ 's quality is low and that current customers of  $j$  will therefore not buy from  $i$  next period. Therefore, since  $i$ 's repeat customers, if any, will take production next period from 2 to 3, the marginal benefit of high quality this period is only  $\delta(v - c)$ , which is less than  $c^q$ , so it is optimal to set low quality. Hence, the auditor's strategy is optimal. This establishes that this is an equilibrium.

However, since (1) is satisfied, there is also an equilibrium in which both groups use the cut-off strategy defined by  $c^* = \delta v$ , i.e. the same one as in the independent costs case. In this equilibrium too, after observing the quality in one group, a consumer attaches probability one to the event that the other group produces the same quality. Thus, if  $c^q \leq c^*$  an auditor knows that next period there will be sales of 3 to new-borns and former  $j$ -customers plus, if and only if quality is high this period, repeat purchases of 1. Therefore the benefit of high quality is  $c^*$ , which outweighs the cost. If  $c^q > c^*$  then the benefit is less, so it is optimal to set low quality. As in the previous equilibrium, a reduction in quality at one group will reduce the payoff at the other, so the externality is present. However, average quality is the same as in the positive-quality equilibrium of the previous section. Moreover, average profit is higher. If costs are independent, the expected trading profit of a producer in group  $i$  (excluding investment cost) is

$$4v\pi^I - 3c$$

where  $\pi^I = F(\delta v)$  is the probability of high quality in the independent case. This is because demand from new-borns and former  $j$ -customers totals 3, paying  $v\pi^I$ , and, with probability  $\pi^I$ , there will be 1 unit of repeat purchases, paying  $v$ . In the common costs case, the corresponding profit is

$$4v\pi^I - c(2 + \pi^I).$$

As above, demand from new-borns will be 2, paying  $v\pi^I$ , and, with probability  $\pi^I$ , demand from repeat customers will be 1, paying  $v$ . In this case, however, previous  $j$ -customers will only be served with probability  $\pi^I$ , though their expected payment will be the same ( $v\pi^I$ ). Expected profit is therefore higher in the common costs case

because of the saving on production cost when quality is low (expected investment cost is of course the same in the two cases). The remainder of the proof of Proposition 2 is in the Appendix.

It is clear that the zero-quality equilibrium which we saw above will also still exist in this setting: if each customer always believes that quality will be low then there can be no incentive to set high quality. Similarly, there are asymmetric equilibria in which one group uses the  $c^*$  cut-off strategy and the other always produces low quality, for all  $c^q$ , (after a deviation in which a consumer buys from a firm in a group which in equilibrium always produces low quality, but observes high quality, assume that he continues to believe that  $c^q$  is uniform on  $[0, a]$ ).

## 4 Equilibrium with a Single Auditor

In this section we return to the model with independent costs and consider the case in which there is a single auditor who, in each period, chooses a pair of qualities  $(q^A, q^B)$ . All the equilibria that we found in the separate auditors case will exist in this game too. To see this, notice that if the consumers have a belief system which assumes that the quality in group  $i$  is set entirely as a function of  $c_i^q$  and so is independent of the quality in group  $j$ , then the auditor cannot gain by setting quality in any other way. A change in the quality in group  $i$  will have no effect on the profits of group- $j$  producers; therefore the auditor must set  $i$ 's quality to maximize  $i$ 's profits, and so he faces the same problem as a separate auditor would. If there are constant marginal costs then these are the only equilibria, as the next Proposition shows.

**PROPOSITION 3:** *Suppose that there is a single auditor, independent costs of investment, and constant marginal costs. Then the set of equilibria is the same as in the separate auditors case.*

**PROOF:** Consider an arbitrary equilibrium and arbitrary date  $t$ . There is a measure 1 of customers of group  $i$  who will again be customers of group  $i$  next period, giving a profit next period of  $\max[v\tilde{\pi}(i, \cdot; i) - c, 0]$ , where  $\tilde{\pi}(\cdot)$  are beliefs corresponding

to the equilibrium. There is also a measure 1 of  $i$ -customers who will be customers of group  $j$  next period, giving a profit next period of  $\max[v\tilde{\pi}(i, \cdot; j) - c, 0]$ . These are the only consumers whose behavior will be affected by the quality in group  $i$  at  $t$ . Therefore the auditor's expected payoff if he sets high quality at group  $i$  at  $t$  differs from his expected payoff if he sets low quality by the amount

$$\begin{aligned} & \delta[\max[v\tilde{\pi}(i, h; i) - c, 0] + \max[v\tilde{\pi}(i, h; j) - c, 0] - \max[v\tilde{\pi}(i, l; i) - c, 0] \\ & \quad - \max[v\tilde{\pi}(i, l; j) - c, 0]] - c_i^q. \end{aligned}$$

He sets high quality if and only if this expression is non-negative. But, since the expression is independent of quality in group  $j$ , the beliefs  $\tilde{\pi}(\cdot)$  must assume independence, and the equilibrium must be one of the separate-auditors equilibria. QED.

In other words, regardless of the quality in group  $j$ , and regardless of the inference that consumers draw from observing this quality, the marginal cost of production will be the same ( $c$ ) and hence the net benefit gained, via repeat customers, from investing in high quality will be the same. Therefore the trade-off between high and low quality in group  $i$  is independent of quality in group  $j$ . But that means that consumers must believe that there is no correlation between the qualities in the two groups. Even though there is only one auditor setting quality for all the producers he cannot credibly announce, say, that there is a common standard for everyone.

If, on the other hand, there are decreasing marginal costs ( $\lambda < 4$ ) then a complementarity may endogenously arise between  $q^A$  and  $q^B$ . For simplicity, we will consider the case<sup>8</sup>  $\lambda = 3$ . If group  $A$ 's quality is high and if, as a result, group  $A$ 's customers are willing to trade in their second period with group  $B$  producers, then  $B$  producers have more to gain from high quality ( $\delta v$ ) than they would if  $A$ 's quality were low and so demand for  $B$ 's products were lower (the benefit then would be  $\delta(v - c)$ ). So, if consumers believe that the qualities are correlated, it will be profitable to make them so, which in turn justifies the belief.

---

<sup>8</sup>For other values of  $\lambda$ , qualitatively similar equilibria will obtain, for different ranges of parameter values.

We will assume that the following two inequalities apply:

$$v \geq 2c \tag{5}$$

and

$$2\delta v \geq a. \tag{6}$$

If (5) and (6) are satisfied then there exists an equilibrium in which, for every pair  $(c_A^q, c_B^q)$  there is a common standard for the two groups.

**PROPOSITION 4:** *Suppose that there is a single auditor, independent costs of investment, and  $\lambda = 3$ , hence marginal costs are decreasing. Suppose also that (1), (5) and (6) hold. Then there is an equilibrium in which both groups always have the same quality: quality is high if and only if*

$$\frac{c_A^q + c_B^q}{2} \leq \delta(2v - c). \tag{7}$$

*This equilibrium Pareto-dominates the  $c^*$ -cutoff equilibrium and has higher average quality.*

**PROOF:** In the equilibrium, the auditor sets high quality in both groups if average cost of investment is below  $\delta(2v - c)$  and otherwise sets low quality in both. Let the probability of the event of high quality be denoted by  $\hat{\pi}$ . Each new generation has belief  $\pi(A) = \pi(B) = \hat{\pi}$ . The beliefs of old generations are given by

$$\tilde{\pi}(i, h; i) = \tilde{\pi}(i, h; j) = 1$$

and

$$\tilde{\pi}(i, l; i) = \tilde{\pi}(i, l; j) = 0$$

for  $i, j \in \{A, B\}$ . That is, if a consumer observes high quality she believes that next period the quality at both groups will be high; similarly, if she observes low quality she believes it will be low next period at both groups. Clearly the beliefs are correct,

given the auditor's strategy.

Each new-born generation buys, since  $v\hat{\pi} \geq c$ . To see this, note that if  $c_A^q < 2\delta(v - c)$  then, since, by (6),  $c_B^q \leq 2\delta v$ , it must be that (7) is satisfied and so quality is high. Therefore

$$\hat{\pi} \geq pr(c_A^q \leq 2\delta(v - c))$$

and so

$$\hat{\pi} \geq F(2\delta(v - c)).$$

By (1),  $vF(\delta v) \geq c$ . Combining with (5) gives  $v\hat{\pi} \geq c$ . This also establishes that  $\hat{\pi} > F(c^*)$ , so that quality is higher in the common-quality equilibrium.

It remains to check that the auditor's strategy is optimal given the consumers' beliefs. Clearly the auditor's maximization problem is stationary and it suffices to consider the effect of changing quality in one period on the profits in the following period. Let the difference between next period's discounted profit and the current cost of quality be denoted by  $\mu(q^A, q^B)$ . The auditor has four possible choices for  $(q^A, q^B)$ :  $(h, h)$ ,  $(h, l)$ ,  $(l, h)$  and  $(l, l)$ .  $\mu$  is given as follows.

$$\mu(h, h) = -c_A^q - c_B^q + 2\delta[2v + 2v\hat{\pi} - 3c]$$

$$\mu(h, l) = -c_A^q + 2\delta[v + 2v\hat{\pi} - 3c]$$

$$\mu(l, h) = -c_B^q + 2\delta[v + 2v\hat{\pi} - 3c]$$

$$\mu(l, l) = 2\delta[2v\hat{\pi} - 2c].$$

For example, if quality is high at both groups, each firm will make  $2v$  from second period consumers, and  $2v\hat{\pi}$  from first-period consumers. If quality is high only at  $A$ , then each firm will make  $2v\hat{\pi}$  from first-period consumers and  $v$  from consumers who bought at  $A$  in their first period. If (7) is satisfied then  $(h, h)$  is better than  $(l, l)$ , and vice versa if (7) is not satisfied.  $(l, h)$  is optimal only if

$$c_A^q \geq 2\delta v,$$

which violates (6). Therefore  $(l, h)$  is never optimal. Similarly, neither is  $(h, l)$ . This shows that the auditor's strategy is optimal given the beliefs of consumers.

To show that the common-quality equilibrium is Pareto-superior to the  $c^*$ -cutoff equilibrium, we consider the event that the auditor deviates by playing the  $c^*$ -cutoff strategy and we show that this deviation gives him a higher expected payoff than the  $c^*$ -cutoff equilibrium does. Since the deviation by definition is inferior to the equilibrium strategy, this shows that the auditor is better off in the former equilibrium, and hence that it is Pareto-superior. If he deviates, his expected investment cost is the same as in the  $c^*$ -cutoff equilibrium and his expected revenue from a repeat customer is also the same ( $vF(c^*)$ ). Like a repeat customer, an old customer who has switched groups will pay  $v$  with probability  $F(c^*)$  and zero with probability  $1 - F(c^*)$ , giving the same expected revenue as in the  $c^*$ -cutoff equilibrium (when she pays  $vF(c^*)$  for sure). The only differences are (i) that in the  $c^*$ -cutoff equilibrium, customers of the latter type are served for sure rather than with probability  $F(c^*)$  hence expected production cost is higher, and (ii) new-borns pay  $vF(c^*)$  rather than  $v\hat{\pi} > vF(c^*)$ . Hence the  $c^*$ -cutoff equilibrium gives lower expected payoff to the auditor. QED.

The conclusion is that, even though there is no reputational externality when the groups are separately audited, it is possible to maintain higher quality and higher expected payoff if the groups merge into a single association as long as two conditions are satisfied: firstly, there is some element of fixed cost in production and, secondly, the potential difference between the two groups is not too great ( $a$  is not too high, as guaranteed by inequality (6)). The two conditions are required because it has to be credible that the auditor will set a common standard. This cannot be credible if the two groups are too different from each other or if there is no complementarity between the two qualities, given the belief that there is a common standard. Intuitively, the reason that the common-standard equilibrium is superior to the separate-auditors equilibrium is that, assuming that the common standard is credible, the market reach of the association is larger and, as a result, the degree of potential repeat purchasing is increased. This improves incentives to set high quality.

If (6) is not satisfied ( $a > 2\delta v$ ) then the common-quality equilibrium cannot exist.

Suppose that the consumers believe that quality is always the same at the two groups. If  $c_A^q > 2\delta v$  and  $c_B^q < 2\delta(v-c)$  then the auditor will want to set high quality at  $B$  since  $\mu(h, h) > \mu(h, l)$  and  $\mu(l, h) > \mu(l, l)$ , and low quality at  $A$ , since  $\mu(l, h) > \mu(h, h)$  and  $\mu(l, l) > \mu(h, l)$ . Therefore there can be no equilibrium of this kind. There may, however, still be a  $c^*$ -cutoff equilibrium. Suppose that  $2\delta v < a < \delta v^2/c$  ((5) ensures that this interval is non-empty). Suppose also that  $F(\cdot)$  is the uniform distribution. In that case inequality (1) is  $\delta v^2/a \geq c$ , which is satisfied, so the  $c^*$ -cutoff equilibrium exists by Proposition 1.

## 5 Asymmetric Cost Distributions and Group Sizes

### 5.1 Asymmetric Cost Distributions

In this section we examine what happens if the distribution of investment costs differs between the two groups. The main question we ask is: who benefits most from forming a merged association, a relatively high quality group (i.e., one with a low expected cost of achieving high quality) or a relatively low quality group? One theory might be that the high quality group gains most because, when the two groups are separately audited, the low quality group exploits the reputation of the high quality group, damaging the latter's interest. We have seen, however, that, if costs are independent, there is no collective reputation phenomenon, so this argument cannot apply. A second theory would be that the high quality group gains most because, when the two groups are jointly audited, the low quality group is burdened with excessive cost of investment. We show that, on the contrary, if the cost distributions are uniform, the low quality group benefits most from merger.

First, we consider general distributions of cost and show that, in the separate auditors case, the high quality group has higher expected profit. More precisely, if the distribution of  $B$ 's cost first-order stochastically dominates the distribution of  $A$ 's cost, then  $A$ 's expected equilibrium profit is higher.

Suppose that  $c_A^q$  is distributed according to c.d.f.  $F_A(\cdot)$  on the interval  $[0, a]$  and

$c_B^q$  is distributed according to  $F_B(\cdot)$  on  $[0, b]$ .  $c_A^q$  and  $c_B^q$  are independent. Suppose also that  $F_B(\cdot)$  first-order stochastically dominates  $F_A(\cdot)$ , that is,  $b \geq a$  and  $F_B(x) \leq F_A(x)$  for all  $x \in [0, b]$ . Thus,  $B$  is a relatively low quality group in the sense that its cost of obtaining high quality tends to be higher.

We consider, for simplicity, the case  $\lambda \leq 3$  and we suppose that parameters are such that the positive-quality equilibrium exists in the separate-auditors case. That is,  $vF_i(\delta v) \geq c$  for  $i = A, B$ . We assume also that  $a > \delta v$ , so that, in equilibrium, there is strictly positive probability of low quality in each group. In this equilibrium, auditor  $i = A, B$  sets high quality if and only if  $c_i^q \leq \delta v$ . The expected payoff in each period of group  $i$  (in ex ante terms, i.e. before  $c_i^q$  is known), denoted  $\Gamma_i^S$ , is

$$\Gamma_i^S = 4vF_i(\delta v) - \lambda c - \int_0^{\delta v} c^q dF_i(c^q).$$

Therefore group  $A$ 's payoff exceeds group  $B$ 's payoff if and only if

$$4v(F_A(\delta v) - F_B(\delta v)) > \int_0^{\delta v} c^q dF_A(c^q) - \int_0^{\delta v} c^q dF_B(c^q). \quad (8)$$

**PROPOSITION 5:** *If there are separate auditors and independent costs of investment, and  $F_B(\cdot)$  first-order stochastically dominates  $F_A(\cdot)$ , then  $A$  has a higher ex ante expected payoff in the positive-quality equilibrium than  $B$ .*

**PROOF:** Using integration by parts,

$$\int_0^{\delta v} c^q dF(c^q) = \delta v F(c^q) - \int_0^{\delta v} F(c^q) dc^q.$$

Therefore (8) is true if and only if

$$(4 - \delta)v[F_A(\delta v) - F_B(\delta v)] > \int_0^{\delta v} [F_B(c^q) - F_A(c^q)] dc^q.$$

By first-order stochastic dominance, the left-hand-side of this inequality is positive and the right-hand-side is negative. QED.

Now we consider the common-quality equilibrium when there is a single auditor. As in section 4 we limit ourselves to the case  $\lambda = 3$ , and we assume that (1) and (5) hold and that (6) holds for both distributions: that is,  $2\delta v \geq b$ . Denoting  $2\delta(2v - c)$  by  $z$ , the quality is high in both groups if and only if  $c_A^q + c_B^q \leq z$ .

In this equilibrium, both groups have the same expected revenue and the same expected cost of production. Therefore expected payoff differs only inasmuch as expected investment cost differs. Let  $\Gamma_i^J$  denote the per-period payoff for group  $i$  in this equilibrium ( $J$  standing for ‘joint’). Then the difference between the two groups’ expected payoffs is given by

$$\begin{aligned} \Gamma_A^J - \Gamma_B^J = & \left( \int_0^{z-a} c^q dF_B(c^q) + \int_{z-a}^b c^q F_A(z - c^q) dF_B(c^q) \right) - \\ & \left( \int_0^{z-b} c^q dF_A(c^q) + \int_{z-b}^a c^q F_B(z - c^q) dF_A(c^q) \right) \end{aligned}$$

since, for example, given cost realization  $c^q$ ,  $B$  will incur cost  $c^q$  for sure if  $c^q < z - a$  and will incur it with probability  $F_A(z - c^q)$  otherwise.

Suppose now that  $F_A(\cdot)$  is the uniform distribution on  $[0, a]$  and  $F_B(\cdot)$  the uniform distribution on  $[0, b]$ . Then, after some calculation, we have

$$\Gamma_A^J - \Gamma_B^J = \frac{(a - b)[(a + b - z)^2 - ab]}{2ab}$$

and

$$\Gamma_A^S - \Gamma_B^S = \frac{\delta v^2 (b - a)(8 - \delta)}{2ab}.$$

Group  $B$ , the inefficient group, benefits more than group  $A$  from merger if  $\Gamma_A^J - \Gamma_B^J < \Gamma_A^S - \Gamma_B^S$ . Since  $a < b$ ,  $(\Gamma_A^J - \Gamma_B^J) - (\Gamma_A^S - \Gamma_B^S)$  has the opposite sign to

$$(a + b - z)^2 - ab + \delta v^2 (8 - \delta),$$

which, since  $\delta v > b/2$  and  $a < 2\delta v$ , is positive. This establishes

PROPOSITION 6: *A low-quality group has most to gain from common auditing. That is, if  $F_A(\cdot)$  and  $F_B(\cdot)$  are independently uniform on  $[0, a]$  and  $[0, b]$  respectively, where  $a < b$ , then  $B$  gains more from merging than  $A$  does, assuming the merged association has the common quality equilibrium.*

## 5.2 Unequal Group Sizes

Suppose now that one of the groups has a larger number of members than the other. Which group has a higher expected payoff after merging into a single association, and which has a greater incentive to merge? We answer these questions in the limit case in which one group is much larger than the other. The answers are that the small group has a lower expected payoff than the large one in the merged association, but, assuming a uniform distribution, the small group has a greater incentive to merge. The intuition is straightforward. If the small group is separately audited, the degree of repeat purchasing is very small, so, there being little reputational incentive to set high quality, quality is low and profits are zero in equilibrium. In the merged association, however, there is a positive-quality, common standard equilibrium as in the case of equal-sized groups. Therefore the small group has a positive incentive to merge. The large group's incentive to merge, on the other hand, is small because the effect of the small group is negligible. In the merged association, the quality is determined largely by the cost of quality in the larger group. The small group's expected investment cost is therefore higher than that of the large group, and so its profit is lower. In effect, since the small group's influence is low, it runs the risk of having to produce a quality which is inappropriately high, given its cost.

We assume, as above, that (1), (5) and (6) hold and that  $\lambda = 3$ . The two groups have the same distribution of investment cost  $c_i^q$ , with support  $[0, a]$ . Group  $A$  now consists of a continuum of firms of measure  $\alpha < 0.5$ , instead of measure 1; group  $B$  has a continuum of firms of measure  $1 - \alpha$ . As before, each firm has, in each period, a continuum of new customers of measure 2; of these,  $2\alpha$  go in their second period to a firm in group  $A$  and  $2(1 - \alpha)$  go to a firm in group  $B$ . Thus, if  $\alpha$  is close to zero (as we will assume) most customers, whether at group  $A$  or group  $B$  in their first period,

will go to group  $B$  in their second.

Consider first the case in which the two groups are separately audited. In a positive-quality equilibrium,  $A$ 's demand in the absence of repeat purchasers would be  $2 + 2(1 - \alpha) > \lambda$ , so marginal cost would be zero. Therefore  $A$  optimally sets high quality if  $c_A^q \leq 2\alpha\delta v$ .  $B$ 's demand in the absence of repeat purchasers is  $2 + 2\alpha < \lambda$  and he sets high quality if  $c_B^q \leq \delta[2(1 - \alpha)v - (\lambda - 2(1 - \alpha))c] = \delta[2(1 - \alpha)v - (1 - 2\alpha)c]$ . If  $\alpha$  is close to zero, then  $A$ 's critical value  $2\alpha\delta v$  is also close to zero, so this cannot be an equilibrium (new customers would not pay enough to cover production cost). Therefore the only equilibrium is the zero-quality one, in which  $A$  producers earn zero profit. In group  $B$ , the critical value is approximately  $\delta(2v - c)$ ; by (1), new customers will be willing to pay more than  $c$ , so the positive-quality equilibrium does exist for this group.

Suppose now that the two groups form a single association. Defining  $\mu(., .)$  as in section 4, we have

$$\mu(h, h) = -\alpha c_A^q - (1 - \alpha)c_B^q + \delta[2v\hat{\pi} - 2c + 2v - c]$$

$$\mu(h, l) = -\alpha c_A^q + \delta[2v\hat{\pi} - 2c + 2\alpha v - 2\alpha c]$$

$$\mu(l, h) = -(1 - \alpha)c_B^q + \delta[2v\hat{\pi} - 2c + 2(1 - \alpha)v - c]$$

$$\mu(l, l) = \delta[2v\hat{\pi} - 2c].$$

By (6),  $c_A^q, c_B^q < 2\delta v$ , so  $(h, l)$  and  $(l, h)$  are both inferior to  $(h, h)$ , while  $(h, h)$  is superior to  $(l, l)$  if  $\alpha c_A^q + (1 - \alpha)c_B^q \leq \delta(2v - c)$ . Therefore there is an equilibrium in which quality is high at both groups if and only if the average cost of investment is less than  $\delta(2v - c)$ , and otherwise is low at both groups. When  $\alpha$  is near zero, this equilibrium is approximately the same as the positive-quality equilibrium of  $B$  on its own, hence  $B$  is approximately indifferent to the merger.  $A$ , on the other hand, benefits from joining  $B$  as long as it earns positive profit in this equilibrium. If  $\alpha \leq \delta(2v - c)$  then the probability of high quality is 1 and  $A$  in that case makes the same expected profit as  $B$ , since they have the same revenue, production cost and

expected investment cost. This profit is, per period,  $4v - 3c - E(c_i^q)$ , which is strictly positive by (5) and (6). If  $a > \delta(2v - c)$  then  $B$ 's expected profit is approximately

$$4F[\delta(2v - c)]v - 2c - F[\delta(2v - c)]c - E[c_B^q \mid c_B^q \leq \delta(2v - c)],$$

while  $A$ 's is

$$4F[\delta(2v - c)]v - 2c - F[\delta(2v - c)]c - E[c_A^q]. \quad (9)$$

$A$  is therefore worse off than  $B$  in this equilibrium, because his expected investment cost is higher. Nevertheless, at least in the uniform distribution case,  $A$  still makes strictly positive profit and so benefits from joining the association. This follows because in that case (9) is strictly positive if

$$8\delta v(2v - c) - 2\delta(2v - c)c > a^2 + 4ac,$$

but

$$8\delta v(2v - c) - 2\delta(2v - c)c > 4\delta^2 v^2 + 8\delta v c \geq a^2 + 4ac.$$

where the first inequality follows from (5) and  $\delta < 1$  and the second from (6).

Summarizing the above, we have

**PROPOSITION 7:** *A small group ( $\alpha$  close to zero) has a lower expected payoff under common auditing than a large group, but gains more from common auditing.*

## 6 Concluding Remarks

One common complaint about self-regulating professions is that they do not actually enforce properly their proclaimed standards. If so, that may be because an auditor who identifies with and is drawn from the profession may not, after an abuse, have the incentive to carry out the required punishment. This issue did not arise in this paper because we assumed that an auditor can commit to enforce his chosen quality. Suppose, however, that the auditor lacks this commitment power. This

would raise questions about the optimal balance between self-regulation and state regulation which we hope to address in subsequent work.

## APPENDIX

**PROOF OF PROPOSITION 2:** First we show that the two equilibria described are the only positive-quality equilibria. If, in some equilibrium, there is positive probability of high quality at both groups then new-borns must buy at both groups (otherwise there would be no incentive to set high quality). If  $c^q$  is such that previous customers of group  $j$  will buy from group  $i$  then  $i$ 's optimal cut-off is  $\delta v$ , while, if not, it is  $\delta(v - c)$ . Therefore there are only two possible equilibrium cut-offs. To see that both groups must use the same cut-off, suppose, for definiteness, that  $A$  uses  $\delta v$  and  $B$  uses  $\delta(v - c)$ . New-borns must be willing to buy from  $B$  (for the reason above). Thus, if  $A$ 's quality is high,  $A$ -customers must be willing to buy in their second period from  $B$  because they have a higher expectation of  $B$ 's quality than new-borns, their conditional expectation of  $c^q$  being lower. So, if  $c^q \leq \delta v$ ,  $B$ 's demand without repeat customers is 3, which means that  $B$ 's benefit of setting high quality is  $\delta v$ , which is a contradiction.

If (4) does not hold then clearly the  $\delta(v - c)$  cut-off strategies do not form an equilibrium. If there are constant marginal costs then the marginal profit is always  $\delta(v - c)$  so the  $\delta v$  cut-off equilibrium does not exist.

Finally, we need to show that the  $\delta v$  cut-off equilibrium Pareto-dominates the  $\delta(v - c)$  cut-off equilibrium. If, in the  $\delta v$  equilibrium, one auditor unilaterally deviates and chooses cut-off  $\delta(v - c)$ , his expected payoff is

$$3vF(\delta v) + vF(\delta(v - c)) - 2c - F(\delta v)c - E(c^q | c^q \leq \delta(v - c)). \quad (10)$$

His expected payoff in the  $\delta(v - c)$  cut-off equilibrium is

$$4vF(\delta(v - c)) - 2c - F(\delta(v - c))c - E(c^q | c^q \leq \delta(v - c)). \quad (11)$$

Since (10) exceeds (11), the Proposition is proved. QED.
