Abstract. *Plasmodium falciparum* and *P. malariae* occur endemically in many parts of Africa. Observations from malariatherapy patients suggest that co-infection with *P. malariae* may increase *P. falciparum* gametocyte production. We determined *P. falciparum* gametocyte prevalence and density by quantitative nucleic acid sequence-based amplification (QT-NASBA) after antimalarial treatment of Kenyan children with either *P. falciparum* mono-infection or *P. falciparum* and *P. malariae* mixed infection. In addition, we analyzed the relationship between mixed species infections and microscopic *P. falciparum* gametocyte prevalence in three datasets from previously published studies. In Kenyan children, QT-NASBA gametocyte density was increased in mixed species infections ($P = 0.03$). We also observed higher microscopic prevalences of *P. falciparum* gametocytes in mixed species infections in studies from Tanzania and Kenya (odds ratio = 2.15, 95% confidence interval = 0.99–4.65 and 2.39, 1.58–3.63) but not in a study from Nigeria. These data suggest that co-infection with *P. malariae* is correlated with increased *P. falciparum* gametocytemia.

INTRODUCTION

Plasmodium falciparum and *P. malariae* are malaria species that occur endemically in many parts of sub Saharan Africa. Mixed infections with both species are usually observed in a small proportion of persons in cross-sectional studies (2–14%),^{1–4} although their cumulative prevalence has been documented at 20–50% in longitudinal studies conducted over 1–2 years.^{2–4} The co-occurrence of *P. falciparum* and *P. malariae* is often higher than would be expected on the basis of their individual parasite prevalence,^{5–8} and one parasite species may influence the infection dynamics of the other. The biologic and subsequent clinical interactions are therefore of interest, especially in light of vaccination trials specifically targeted at *P. falciparum*.

In mixed infections, the presence of *P. malariae* parasites can influence the disease manifestation of *P. falciparum* with a reduction in disease severity⁹ and a lower peak parasitemia,¹⁰ possibly as a consequence of heterologous immunity.^{11,12} Observations from malariatherapy patients indicate that co-infection with *P. malariae* may increase *P. falciparum* gametocytemia.¹³ If this increased gametocyte production is manifested in co-infections in field settings, this could have implications for the spread of malaria and malaria control. Predictably few field studies have addressed this issue: most clinical studies focus on *P. falciparum* mono-infections and use co-infection with other malaria species as an exclusion criterion. A study of 5,682 symptomatic patients in Thailand found that *P. falciparum* gametocytes were less common in mixed infections with *P. vivax*.¹⁴ A small cross-sectional study in 25 households in Mozambique suggested that *P. falciparum* gametocytes may also be less common in the presence of *P. malariae*.¹ We examined the relation between *P. falciparum* gametocytemia and mixed infection with *P. malariae* in four

separate studies. We compare *P. falciparum* gametocyte prevalence and density assessed by molecular methods after anti-malarial treatment of Kenyan children naturally infected with either *P. falciparum* mono-infection or *P. falciparum* and *P. malariae* mixed infection. In addition, we present analyses of the relationship between mixed species infections and microscopic *P. falciparum* gametocyte prevalence in three large datasets from previously published studies conducted in Tanzania, Kenya, and Nigeria.

MATERIALS AND METHODS

Gametocytemia and mixed species infections after antimalarial drug treatment. The study assessing *P. falciparum* gametocyte prevalence and density after antimalarial treatment was conducted from October to December 2004 in Mbita, a rural village on the shores of Lake Victoria in the Suba District of western Kenya. Transmission intensity is high and perennial in the study area (entomologic inoculation rate approximately six infectious bites per person per month)¹⁵ with *P. falciparum* as predominant parasite species accounting for more than 95% of the clinical malaria cases.¹⁶ Patients with *P. falciparum* mono-infection were enrolled as part of a larger drug sensitivity study that was reported previously (Clinical Trials registration no. ISRCTN31291803 available from <http://www.controlled-trials.com/ISRCTN31291803>).¹⁷ Children 6 months to 10 years of age with a temperature > 37.5°C measured by earthermometer or a history of fever within the last 48 hours and with *P. falciparum* mono-infection at a density between 500 and 100,000 parasites/μL were eligible for recruitment. Exclusion criteria were inability to take drugs orally, known hypersensitivity to any of the drugs given, reported treatment with antimalarial chemotherapy in the past two weeks, evidence of chronic disease or acute infection other than malaria, and domicile outside the study area and signs of severe malaria. Children with *P. falciparum* and *P. malariae* mixed infection were enrolled in the study on the basis of the same criteria but no minimum parasite density was used as an inclusion criterion. All subjects included in the

analyses were treated with sulfadoxine-pyrimethamine (SP; Fansidar®; Hoffmann LaRoche, Basel, Switzerland) plus amodiaquine (AQ), 10 mg/kg, once a day for three days (Camoquine®; Pfizer, Dakar, Senegal) and subsequently followed for 28 days. The study protocol (SSC no. 791) was reviewed and approved by the Scientific Steering Committee and Ethical Review Committee of the Kenya Medical Research Institute, Nairobi, Kenya.

Microscopy and molecular parasite detection. Giemsa-stained blood smears were screened for asexual parasites and gametocytes at enrollment and on days 3, 7, 14, and 28 after treatment. Slides were declared negative if no parasites were observed in 100 microscopic fields, each containing approximately 15–20 leukocytes; asexual parasites and gametocytes were counted against 200 and 500 leukocytes, respectively. Conversion to parasites/microliter was made using a conversion rate of 8,000 leukocytes/ μ L. Parasite detection by quantitative nucleic acid sequence-based amplification (QT-NASBA) was done for a random selection of *P. falciparum* mono-infections with complete follow-up (47 of 127)¹⁷ and for all *P. falciparum* plus *P. malariae* mixed infections (21 of 21). Nucleic acids were extracted from 50- μ L finger prick blood samples by the method described by Boom and others.¹⁸ *Plasmodium falciparum* QT-NASBA was performed on a NucliSens EasyQ analyzer (bioMérieux, Boxtel, The Netherlands) as described elsewhere for *Pfs25* mRNA.¹⁹ *Pfs25* mRNA is only expressed in stage V *P. falciparum* gametocytes,²⁰ and the *Pfs25* QT-NASBA has a detection limit of 20–100 gametocytes/mL. Nuclisens Basic kits (bioMérieux) were used for amplification according to the manufacturer's instructions at a KCl concentration of 80 mM. A standard dilution series of *in vitro* cultured mature NF54 gametocytes²¹ was included in each run to ascertain gametocyte density. The presence of *P. malariae* parasites in mixed infections was confirmed by detecting *P. malariae*-specific 18S ribosomal RNA using QT-NASBA.²²

Data analyses. Nonparametric Wilcoxon rank sum tests were used to test differences between groups for statistical significance in case of continuous variables; chi-square tests were used for dichotomous variables. Multiple logistic regression models with generalized estimating equations (GEEs) were used to test the influence of *P. falciparum* plus *P. malariae* mixed infection on *Pfs25* QT-NASBA gametocyte prevalence. A similar procedure was carried out using GEEs for *Pfs25* QT-NASBA gametocyte density. Estimates were adjusted for potential confounding factors (i.e., age, treatment outcome, microscopic asexual parasite density at enrollment, and fever at enrollment) and a random effect was included in the models to show correlations within persons. To quantify the influence of co-infection with *P. malariae* on *P. falciparum* gametocyte densities during follow-up, we determined the area under the curve (AUC) of *Pfs25* QT-NASBA gametocyte density versus time.^{23,24} This measure incorporates both the magnitude and the duration of transmission potential and was described by Mendez and others.²⁴ The AUC from days 0 to 42 was calculated as $AUC = [(3 - 0) \times (g_0 + g_3)/2 + (7 - 3) \times (g_3 + g_7)/2 + (14 - 7) \times (g_7 + g_{14})/2 + (28 - 14) \times (g_{14} + g_{28})/2]/28$ where g_d represents *Pfs25* QT-NASBA gametocyte density on day d . Gametocyte negative samples were included as zeroes. The measure was scaled by 28 so that it represents AUC per day and this was transformed by \log_{10} for comparisons. Statistical analyses were

performed using procedures available in SPSS version 12.0 (SPSS Inc., Chicago, IL) and Stata version 8.0 (Stata Corporation, College Station, TX).

Analyses on data from three previously conducted studies. Data from three studies were analyzed on the basis of the availability of information on the prevalence of *P. falciparum* asexual parasites and gametocytes and *P. malariae* asexual parasites.

The first dataset was obtained from a series of cross-sectional studies in six altitude transects (150–1,800 meters) in the Kilimanjaro and Tanga regions in northern Tanzania.²⁵ Cross-sectional surveys in individuals 6 months to 45 years of age were conducted twice in a period of 6 months; 100 microscopic fields were screened for asexual parasites of *P. falciparum* and *P. malariae* and gametocytes of *P. falciparum*. Asexual and gametocyte densities were recorded per 200 leukocytes and 500 leukocytes, respectively.

The second dataset was obtained from a longitudinal study in Mbita in western Kenya.²⁶ Children 6 months to 16 years of age were screened weekly for five weeks; 100 microscopic fields were screened for asexual parasites of *P. falciparum* and *P. malariae* and gametocytes of *P. falciparum*.

The third dataset was obtained from the Garki dataset from 1970 and 1971, the years prior to the transmission-reducing intervention (<http://www.sti.ch/research/biostatistics/downloads.html>).²⁷ In this part of the study, surveys were conducted in the general population (0–72 years of age) of villages in Garki in northern Nigeria. Every ten weeks slides were collected and 200 or 400 microscopic fields were screened for asexual parasites of *P. falciparum* and *P. malariae* and gametocytes of *P. falciparum*. Parasite densities were calculated as the percentage of positive fields. Sampling took place every 10 weeks.

Microscopic gametocyte density data were available for the Kenyan and Tanzanian datasets but because there was little variation in these densities (typically 16–32 gametocytes/ μ L), we considered it appropriate to present microscopic gametocyte prevalence data only. Although the sampling interval in the Tanzanian and Nigerian datasets was relatively large, this may not guarantee independence of observations.²⁸ Therefore, multiple logistic regression models with GEEs were initially used to test the relation between *P. falciparum* gametocyte prevalence and the presence of *P. falciparum* and *P. malariae* mixed infections in all data sets. Estimates were adjusted for potential confounding factors and a random effect was included in the models to show correlations within persons. If the addition of the random effect did not improve the model, as was the case for data from Tanzania, outcomes of conventional logistic regression models were presented.

RESULTS

Gametocytemia and mixed species infections after antimalarial drug treatment. In Mbita, Kenya, 127 *P. falciparum* mono-infections and 21 *P. falciparum* and *P. malariae* mixed infections were treated with SP plus AQ. The presence of *P. malariae* parasites was confirmed by *P. malariae* 18S ribosomal RNA QT-NASBA in all mixed species infections (21 of 21) and in none of the *P. falciparum* mono-infections (0 of 47) tested. Complete 28-day follow-up data were available for 115 *P. falciparum* mono-infections and 20 mixed species infec-

tions. An adequate clinical response was observed in 87.0% (100 of 115) of the *P. falciparum* mono-infections and 100% (20 of 20) of the mixed species infections ($P = 0.13$). Children with mixed species infections were significantly older than those with *P. falciparum* mono-infections ($P = 0.007$; Table 1). Microscopic *P. falciparum* gametocyte prevalence was non-significantly higher in mixed species infections ($P = 0.26$; Table 1).

Gametocyte prevalence by *Pfs25* QT-NASBA was 91.1% (41 of 45) in *P. falciparum* mono-infections at enrollment and 90.5% (19 of 21) in mixed species infections ($P = 0.93$; Table 1). The *Pfs25* QT-NASBA gametocyte prevalence at enrollment was negatively associated with age ($\beta = -0.36$, SE = 0.17, $P = 0.04$) and showed a weak positive association with microscopic asexual parasite density ($\beta = 0.38$, SE = 0.35, $P = 0.28$). On the third day after the initiation of treatment, *Pfs25* QT-NASBA gametocyte prevalence was non-significantly higher in mixed species infections ($P = 0.07$) (Figure 1A) without any clear difference during the rest of follow-up. When the entire period of follow-up was considered, there was no statistically significant difference in the prevalence of gametocytes by *Pfs25* QT-NASBA between *P. falciparum* mono-infections and mixed species infections (GEE $\beta = 0.21$, SE = 0.42, $P = 0.62$), after adjustment for age and asexual parasite density at enrollment. However, in *Pfs25* QT-NASBA gametocyte carriers, the *Pfs25* QT-NASBA gametocyte density was consistently increased in mixed species infections (Figure 1B). The geometric mean *Pfs25* QT-NASBA density was more than two-fold higher on the third day after initiation of treatment in mixed species infections: 2.9 gametocytes/ μL (95% confidence interval [CI] = 0.7–12.4) for *P. falciparum* mono-infections and 8.2 gametocytes/ μL (95% CI = 3.1–21.3) for mixed species infections ($P = 0.11$). The *Pfs25* QT-NASBA gametocyte density throughout the study period was significantly higher in mixed infections than in mono-infections (GEE $\beta = 0.38$, SE = 0.17, $P = 0.03$) after adjustment for age and microscopic *P. falciparum* asexual parasite density at enrollment. Treatment outcome and the presence of fever at enrollment did not confound this relationship.

The transmission potential during follow-up, quantified as the AUC of *Pfs25* QT-NASBA gametocyte density versus time, was significantly higher for mixed species infections ($P = 0.02$; Table 2). The number of sampling times when gametocytes were detected by *Pfs25* QT-NASBA was not significantly different between the two groups ($P = 0.45$), but

FIGURE 1. *Plasmodium falciparum* gametocyte prevalence and density determined by *Pfs25* quantitative nucleic acid sequence-based amplification (QT-NASBA) in *P. falciparum* mono-infections and mixed infections with *P. malariae*. Shown are QT-NASBA gametocyte prevalence (A) and density (B) for *P. falciparum* mono-infections (closed triangles, broken line) and *P. falciparum* plus *P. malariae* mixed infections (open squares, solid line). Bars indicate the 95% confidence intervals.

the geometric mean *Pfs25* QT-NASBA gametocyte density in *Pfs25* QT-NASBA gametocyte-positive samples was higher in mixed species infections ($P = 0.03$; Table 2).

Gametocyte prevalence in mixed species infections in previously conducted studies. We analyzed three datasets on the relationship between *P. falciparum* and *P. malariae* mixed

infection and the prevalence of *P. falciparum* gametocytes. Prevalence data were available from multiple time points. Data were presented for all time points combined; the fact that multiple observations were derived from the same persons was taken into account in the statistical analysis. There was considerable variation in the strength of the association between microscopic *P. falciparum* gametocyte prevalence and mixed species infection (Table 3). We observed a borderline significant increase in *P. falciparum* gametocyte prevalence for mixed species infections in data from different sites in north eastern Tanzania (odds ratio [OR] = 2.15, 95% CI = 0.99–4.65) and this increase was statistically significant for data from Kenya (OR = 2.39, 95% CI = 1.58–3.63), after adjustment for age and concurrent microscopic asexual parasite density. In the dataset from Nigeria, the effect varied between different age groups. There was a borderline significant lower microscopic *P. falciparum* gametocyte prevalence in mixed species infections for persons less than 10 years of age (OR = 0.88, 95% CI 0.56–1.00), and there was a weak and non-significant higher risk in older children after adjustment for age and concurrent microscopic *P. falciparum* asexual parasite density (OR = 1.13, 95% CI 0.87–1.48).

DISCUSSION

In this study, we show that co-infection with *P. malariae* is correlated with an increase in *P. falciparum* gametocytes. This finding is consistent in three different studies from different malaria-endemic areas, using both microscopy and molecular methods; the effect was not apparent in a fourth study.

In Kenyan children with symptomatic malaria, we observed a non-significantly higher microscopic *P. falciparum* gametocyte prevalence prior to treatment. Although *Pfs25* QT-NASBA gametocyte prevalence was not significantly increased, *Pfs25* QT-NASBA gametocyte density was consistently higher in mixed species infections throughout one month of follow-up. This finding could not be explained by differences in treatment efficacy, age, fever, or enrollment parasite density. Kenyan children with mixed species infec-

tions were more likely to respond well to treatment, were older, and had lower *P. falciparum* asexual parasite densities at enrollment; all factors previously associated with lower rather than higher gametocyte prevalence and density.^{26,29}

In *P. falciparum*, most gametocytes that appear after treatment are likely to have been committed to sexual stage development prior to treatment. Gametocytes take 8–12 days to develop³⁰ and the peak in gametocyte prevalence and density that is commonly seen after treatment is at least partly the result of an efflux of these sequestered gametocytes.³¹ Although a more pronounced release of gametocytes in the presence of *P. malariae* co-infection could explain our findings after antimalarial treatment, it seems more plausible that mixed species infections have a higher commitment to production of *P. falciparum* gametocytes that persist after treatment, without a causative role for treatment as such. This finding is also suggested by the non-significantly increased microscopic gametocyte prevalence and *Pfs25* QT-NASBA gametocyte density in mixed species infections prior to treatment.

Retrospective analysis of data from previously conducted epidemiologic studies show a similar picture. In studies conducted in Kenya and Tanzania, we observed a significantly higher microscopic prevalence of *P. falciparum* gametocytes in mixed species infections. Because microscopy underestimates the total proportion of gametocyte carriers and only detects relatively high gametocyte densities,¹⁹ these microscopic findings can be interpreted as a higher prevalence of high density gametocyte carriage in mixed species infections.

The Nigerian Garki study did not confirm the relationship between *P. falciparum* gametocytemia and mixed species infections. In contrast, there was a non-significantly lower *P. falciparum* gametocyte prevalence associated with mixed species infection in children less than 10 years of age,¹ and there was a weak and non-significant increased risk of *P. falciparum* gametocyte carriage in older persons with mixed species infections. This finding indicates that the relationship between mixed species infections and gametocytemia may be different under different endemicities. Despite this consideration, our

‡ Adjusted for correlations between observations from the same individual. Data were derived from previously published studies that were conducted in Tanzania,²⁴ Kenya,²⁵ and Nigeria.²⁶

findings in three independent datasets strengthen our conclusion that *P. falciparum* gametocyte production may be higher in the presence of *P. malariae* parasites. This would confirm observations from malariatherapy patients where co-infection with *P. malariae* stimulates *P. falciparum* gametocyte production.¹³ A possible influence in the other direction, i.e., a change in *P. malariae* gametocytemia in mixed species infections, could not be determined. *Plasmodium malariae* gametocytes were not recorded in any of the studies discussed in this report and a molecular tool to detect sexual stage parasites of other species than *P. falciparum* is currently unavailable.

Although three different studies show a similar relationship between mixed species infections and *P. falciparum* gametocytemia, our findings should be interpreted with caution. Malaria-associated leukopenia may have impaired our estimate of microscopic gametocyte density in Kenyan children with symptomatic malaria, where a standard leukocyte concentration of 8,000 cells/ μ L was assumed.³² Moreover, the extent of leukopenia may differ between different plasmodium species³² and could therefore confound relationships between mixed species infections and microscopically estimated asexual parasite or gametocyte densities. Leukocyte counts are, however, unlikely to have influenced the major outcome measures of this study, which were *Pfs25* QT-NASBA gametocyte density and prevalence and microscopic gametocyte prevalence. In addition, none of the conducted studies were specifically designed to detect interactions between malaria species. This would ideally require longitudinal studies in the absence of antimalarial treatment. Our design hampers us to draw conclusions on causality in the observed relations. *Plasmodium falciparum* infections show parasitic waves that may be followed by an increased gametocyte production.³³ Similarly, *P. malariae* parasite densities may increase when *P. falciparum* densities decrease.³⁴ This may result in a simultaneous increase in concentrations of *P. malariae* asexual parasites and *P. falciparum* gametocytes, making them more likely to be detected by microscopy, without any causal relationship between the two.

If there is a causal relationship between mixed species infections and gametocyte production, it is likely to be mediated by cross-species immune responses. Mixed genotype infections have been associated with higher transmission success and higher gametocytemia in animal models.³⁵ A similar phenomenon may play a role in mixed species infections and may indicate a response of parasites in terms of transmission potential in the presence of a competitor. Although antibody-mediated parasite immunity seems to be largely species and strain-specific, it is likely that there is a certain degree of cross-reactive immunity between species.^{36,37} There is evidence for heterologous protective immunity for *P. falciparum* induced by *P. malariae*^{9,37} and for cross-species regulation of parasite densities.^{12,38,39} This cross-species immunity may also influence malaria transmission.³⁶ A higher infectivity of parasites to mosquitoes in the presence of a different malaria species was observed for simian malaria species⁴⁰ and for human *P. vivax* and *P. falciparum* in *Aotus* monkeys.⁴¹ Although we did not determine immune responses, we hypothesize that cross-reactive antibodies may play a role in explaining our findings. Antibodies that are cross-reactive between species may increase the immune stress experienced by *P. falciparum*, thereby stimulating this species to invest in trans-

mission stages. The observation from the Garki dataset that increased gametocyte prevalence is only observed in children more than 10 years of age may be related to the development of clinical immunity in this age group. Further analysis allowing for the effects of transmission intensity of both *P. falciparum* and *P. malariae* is warranted but beyond the scope of this report.

The relevance of our findings for malaria transmission depends on prevalence of mixed species infections and influence of an increase in gametocyte density on malaria transmission potential. We have recently shown a positive association between gametocyte density and the proportion of infected mosquitoes, including submicroscopic gametocyte densities.⁴² Thus, the higher densities of gametocytes (and the higher prevalence of high density gametocyte carriage) in mixed species infections are likely to result in a higher proportion of infected mosquitoes. The infectiousness of gametocytes in symptomatic Kenyan children was confirmed on day 14 after the initiation of treatment, with 23 of 28 children with *P. falciparum* mono-infections¹⁷ and 3 of 4 children with *P. falciparum* and *P. malariae* mixed infections infecting at least one mosquito. The prevalence of mixed species infections in a given population is highly variable. *Plasmodium falciparum* and *P. malariae* mixed infections may account for 6% of the *P. falciparum* malaria cases in western Kenya,⁴³ but the prevalence may be much higher in longitudinal studies²⁻⁴ or in studies using species specific molecular detection techniques.^{1,44} In our study, we found no sub-patent *P. malariae* infections in children with apparent *P. falciparum* mono-infections although a study from Mozambique found a two-fold increase in the proportion of mixed species infections using a polymerase chain reaction.¹ The prevalence of *P. malariae* infections may further increase when *P. falciparum*-specific control programs are implemented,² such as current vaccine trials.

In conclusion, our data suggest that the transmission potential of *P. falciparum* is increased by co-infection with *P. malariae*. Longitudinal studies are needed to confirm this relationship, to identify possible mechanisms, and to determine the duration and relevance of the potential increase in malaria transmission that we observe. These longitudinal studies should preferably use molecular tools to detect and quantify the different stages of parasite species in the absence of malaria treatment.

Received May 7, 2007. Accepted for publication November 19, 2007.

Acknowledgments: We thank the community of Mbita for their cooperation; and S. Kaniaru (Kenya Medical Research Institute), G. Omweri, N. Makio, P. Sawa, B. Kapesa, K. Okoth and P. Ongele (International Centre of Insect Physiology and Ecology) for their work at the clinic and in the field. We also thank the Joint Malaria Programme (a collaboration between the Tanzanian National Institute for Medical Research; Kilimanjaro Christian Medical Centre; the London School of Hygiene and Tropical Medicine, and the Centre for Medical Parasitology, University of Copenhagen) for access to the data from the Usambara Mountains.

Financial support: J. Teun Bousema is supported by The Netherlands Foundation for the Advancement of Tropical Research (W 07.05.203.00) through Poverty Related Infection Oriented Research, and Chris J. Drakeley is supported by a research fellowship in tropical medicine (#063516) from the Wellcome Trust.
