## AN ABSTRACT OF THE RESEARCH PAPER OF

SUNG-HO KIM, for the Master of Science degree in MATHEMATICS, presented on JUNE 28, 2017, at Southern Illinois University Carbondale.

TITLE: PREDICTION INTERVALS FOR PARTIAL LEAST SQUARES AND PRINCIPAL COMPONENT REGRESSION USING D VARIABLES

MAJOR PROFESSOR: Dr. David J. Olive

This paper, taken from Olive (2017d), presents and examines a prediction interval for the multiple linear regression model $Y=\beta_{1} x_{1}+\cdots+\beta_{p} x_{p}+e$, where the partial least squares or principal component regression is selected using $\mathrm{d}=\min (\lceil n / J\rceil, p)$ variables $v_{1}, v_{2}, \ldots, v_{d}$ for some positive integer $J$ such as 10 or 20 . Here $v_{1}$ corresponds to a constant and $v_{i}$ is a PLS component or principal component for $i \geq 2$.

## CHAPTER 1

## INTRODUCTION

Suppose that the response variable $Y_{i}$ and at least one predictor variable $x_{i, j}$ are quantitative with $x_{i, 1} \equiv 1$. Let $\boldsymbol{x}_{i}^{T}=\left(x_{i, 1}, \ldots, x_{i, p}\right)=\left(\begin{array}{ll}1 & \boldsymbol{u}_{i}^{T}\end{array}\right)$ and $\boldsymbol{\beta}=\left(\beta_{1}, \ldots, \beta_{p}\right)^{T}$ where $\beta_{1}$ corresponds to the intercept. Then the multiple linear regression (MLR) model is

$$
\begin{equation*}
Y_{i}=\beta_{1}+x_{i, 2} \beta_{2}+\cdots+x_{i, p} \beta_{p}+e_{i}=\boldsymbol{x}_{i}^{T} \boldsymbol{\beta}+e_{i} \tag{1.1}
\end{equation*}
$$

for $i=1, \ldots, n$. This model is also called the full model. Here $n$ is the sample size and the random variable $e_{i}$ is the $i$ th error. In matrix notation, these $n$ equations become

$$
\begin{equation*}
\boldsymbol{Y}=\boldsymbol{X} \boldsymbol{\beta}+\boldsymbol{e} \tag{1.2}
\end{equation*}
$$

where $\boldsymbol{Y}$ is an $n \times 1$ vector of dependent variables, $\boldsymbol{X}$ is an $n \times p$ matrix of predictors, $\boldsymbol{\beta}$ is a $p \times 1$ vector of unknown coefficients, and $\boldsymbol{e}$ is an $n \times 1$ vector of unknown errors. Ordinary least squares (OLS) is often used for inference if $n / p$ is large.

It is often convenient to use the centered response $\boldsymbol{Z}=\boldsymbol{Y}-\overline{\boldsymbol{Y}}$ and the $n \times(p-1)$ matrix of standardized nontrivial predictors $\boldsymbol{W}=\left(W_{i j}\right)$. For $j=1, \ldots, p-1$, let $W_{i j}$ denote the $(j+1)$ th variable standardized so that $\sum_{i=1}^{n} W_{i j}=0$ and $\sum_{i=1}^{n} W_{i j}^{2}=n$. Hence

$$
W_{i j}=\frac{x_{i, j+1}-\bar{x}_{j+1}}{\tilde{\sigma}_{j+1}} \text { where } \tilde{\sigma}_{\mathrm{j}+1}^{2}=\frac{1}{\mathrm{n}} \sum_{\mathrm{i}=1}^{\mathrm{n}}\left(\mathrm{x}_{\mathrm{i}, \mathrm{j}+1}-\overline{\mathrm{x}}_{\mathrm{j}+1}\right)^{2} .
$$

Note that the sample correlation matrix of the nontrivial predictors $\boldsymbol{u}_{i}$ is

$$
\boldsymbol{R}_{\boldsymbol{u}}=\frac{\boldsymbol{W}^{T} \boldsymbol{W}}{n}
$$

Then regression through the origin is used for the model

$$
\begin{equation*}
\boldsymbol{Z}=\boldsymbol{W} \boldsymbol{\eta}+e \tag{1.3}
\end{equation*}
$$

where the vector of fitted values $\hat{\boldsymbol{Y}}=\overline{\boldsymbol{Y}}+\hat{\boldsymbol{Z}}$.

There are many alternative methods for estimating $\boldsymbol{\beta}$, including forward selection with OLS, principal component regression (PCR), and partial least squares (PLS) due to Wold (1975). Forward selection, PCR, and PLS use variables $v_{1}=1$ (the constant or trivial predictor) and $v_{j}=\gamma_{j}^{T} \boldsymbol{x}$ that are linear combinations of the predictors for $j=$ $2, \ldots, p$. Model $I_{i}$ uses variables $v_{1}, v_{2}, \ldots, v_{i}$ for $i=1, \ldots, M$ where $M \leq p$ and often $M \leq$ $\min (p, n / 10)$. Then $M$ models $I_{i}$ are used where OLS is used to regress $Y$ (or $Z$ ) on $v_{1}, \ldots, v_{i}$. Then a criterion chooses the final submodel $I_{d}$ from candidates $I_{1}, \ldots, I_{M}$. See James, Witten, Hastie, and Tibshirani (2013, ch. 6), Olive (2017d), Pelawa Watagoda (2017), and Pelawa Watagoda and Olive (2017) for more details about these three methods.

Partial least squares (PLS) uses variables $v_{1}=1$ and "PLS components" $v_{j}=\boldsymbol{\gamma}_{j}^{T} \boldsymbol{x}$ for $j=2, \ldots, p$. Often $k$-fold cross validation is used to pick the PLS model from $I_{1}, \ldots, I_{M}$. If $M=p$, then the PLS $I_{p}$ model is the OLS full model. Chun and Keleş (2010) show that PLS does not give a consistent estimator of $\boldsymbol{\beta}$ unless $p / n \rightarrow 0$. Also see Cook, Helland, and Su (2013), and Wold (1985, 2006). Denham (1997) suggested a prediction interval (PI) for PLS that assumes the number of components is selected in advance.

Some notation for eigenvalues, eigenvectors, orthonormal eigenvectors, positive definite matrices, and positive semidefinite matrices will be useful before defining principal component regression, which is also called principal components regression. See Olive (2017d, ch. 3).

Notation: Recall that a square symmetric $p \times p$ matrix $\boldsymbol{A}$ has an eigenvalue $\lambda$ with corresponding eigenvector $\boldsymbol{x} \neq \mathbf{0}$ if

$$
\begin{equation*}
\boldsymbol{A x}=\lambda \boldsymbol{x} . \tag{1.4}
\end{equation*}
$$

The eigenvalues of $\boldsymbol{A}$ are real since $\boldsymbol{A}$ is symmetric. Note that if constant $c \neq 0$ and $\boldsymbol{x}$ is an eigenvector of $\boldsymbol{A}$, then $c \boldsymbol{x}$ is an eigenvector of $\boldsymbol{A}$. Let $\boldsymbol{e}$ be an eigenvector of $\boldsymbol{A}$ with unit length $\|\boldsymbol{e}\|=\sqrt{\boldsymbol{e}^{T} \boldsymbol{e}}=1$. Then $\boldsymbol{e}$ and $-\boldsymbol{e}$ are eigenvectors with unit length, and $\boldsymbol{A}$ has $p$ eigenvalue eigenvector pairs $\left(\lambda_{1}, \boldsymbol{e}_{1}\right),\left(\lambda_{2}, \boldsymbol{e}_{2}\right), \ldots,\left(\lambda_{p}, \boldsymbol{e}_{p}\right)$. Since $\boldsymbol{A}$ is symmetric, the eigenvectors are chosen such that the $\boldsymbol{e}_{i}$ are orthonormal: $\boldsymbol{e}_{i}^{T} \boldsymbol{e}_{i}=1$ and $\boldsymbol{e}_{i}^{T} \boldsymbol{e}_{j}=0$ for
$i \neq j$. The symmetric matrix $\boldsymbol{A}$ is positive definite iff all of its eigenvalues are positive, and positive semidefinite iff all of its eigenvalues are nonnegative. If $\boldsymbol{A}$ is positive semidefinite, let $\lambda_{1} \geq \lambda_{2} \geq \cdots \geq \lambda_{p} \geq 0$. If $\boldsymbol{A}$ is positive definite, then $\lambda_{p}>0$.

Theorem 1. Let $\boldsymbol{A}$ be a $p \times p$ symmetric matrix with eigenvector eigenvalue pairs $\left(\lambda_{1}, \boldsymbol{e}_{1}\right),\left(\lambda_{2}, \boldsymbol{e}_{2}\right), \ldots,\left(\lambda_{p}, \boldsymbol{e}_{p}\right)$ where $\boldsymbol{e}_{i}^{T} \boldsymbol{e}_{i}=1$ and $\boldsymbol{e}_{i}^{T} \boldsymbol{e}_{j}=0$ if $i \neq j$ for $i=1, \ldots, p$. Then the spectral decomposition of $\boldsymbol{A}$ is

$$
\boldsymbol{A}=\sum_{i=1}^{p} \lambda_{i} \boldsymbol{e}_{i} \boldsymbol{e}_{i}^{T}=\lambda_{1} \boldsymbol{e}_{1} \boldsymbol{e}_{1}^{T}+\cdots+\lambda_{p} \boldsymbol{e}_{p} \boldsymbol{e}_{p}^{T}
$$

Using the same notation as Johnson and Wichern (1988, pp. 50-51), let $\boldsymbol{P}=$ $\left[\boldsymbol{e}_{1} \boldsymbol{e}_{2} \cdots \boldsymbol{e}_{p}\right]$ be the $p \times p$ orthogonal matrix with $i$ th column $\boldsymbol{e}_{i}$. Then $\boldsymbol{P} \boldsymbol{P}^{T}=\boldsymbol{P}^{T} \boldsymbol{P}=\boldsymbol{I}$. Let $\boldsymbol{\Lambda}=\operatorname{diag}\left(\lambda_{1}, \ldots, \lambda_{p}\right)$ and let $\boldsymbol{\Lambda}^{1 / 2}=\operatorname{diag}\left(\sqrt{\lambda_{1}}, \ldots, \sqrt{\lambda_{p}}\right)$. If $\boldsymbol{A}$ is a positive definite $p \times p$ symmetric matrix with spectral decomposition $\boldsymbol{A}=\sum_{i=1}^{p} \lambda_{i} \boldsymbol{e}_{i} \boldsymbol{e}_{i}^{T}$, then $\boldsymbol{A}=\boldsymbol{P} \boldsymbol{\Lambda} \boldsymbol{P}^{T}$ and

$$
\boldsymbol{A}^{-1}=\boldsymbol{P} \boldsymbol{\Lambda}^{-1} \boldsymbol{P}^{T}=\sum_{i=1}^{p} \frac{1}{\lambda_{i}} \boldsymbol{e}_{i} \boldsymbol{e}_{i}^{T} .
$$

Theorem 2. Let $\boldsymbol{A}$ be a positive definite $p \times p$ symmetric matrix with spectral decomposition $\boldsymbol{A}=\sum_{i=1}^{p} \lambda_{i} \boldsymbol{e}_{i} \boldsymbol{e}_{i}^{T}$. The square root matrix $\boldsymbol{A}^{1 / 2}=\boldsymbol{P} \boldsymbol{\Lambda}^{1 / 2} \boldsymbol{P}^{T}$ is a positive definite symmetric matrix such that $\boldsymbol{A}^{1 / 2} \boldsymbol{A}^{1 / 2}=\boldsymbol{A}$.

Principal component regression (PCR) uses OLS regression on the principal components of the correlation matrix $\boldsymbol{R}_{\boldsymbol{u}}$ of the $p-1$ nontrivial predictors $u_{1}=x_{2}, \ldots, u_{p-1}=x_{p}$. Suppose $\boldsymbol{R} \boldsymbol{u}$ has eigenvalue eigenvector pairs $\left(\hat{\lambda}_{1}, \hat{\boldsymbol{e}}_{1}\right), \ldots,\left(\hat{\lambda}_{K}, \hat{\boldsymbol{e}}_{K}\right)$ where $\hat{\lambda}_{1} \geq \hat{\lambda}_{2} \geq \cdots \geq$ $\hat{\lambda}_{K} \geq 0$ where $K=\min (n, p-1)$. Then $\boldsymbol{R} \boldsymbol{u} \hat{\boldsymbol{e}}_{i}=\hat{\lambda}_{i} \hat{\boldsymbol{e}}_{i}$ for $i=1, \ldots, K$. Since $\boldsymbol{R} \boldsymbol{u}$ is a symmetric positive semidefinite matrix, the $\hat{\lambda}_{i}$ are real and nonnegative.

The eigenvectors $\hat{\boldsymbol{e}}_{i}$ are orthonormal: $\hat{\boldsymbol{e}}_{i}^{T} \hat{\boldsymbol{e}}_{i}=1$ and $\hat{\boldsymbol{e}}_{i}^{T} \hat{\boldsymbol{e}}_{j}=0$ for $i \neq j$. If the eigenvalues are unique, then $\hat{\boldsymbol{e}}_{i}$ and $-\hat{\boldsymbol{e}}_{i}$ are the only orthonormal eigenvectors corresponding to $\hat{\lambda}_{i}$. For example, the eigenvalue eigenvector pairs can be found using the singular value decomposition of the matrix $\boldsymbol{W} / \sqrt{n-a}$ where $\boldsymbol{W}$ is the matrix of the standardized nontrivial
predictors $\boldsymbol{w}_{i}$, the sample covariance matrix

$$
\hat{\boldsymbol{\Sigma}}_{\boldsymbol{w}}=\frac{1}{n-a} \sum_{i=1}^{n}\left(\boldsymbol{w}_{i}-\overline{\boldsymbol{w}}\right)\left(\boldsymbol{w}_{i}-\overline{\boldsymbol{w}}\right)^{T}=\frac{1}{n-a} \sum_{i=1}^{n} \boldsymbol{w}_{i} \boldsymbol{w}_{i}^{T}=\boldsymbol{R} \boldsymbol{u}
$$

and usually $a=0$ or $a=1$. If $n>K=p-1$, then the spectral decomposition of $\boldsymbol{R}_{\boldsymbol{u}}$ is

$$
\boldsymbol{R} \boldsymbol{u}=\sum_{i=1}^{p-1} \hat{\lambda}_{i} \hat{\boldsymbol{e}}_{i} \hat{\boldsymbol{e}}_{i}^{T}=\hat{\lambda}_{1} \hat{\boldsymbol{e}}_{1} \hat{\boldsymbol{e}}_{1}^{T}+\cdots+\hat{\lambda}_{p-1} \hat{\boldsymbol{e}}_{p-1} \hat{\boldsymbol{e}}_{p-1}^{T}
$$

and $\sum_{i=1}^{p-1} \hat{\lambda}_{i}=p-1$.
Let $\boldsymbol{w}_{1}, \ldots, \boldsymbol{w}_{n}$ denote the standardized vectors of nontrivial predictors. Then the $K$ principal components corresponding to the $j$ th case $\boldsymbol{w}_{j}$ are $P_{j 1}=\hat{\boldsymbol{e}}_{1}^{T} \boldsymbol{w}_{j}, \ldots, P_{j K}=\hat{\boldsymbol{e}}_{K}^{T} \boldsymbol{w}_{j}$.

Principal components have a nice geometric interpretation if $n>K=p-1$. If $n>K$ and $\boldsymbol{R}_{\boldsymbol{u}}$ is nonsingular, then the hyperellipsoid

$$
\left\{\boldsymbol{w} \mid D_{\boldsymbol{w}}^{2}\left(\mathbf{0}, \boldsymbol{R}_{\boldsymbol{u}}\right) \leq h^{2}\right\}=\left\{\boldsymbol{w}: \boldsymbol{w}^{T} \boldsymbol{R}_{\boldsymbol{u}}^{-1} \boldsymbol{w} \leq h^{2}\right\}
$$

is centered at $\mathbf{0}$. The volume of the hyperellipsoid is

$$
\frac{2 \pi^{K / 2}}{K \Gamma(K / 2)}|\boldsymbol{R} \boldsymbol{u}|^{1 / 2} h^{K}
$$

Then points at squared distance $\boldsymbol{w}^{T} \boldsymbol{R}_{\boldsymbol{u}}^{-1} \boldsymbol{w}=h^{2}$ from the origin lie on the hyperellipsoid centered at the origin whose axes are given by the eigenvectors $\hat{\boldsymbol{e}}_{i}$ where the half length in the direction of $\hat{\boldsymbol{e}}_{i}$ is $h \sqrt{\hat{\lambda}_{i}}$. Let $j=1, \ldots, n$. Then the first principal component $P_{j 1}$ is obtained by projecting the $\boldsymbol{w}_{j}$ on the (longest) major axis of the hyperellipsoid, the second principal component $P_{j 2}$ is obtained by projecting the $\boldsymbol{w}_{j}$ on the next longest axis of the hyperellipsoid, $\ldots$, and the $(p-1)$ th principal component $P_{j, p-1}$ is obtained by projecting the $\boldsymbol{w}_{j}$ on the (shortest) minor axis of the hyperellipsoid. Examine Figure 1.1 for two ellipsoids with 2 nontrivial predictors. The axes of the hyperellipsoid are a rotation of the usual axes about the origin.

Let the random variable $V_{i}$ correspond to the $i$ th principal component, and let $\left(P_{1 i}, \ldots, P_{n i}\right)^{T}=\left(V_{1 i}, \ldots, V_{n i}\right)^{T}$ be the observed data for $V_{i}$. Then the sample mean

$$
\bar{V}_{i}=\frac{1}{n} \sum_{k=1}^{n} V_{k i}=\frac{1}{n} \sum_{k=1}^{n} \hat{\boldsymbol{e}}_{i}^{T} \boldsymbol{w}_{k}=\hat{\boldsymbol{e}}_{i}^{T} \overline{\boldsymbol{w}}=\hat{\boldsymbol{e}}_{i}^{T} \mathbf{0}=0
$$

a)

b)

Figure 1.1. Population Prediction Regions for 2 MVN Distributions
and the sample covariance of $V_{i}$ and $V_{j}$ is

$$
\operatorname{Cov}\left(V_{i}, V_{j}\right)=\frac{1}{n} \sum_{k=1}^{n}\left(V_{k i}-\bar{V}_{i}\right)\left(V_{k j}-\bar{V}_{j}\right)=\frac{1}{n} \sum_{k=1}^{n} \hat{\boldsymbol{e}}_{i}^{T} \boldsymbol{w}_{k} \boldsymbol{w}_{k}^{T} \hat{\boldsymbol{e}}_{j}=\hat{\boldsymbol{e}}_{i}^{T} \boldsymbol{R}_{\boldsymbol{u}} \hat{\boldsymbol{e}}_{j}
$$

$=\hat{\lambda}_{j} \hat{e}_{i}^{T} \hat{\boldsymbol{e}}_{j}=0$ for $i \neq j$ since the sample covariance matrix of the standardized data is

$$
\frac{1}{n} \sum_{k=1}^{n} \boldsymbol{w}_{k} \boldsymbol{w}_{k}^{T}=\boldsymbol{R}_{\boldsymbol{u}}
$$

and $\boldsymbol{R}_{\boldsymbol{u}} \hat{\boldsymbol{e}}_{j}=\hat{\lambda}_{j} \hat{\boldsymbol{e}}_{j}$. Hence $V_{i}$ and $V_{j}$ are uncorrelated.
PCR uses linear combinations of the standardized data as predictors. Let $v_{1}=1$ and $v_{j}=\boldsymbol{\gamma}_{j}^{T} \boldsymbol{w}=\hat{\boldsymbol{e}}_{j-1}^{T} \boldsymbol{w}=V_{j-1}$ for $j=2, \ldots, K$. Let model $I_{i}$ contain $v_{1}, \ldots, v_{i}$. Then for model $I_{i}, \mathrm{PCR}$ uses OLS regression of $Y$ on $v_{1}, \ldots, v_{i}$.

Alternatively let $v_{j}=\hat{\boldsymbol{e}}_{j}^{T} \boldsymbol{w}$ for $j=1, \ldots, K$ and let model $I_{i}$ contain $v_{1}, \ldots, v_{i}$. Then for model $I_{i}$, use OLS regression of $Z=Y-\bar{Y}$ on $v_{1}, \ldots, v_{i}$ with $\hat{Y}=\hat{Z}+\bar{Y}$.

Generally there is no reason why the predictors should be ranked from best to worst by $v_{1}, v_{2}, \ldots, v_{K}$. Performing OLS forward selection or lasso on $v_{1}, \ldots, v_{K}$ may be more effective. There is one exception. Suppose $\sum_{i=1}^{J} \hat{\lambda}_{i} \geq q(p-1)$ where $0.5 \leq q \leq 1$, e.g. $q=0.8$ where $J$ is a lot smaller than $p-1$. Then the $J$ predictors $V_{1}, \ldots, V_{J}$ capture much of the information of the standardized nontrivial predictors $w_{1}, \ldots, w_{p-1}$. Then regressing $Y$ on $1, V_{1}, \ldots, V_{J}$ may be competitive with regressing $Y$ on $1, w_{1}, \ldots, w_{p-1}$. This exception tends to occur when $p$ is very small, and is an example of dimension reduction. PCR is equivalent to OLS on the full model when $Y$ is regressed on a constant and all $K$ of the principal components. PCR can also be useful if $\boldsymbol{X}$ is singular or nearly singular (ill conditioned). In general, PCR does not give a consistent estimator of $\boldsymbol{\beta}$ unless PCR is the full OLS model so all $p-1$ principal components are used.

Variable selection is the search for a subset of predictor variables that can be deleted without important loss of information. Following Olive(2017c, p.99), a model for variable selection can be described by

$$
\begin{equation*}
\boldsymbol{x}^{T} \boldsymbol{\beta}=\boldsymbol{x}_{S}^{T} \boldsymbol{\beta}_{S}+\boldsymbol{x}_{E}^{T} \boldsymbol{\beta}_{E}=\boldsymbol{x}_{S}^{T} \boldsymbol{\beta}_{S} \tag{1.5}
\end{equation*}
$$

where $\boldsymbol{x}=\left(\boldsymbol{x}_{S}^{T}, \boldsymbol{x}_{E}^{T}\right)^{T}, \boldsymbol{x}_{S}$ is a $k_{S} \times 1$ vector, and $\boldsymbol{x}_{E}$ is a $\left(p-k_{S}\right) \times 1$ vector. Given that $\boldsymbol{x}_{S}$ is in the model, $\boldsymbol{\beta}_{E}=\mathbf{0}$ and $E$ denotes the subset of terms that can be eliminated given that the subset $S$ is in the model. Let $\boldsymbol{x}_{I}$ be the vector of $k$ terms from a candidate subset indexed by $I$, and let $\boldsymbol{x}_{O}$ be the vector of the remaining predictors (out of the candidate submodel). Suppose that $S$ is a subset of $I$ and that model (1.5) holds. Then

$$
\begin{equation*}
\boldsymbol{x}^{T} \boldsymbol{\beta}=\boldsymbol{x}_{S}^{T} \boldsymbol{\beta}_{S}=\boldsymbol{x}_{S}^{T} \boldsymbol{\beta}_{S}+\boldsymbol{x}_{I / S}^{T} \boldsymbol{\beta}_{(I / S)}+\boldsymbol{x}_{O}^{T} \mathbf{0}=\boldsymbol{x}_{I}^{T} \boldsymbol{\beta}_{I} \tag{1.6}
\end{equation*}
$$

where $\boldsymbol{x}_{I / S}$ denotes the predictors in $I$ that are not in $S$. Since this is true regardless of the values of the predictors, $\boldsymbol{\beta}_{O}=\mathbf{0}$ if $S \subseteq I$.

When there is a sequence of $M$ submodels, the final submodel $I_{d}$ needs to be selected. Suppose the $e_{i}$ are independent and identically distributed (iid) with variance $V\left(e_{i}\right)=\sigma^{2}$. Then there are many criteria used to select the final submodel $I_{d}$. A simple method is to take the model that uses $d=\min (\lceil n / J\rceil, p)$ variables $V_{1}, \ldots, V_{d}$. This is the method that we will investigate. If $p$ is fixed, the method will use the full OLS model once $n / J \geq p$. Hence the PI (2.4) described below will be asymptotically optimal for a wide class of zero mean error distributions.

Consider predicting a future test response variable $Y_{f}$ given a $p \times 1$ vector of predictors $\boldsymbol{x}_{f}$ and training data $\left(\boldsymbol{x}_{1}, Y_{1}\right), \ldots,\left(\boldsymbol{x}_{n}, Y_{n}\right)$. A large sample $100(1-\delta) \%$ prediction interval (PI) has the form [ $\hat{L}_{n}, \hat{U}_{n}$ ] where $P\left(\hat{L}_{n} \leq Y_{f} \leq \hat{U}_{n}\right) \rightarrow 1-\delta$ as the sample size $n \rightarrow \infty$.

The $\operatorname{shorth}(c)$ estimator is useful for making prediction intervals. Let $Z_{(1)}, \ldots, Z_{(n)}$ be the order statistics of $Z_{1}, \ldots, Z_{n}$. Then let the shortest closed interval containing at least $c$ of the $Z_{i}$ be

$$
\begin{equation*}
\operatorname{shorth}(\mathrm{c})=\left[\mathrm{Z}_{(\mathrm{s})}, \mathrm{Z}_{(\mathrm{s}+\mathrm{c}-1)}\right] . \tag{1.7}
\end{equation*}
$$

Let

$$
\begin{equation*}
k_{n}=\lceil n(1-\delta) .\rceil \tag{1.8}
\end{equation*}
$$

Frey (2013) showed that for large $n \delta$ and iid data, the $\operatorname{shorth}\left(k_{n}\right)$ PI has maximum undercoverage $\approx 1.12 \sqrt{\delta / n}$, and used the shorth $(c)$ estimator as the large sample $100(1-\delta) \%$

PI where

$$
\begin{equation*}
c=\min (n,\lceil n[1-\delta+1.12 \sqrt{\delta / n}]\rceil) . \tag{1.9}
\end{equation*}
$$

A problem with the prediction intervals that cover $\approx 100(1-\delta) \%$ of the training data cases $Y_{i}$ (such as the $\operatorname{shorth}\left(k_{n}\right) \mathrm{PI}$ ), is that they have coverage lower than the nominal coverage of $1-\delta$ for moderate $n$. This result is not surprising since empirically statistical methods perform worse on test data. Increasing $c$ will improve the coverage for moderate samples.

Example 1. (Example 5.3 from Olive (2017b).) Given below were votes for preseason 1A basketball poll from Nov. 22, 2011 WSIL News where the 778 was a typo: the actual value was 78. As shown below, finding shorth(3) from the ordered data is simple. If the outlier was corrected, $\operatorname{shorth}(3)=[76,78]$.
$\begin{array}{lllll}111 & 89 & 778 & 78 & 76\end{array}$
order data: 767889111778

$$
13=89-76
$$

```
33 = 111 - 78
```

$$
689=778-89
$$

$\operatorname{shorth}(3)=[76,89]$
Olive (2007) developed prediction intervals for the full MLR model. Olive (2013) developed prediction intervals for models of the form $Y_{i}=m\left(\boldsymbol{x}_{i}\right)+e_{i}$, and variable selection models for (1.1) have this form, as noted by Olive (2017a). Both these PIs need $n / p$ large. Let $c$ be given by (2.2) with $d$ replaced by $p$, and let

$$
\begin{equation*}
b_{n}=\left(1+\frac{15}{n}\right) \sqrt{\frac{n+2 p}{n-p}} . \tag{1.10}
\end{equation*}
$$

Compute the $\operatorname{shorth}(c)$ of the residuals $=\left[r_{(s)}, r_{(s+c-1)}\right]=\left[\tilde{\xi}_{\delta_{1}}, \tilde{\xi}_{1-\delta_{2}}\right]$ where the $i$ th residual $r_{i}=Y_{i}-\hat{Y}_{i}=Y_{i}-\hat{m}\left(\boldsymbol{x}_{i}\right)$. Then a $100(1-\delta) \%$ large sample PI for $Y_{f}$ is

$$
\begin{equation*}
\left[\hat{m}\left(\boldsymbol{x}_{f}\right)+b_{n} \tilde{\xi}_{\delta_{1}}, \hat{m}\left(\boldsymbol{x}_{f}\right)+b_{n} \tilde{\xi}_{1-\delta_{2}}\right] . \tag{1.11}
\end{equation*}
$$

Note that correction factors $b_{n} \rightarrow 1$ are used in large sample confidence intervals and tests if the limiting distribution is $\mathrm{N}(0,1)$ or $\chi_{p}^{2}$, but a $t_{d_{n}}$ or $p F_{p, d_{n}}$ cutoff is used: $t_{d_{n}, 1-\delta} / z_{1-\delta} \rightarrow 1$ and $p F_{p, d_{n}, 1-\delta} / \chi_{p, 1-\delta}^{2} \rightarrow 1$ if $d_{n} \rightarrow \infty$ as $n \rightarrow 1$. Using correction factors for prediction intervals and bootstrap confidence regions improves the performance for moderate sample size $n$.

## CHAPTER 2

## PREDICTION INTERVALS AFTER VARIABLE SELECTION

If $n / p$ is large, the PI (1.11) can be used for the variable selection estimators with $\hat{m}\left(\boldsymbol{x}_{f}\right)=\hat{Y}_{f}=\boldsymbol{x}_{f, I_{d}}^{T} \hat{\boldsymbol{\beta}}_{I_{d}}$ where $I_{d}$ denotes the index of predictors selected from the variable selection method. For example, $I_{d}=I_{\text {min }}$ is the model that minimizes $C_{p}$ for forward selection. Now we want $I_{d}$ to use $d=M=\min (\lceil n / J\rceil, p)$ variables where $n / p$ is not necessarily large.

PI (1.11) needs the shorth of the residuals to be a consistent estimator of the population shorth of the error distribution. Olive and Hawkins (2003) show that if the $\left\|\boldsymbol{x}_{i}\right\|$ are bounded and $\hat{\boldsymbol{\beta}}$ is a consistent estimator of $\boldsymbol{\beta}$, then $\max _{i=1, \ldots, n}\left|r_{i}-e_{i}\right| \xrightarrow{P} 0$ and the sample quantiles of the residuals estimate the population quantiles of the error distribution. For OLS, each submodel $I$ produces a $\sqrt{n}$ consistent estimator provided that $S \subseteq I$.

The Cauchy Schwartz inequality says $\left|\boldsymbol{a}^{T} \boldsymbol{b}\right| \leq\|\boldsymbol{a}\|\|\boldsymbol{b}\|$. Suppose $\sqrt{n}(\hat{\boldsymbol{\beta}}-\boldsymbol{\beta})=O_{P}(1)$ is bounded in probability. This will occur if $\sqrt{n}(\hat{\boldsymbol{\beta}}-\boldsymbol{\beta}) \xrightarrow{D} N_{p}(\mathbf{0}, \boldsymbol{\Sigma})$, e.g. if $\hat{\boldsymbol{\beta}}$ is the OLS estimator. Then

$$
\left|r_{i}-e_{i}\right|=\left|Y_{i}-\boldsymbol{x}_{i}^{T} \hat{\boldsymbol{\beta}}-\left(Y_{i}-\boldsymbol{x}_{i}^{T} \boldsymbol{\beta}\right)\right|=\left|\boldsymbol{x}_{i}^{T}(\hat{\boldsymbol{\beta}}-\boldsymbol{\beta})\right| .
$$

Hence

$$
\sqrt{n} \max _{i=1, \ldots, n}\left|r_{i}-e_{i}\right| \leq\left(\max _{i=1, \ldots, n}\left\|\boldsymbol{x}_{i}\right\|\right) \quad\|\sqrt{n}(\hat{\boldsymbol{\beta}}-\boldsymbol{\beta})\|=O_{P}(1)
$$

since max $\left\|\boldsymbol{x}_{i}\right\|=O_{P}(1)$ or there is extrapolation. Hence OLS residuals behave well if the zero mean error distribution of the iid $e_{i}$ has a finite variance $\sigma^{2}$.

Let $d$ be a crude estimate of the model degrees of freedom. For forward selection with OLS, PCR, and PLS, $d=j$ is the number of components $V_{1}, \ldots, V_{j}$ in model $I_{j}$. The Olive (2017d) and Pelawa Watagoda and Olive (2017) PI that can work if $n \gg p$ or $p>n$ is defined below. The PI is similar to the Olive (2013) PI (1.11) with $p$ replaced by $d$, but some care needs to be taken to that the PI is well defined and does not have infinite length.

Let $q_{n}=\min (1-\delta+0.05,1-\delta+d / n)$ for $\delta>0.1$ and

$$
\begin{equation*}
q_{n}=\min (1-\delta / 2,1-\delta+10 \delta d / n), \quad \text { otherwise } \tag{2.1}
\end{equation*}
$$

If $1-\delta<0.999$ and $q_{n}<1-\delta+0.001$, set $q_{n}=1-\delta$. Let

$$
\begin{equation*}
c=\left\lceil n q_{n}\right\rceil \tag{2.2}
\end{equation*}
$$

and let

$$
\begin{equation*}
b_{n}=\left(1+\frac{15}{n}\right) \sqrt{\frac{n+2 d}{n-d}} \tag{2.3}
\end{equation*}
$$

if $d \leq 8 n / 9$, and

$$
b_{n}=5\left(1+\frac{15}{n}\right)
$$

otherwise. Compute the $\operatorname{shorth}(c)$ of the residuals $=\left[r_{(s)}, r_{(s+c-1)}\right]=\left[\tilde{\xi}_{\delta_{1}}, \tilde{\xi}_{1-\delta_{2}}\right]$. Then a $100(1-\delta) \%$ large sample PI for $Y_{f}$ is

$$
\begin{equation*}
\left[\hat{m}\left(\boldsymbol{x}_{f}\right)+b_{n} \tilde{\xi}_{\delta_{1}}, \hat{m}\left(\boldsymbol{x}_{f}\right)+b_{n} \tilde{\xi}_{1-\delta_{2}}\right] . \tag{2.4}
\end{equation*}
$$

## CHAPTER 3

## EXAMPLES AND SIMULATIONS

Let $\boldsymbol{x}=\left(1 \boldsymbol{u}^{T}\right)^{T}$ where $\boldsymbol{u}$ is the $p-1 \times 1$ vector of nontrivial predictors. For the simulations, for $i=1, \ldots, n$, we generated $\boldsymbol{w}_{i} \sim N_{p-1}(\mathbf{0}, \boldsymbol{I})$ where the $m=p-1$ elements of the vector $\boldsymbol{w}_{i}$ are iid $\mathrm{N}(0,1)$. Let the $m \times m$ matrix $\boldsymbol{A}=\left(a_{i j}\right)$ with $a_{i i}=1$ and $a_{i j}=\psi$ where $0 \leq \psi<1$ for $i \neq j$. Then the vector $\boldsymbol{u}=\boldsymbol{A} \boldsymbol{w}_{i}$ so that $\operatorname{Cov}(\boldsymbol{u})=\boldsymbol{\Sigma} \boldsymbol{u}=\boldsymbol{A} \boldsymbol{A}^{T}=\left(\sigma_{i j}\right)$ where the diagonal entries $\sigma_{i i}=\left[1+(m-1) \psi^{2}\right]$ and the off diagonal entries $\sigma_{i j}=\left[2 \psi+(m-2) \psi^{2}\right]$. Hence the correlations are $\operatorname{cor}\left(x_{i}, x_{j}\right)=\rho=\left(2 \psi+(m-2) \psi^{2}\right) /\left(1+(m-1) \psi^{2}\right)$ for $i \neq j$ where $x_{i}$ and $x_{j}$ are nontrivial predictors. If $\psi=1 / \sqrt{c p}$, then $\rho \rightarrow 1 /(c+1)$ as $p \rightarrow \infty$ where $c>0$. As $\psi$ gets close to 1 , the predictor vectors cluster about the line in the direction of $(1, \ldots, 1)^{T}$. Then $Y_{i}=1+1 x_{i, 2}+\cdots+1 x_{i, k}+e_{i}$ for $i=1, \ldots, n$. Hence $\boldsymbol{\beta}=(1, . ., 1,0, \ldots, 0)^{T}$ with $k+1$ ones and $p-k-1$ zeros. The zero mean errors $e_{i}$ were iid of five types: i) $\mathrm{N}(0,1)$ errors, ii) $t_{3}$ errors, iii) $\operatorname{EXP}(1)-1$ errors, iv) uniform( $-1,1$ ) errors, and v) $0.9 \mathrm{~N}(0,1)+$ $0.1 \mathrm{~N}(0,100)$ errors.

The lengths of the asymptotically optimal $95 \%$ PIs are i) $3.92=2(1.96)$, ii) 6.365 , iii) 2.996 , iv) $1.90=2(0.95)$, and v) 13.490. Suppose the simulation uses $K$ runs and $W_{i}=1$ if $Y_{f}$ is in the $i$ th PI, and $W_{i}=0$ otherwise, for $i=1, \ldots, K$. Then the $W_{i}$ are iid $\operatorname{binomial}\left(1,1-\delta_{n}\right)$ where $\rho_{n}=1-\delta_{n}$ is the true coverage of the PI when the sample size is $n$. Let $\hat{\rho}_{n}=\bar{W}$. Since $\sum_{i=1}^{K} W_{i} \sim \operatorname{binomial}\left(\mathrm{~K}, \rho_{\mathrm{n}}\right)$, the standard error $S E(\bar{W})=\sqrt{\rho_{n}\left(1-\rho_{n}\right) / K}$. For $K=5000$ and $\rho_{n}$ near 0.9 , we have $3 S E(\bar{W}) \approx 0.01$. Hence an observed coverage of $\hat{\rho}_{n}$ within 0.01 of the nominal coverage $1-\delta$ suggests that there is no reason to doubt that the nominal PI coverage is different from the observed coverage. So for a large sample $95 \%$ PI, we want the observed coverage to be between 0.94 and 0.96 . Also a difference of 0.01 is not large. Coverage slightly higher than the nominal coverage is better than coverage slightly lower than the nominal coverage.

We used $\mathrm{J}=5,10,20,50$, and $\lceil n / p\rceil$ as long as $J \leq n / p$ since $n / J \geq p$ uses the
full model. The selected model used the $d$ variables. The simulation used 5000 runs with $p=20,40, n$, and $2 n$. The simulation used $\psi=0,1 / \sqrt{p}$, and 0.9 . An observed coverage in $[0.94,0.96]$ gives no reason to doubt that the PI has the nominal coverage of 0.95 . The simulation used $k=1,19$, and $p-1$. Table 1 shows some simulations for the new large sample prediction interval (2.4).

Table 3.1. Simulated PI Coverages and Lengths, Error type $=$ i)

## CHAPTER 9

## CONCLUSIONS

0 . When $n / J \geq p$, the method is doing a full OLS. In other words both PCR and PLS produce same coverage and lengths which are those of the OLS, as stated before.

1. When $p=n$, or $2 n$, typically PLS coverage $\ll$ PCR coverage implying that PLS does not work for sufficiently large value of $p$. This was already stated before, Chun and Keles (2010) show that PLS does not give a consistent estimator of $\boldsymbol{\beta}$ unless $p / n \rightarrow 0$. This can also be seen by the tables on previous pages, when $p=n$, or $2 n$. Refer to table 9.1.
2. When $n>2 p, n / J<p$, and $k=1$, PLS seems to work slightly better than PCR. This is seen by the coverage percentage and length, PCR gives us a longer coverage length. Refer to table 9.2.
3. When $n>2 p, n / J<k+1$, or maybe when $k=p-1$, PLS seems much more reliable than PCR. Refer to table 9.3 for examples. This is could also be due to the fact that $\psi=0$ implying that there was no correlation between the predictors which usually lead to much longer PCR lengths than what was expected given the error types. Refer to table 9.3.

Bachelor of Science, Mathematics, August 2015

Research Paper Title:
Prediction Intervals for partial least squares and principal component regression Using D Variables

Major Professor: Dr. David J. Olive
