8 **Abstract**

9 Winter precipitation over Central Asia and the western Tibetan Plateau (CAWTP) is mainly

10 a result of the interaction between the westerly circulation and the high mountains around

11 the plateau. Empirical Orthogonal Functions (EOFs), Singular Value Decomposition (SVD),

12 linear regression and composite analysis were used to analyze winter daily precipitation and

13 other meteorological elements in this region from 1979 to 2013,in order to understand how

14 interactions between the regional circulation and topography affect the intraseasonal

15 variability in precipitation. The SVD analysis showed that the winter daily precipitation

16 variability distribution is characterized by a dipole pattern with opposite signs over the

17 northern Pamir Plateau and over the Karakoram Himalaya, similar to the second mode of EOF

18 analysis. This dipole pattern of precipitation anomaly is associated with local anomalies in

19 both the 700hPa moisture transport and the 500hPa geopotential height and is probably

20 caused by oscillations in the regional and large-scale circulations, which can influence the

21 westerly disturbance tracks and water vapor transport. The linear regression showed that the

22 anomalous mid-tropospheric circulation over CAWTP corresponds to an anti-phase variation

* Corresponding author. E-mail address: liuheng@ieecas.cn

23 of the 500 hPa geopotential height anomalies over the southern and northern North Atlantic

24 10 days earlier (at 95% significance level), that bear a similarity to   the North Atlantic

25 Oscillation (NAO). The composite analysis revealed that the NAO impacts the downstream

26 regions including CAWTP by controlling south-north two branches of the middle latitude

27 westerly circulation around the Eurasian border. During the positive phases of the NAO, the

28 northern branch of the westerly circulation goes around the northwest Tibetan Plateau,

29 whereas the southern branch encounters the southwest Tibetan Plateau, which leads to a

30 reduced precipitation over the northern Pamir Plateau and an increased precipitation over

31 the Karakoram Himalaya, and vice versa.

32 KEY WORDS: Topographic precipitation; North Atlantic Oscillation; Westerly circulation;

33 Statistical analysis; Intraseasonal variability.

34

35 **1   Introduction**

36   The geographical region covered by Central Asia and the western Tibetan Plateau (CAWTP,

37 30–45° N, 60–85° E) has complex terrains and a unique climate. The Turan Depression is

38 located in the northwest, whereas the high mountains and plateaus (e.g. the Iran Plateau, the

39 Hindu Kush, the Karakoram Himalaya, the Pamir Plateau and the Tian Shan mountains) are

40 located from the southwest to the northeast (Fig. 1). The CAWTP region has an arid to semiarid

41 climate with an annual precipitation less than 400 mm, except for a few of the high mountain

42 areas. Because of the scarcity of water resources, there is a high risk that global climate change

43 will threaten both the natural environment and the human population in this region (Ragab &

44   Prudhomme 2002, WB et al. 2009).

45   Despite the complex topography and lack of meteorological stations, satellite remote

46   sensing data have been used to determine the spatiotemporal distribution of precipitation

47   over Central Asia (Guo et al. 2015) and the western Tibetan Plateau (Pohl et al. 2015). High-

48   resolution regional climate models have also been used to determine the patterns of

49   precipitation over CAWTP (Small et al. 1999, Schiemann et al. 2008, Ozturk et al. 2012,

50   Maussion et al. 2014).

51   Previous studies have reported the spatiotemporal distribution and regional differences

52   in precipitation over CAWTP and have found that the major weather system controlling the

53   winter precipitation over CAWTP is the westerly circulation (Schiemann et al. 2009, Yin et al.

54   2014). In winter, the westerly circulation transports moisture to Central Asia (Bothe et al.

55   2012), southwest Asia (Malik et al. 2015) and the western Tibetan Plateau (Curio et al. 2015).

56   The westerly circulation is disturbed by the high mountains in this region and causes heavy

57   precipitation and storms over the Pamir Plateau, the Hindu Kush, the Karakoram Himalaya and

58   the western Himalaya (Lang & Barros 2004, Cannon et al. 2015a, b). Yin et al. (2014) compared

59   the differences in precipitation climatology between the arid area of Central Asia and the East

60   Asia monsoon region and showed that winter is the rainy season in Central Asia, whereas the

61   rainy season occurs in summer for East Asia. They further showed that the control

62   atmospheric circulation over the western area changes between winter and summer. In winter

63   it is dominated by westerly upper-air flows, bringing moisture from the upstream to the region

64   while in summer it is dominated by northeasterly winds from the Asian interior, resulting in a

65   dry condition. The westerly circulation is not only the major weather system controlling the

66   winter mean precipitation over CAWTP, but also precipitation interannual variability and trend

67   in the region (Chen et al. 2011, Yin et al. 2014, Cannon et al. 2015a).

68   There have been many reports that large-scale atmospheric teleconnections regulate the

69   mid-latitude westerly circulation variability which in turn may influence interannual

70   precipitation variation over CAWTP (e.g. Aizen et al. 2001, Syed et al. 2006, Mariotti 2007,

71   Filippi et al. 2014, Yin et al. 2014, Cannon et al. 2015a, b, Hoell et al. 2015). Although some

72   evidence has been found that at interannual time scale the El Niño–Southern Oscillation may

73   be related to the precipitation variation in the cold season over Central and Western Asia

74   (Mariotti 2007, Hoell et al. 2015), other research has shown a close relationship between the

75   winter interannual precipitation variation over CAWTP and the North Atlantic Oscillation (NAO)

76   (Aizen et al. 2001, Syed et al. 2006, 2010, Yadav et al. 2009, Filippi et al. 2014, Yao and Chen

77   2015). Aizen et al. (2001) analyzed the relationship between mid-latitude precipitation in Asia

78   and the large-scale circulation of the atmosphere using data from hydro-meteorological

79   stations. Their results showed more precipitation over the Pamir and Tian Shan mountains

80   during the positive phases of the NAO. Syed et al. (2006) found a positive precipitation

81   anomaly over northwestern Asia that is well matched with the positive phase of the NAO.

82   Syed et al. (2010) presented a regional climate modeling study on both NAO and ENSO and

83   discussed the influence of westerly disturbances. Filippi et al. (2014) verified that winter

84   interannual precipitation variation over the Hindu Kush–Karakoram Himalaya region is

85   affected by the NAO. During the positive phases of the NAO, the Middle East, which is

4

86 upstream of CAWTP, experiences stronger westerly winds and evaporation, which leads to an

87 enhanced moisture transport and therefore enhanced precipitation over the Hindu Kush. Yao

88 and Chen (2015) found a significant negative correlation between the yearly precipitation on

89 mountains of the Syr Darya River Basin and NAO index from 1891 to 2011 but it turned out

90 non-significant on plains.

91 Previous studies have mainly considered the interannual variation in winter precipitation

92 over a specific area and its connection with the NAO and other large-scale circulations (e.g.

93 Aizen et al. 2001, Syed et al. 2006, Mariotti 2007, Filippi et al. 2014, Yin et al. 2014, Cannon et

94 al. 2015a, Hoell et al. 2015). However, little attention has been paid to the spatiotemporal

95 distribution of precipitation variability over CAWTP at the intraseasonal time scale. Therefore

96 it is important to investigate the spatial and temporal distribution of winter precipitation

97 variation over CAWTP on this time scale, to analyze its connection with regional and large-

98 scale circulations and to elucidate physical processes involved by using daily precipitation data

99 and other meteorological parameters.

100

101 **2   Data and methods**

102 Daily precipitation data from the Climate Prediction Center (Chen et al. 2008) and daily

103 meteorological variables of ERA-Interim from the European Centre for Medium-Range

104 Weather Forecasts (Dee et al. 2011) were used in this study. Sapna Rana (2017) have already

105 used the CPC Unified Rain gauge data and compared it with 9 other precipitation products

106 over the central southwest Asia. Their results show that the CPC data can reasonably reflect

5

107 the spatial-temporal distribution of winter precipitation over CAWTP despite some systematic

108 differences in the time means The used ERA-Interim variables include the daily 700 and 500

109 hPa geopotential height, meridional and zonal winds, the total column of water vapor (TCWV)

110 and the mean sea level pressure. The horizontal resolution of all the data is 0.5°longitude ×

111 0.5° latitude. In consideration of the higher accuracy of the reanalysis data obtained over high

112 mountain areas after 1979, when satellite data were first applied (Cannon et al. 2015b), we

113 chose all winters (December-March), consistent with other studies analyzing the relationships

114 between teleconnection patterns and precipitation in this area (Syed et al. 2006, 2010, Yadav

115 et al. 2009, Filippi et al. 2014) from 1979 to 2013, a total of 4244 days, as the study period.

116 The daily average data were obtained from four records with a six-hour interval for each day.

117 The encounter of westerly wind with high mountains of Tibetan Plateau happened around

118 700 hPa , which is closely connected with topographic precipitation, and therefore 700 hPa

119 wind is used to indicate low tropospheric circulation. The 500hPa geopotential height anomaly

120 can indicate the teleconnections.

121   To determine the characteristics of the winter intraseasonal precipitation and circulation

122 variability in CAWTP, the climatological seasonal cycle from December to the next March in

123 the daily data was removed before the analysis. We averaged the data of the same date of all

124 the years (1979-2013) and then calculated the 21 day moving mean as the climate mean state.

125 Thus, the daily values with climatological seasonal cycle removed were obtained by

126 subtracting the climate mean state from the actual data according to the following formula:

127
$$Z_n^* = Z_n - (\sum_{i=-10,10} (\sum_{j=1,35} Z_{k+(i-1)\times 365+j})/35)/21$$

6

128 where n is the number of days from December 1, 1979; k is the number of days from

129 December 1 of a specific year; i is the number of years from 1979; j is the day from 10 days

130 before to 10 days after a specific day; and Z_n^* is the value after removing the climatological

131 seasonal cycle.

132 The EOF analysis was used to decompose winter daily precipitation variability over

133 CAWTP to find the spatial patterns as well as their time variation (Bjornsson and Venegas

134 1997). Figure 1 shows the study area with 1581 grid boxes and 4244 day time series at each

135 grid box, which is the basis for the EOF analysis.

136 Singular value decomposition (SVD) analysis (Wallace et al. 1992) was applied to show

137 the spatiotemporal relationship between the winter daily precipitation and the regional

138 circulation variations over CAWTP. This method identifies a pair of covaried spatial patterns,

139 their temporal variations and the covariance between two variables (Bjornsson and Venegas

140 1997).

141 Lead-lag linear regression was applied to study the connection between the 500 hPa

142 geopotential height variability over CAWTP and the upstream westerly jet variability (Wang

143 and Zhang 2015).

144 We also constructed composites of the precipitation distribution in CAWTP during

145 positive and negative NAO cases respectively, and discussed the relationship between the

146 NAO and the precipitation variability at the intraseasonal time scale. The NAO index was

147 defined as the standardized difference in mean sea level pressure between the southern

148 North Atlantic (25°–40°N, 50°–10°W) and the northern North Atlantic (50°–65°N, 10°–50°W)

7

149 (Hurrell 1996). After calculating the daily index for every winter from 1979 to 2013, the central

150 day of a positive (negative) NAO phase event was defined as the day with the relative

151 maximum (minimum) value of the NAO index in continuous five days and being greater (less)

152 than 1.5 (-1.5) at the same time. In this way, a total of 85 positive NAO phase cases and 82

153 negative phase cases were selected for the composites. Here we did composite analysis

154 based on cases with strong NAO anomalies in order to see teleconnections between two

155 regions and significant NAO related remote climatic anomalies over CAWTP. To trace westerly

156 wind disturbance (WWD) tracks, a wave-tracking approach was applied as documented in

157 Cannon (2015b) who defined the centers of the disturbances by standardized 500 hPa

158 geopotential height anomaly and a set of spatial threshold and temporal correlation to

159 identify the tracks. Here we used the 500hPa geopotential height anomaly of 1 standard

160 deviation and the spatial extent of 5 degrees as a set of thresholds to identify the location of

161 centers to count the WWDs. Then the WWD frequency in every grid was calculated.

162

163 **3 Spatial and temporal distribution of winter precipitation over CAWTP and its connection**

164 **with the contemporaneous regional circulation**

165 3.1 Winter precipitation climatology over CAWTP

166   The climate of Central Asia is controlled on an annual basis by westerly winds containing

167 little moisture, and it is classified as a typical arid to semiarid region. The rainy season usually

168 occurs in winter (from December to March) (Yin et al. 2014) and most of the moisture

169 transported by the strong westerly winds is intercepted to condense by the high mountains

170 of the region during this period (Syed et al. 2006). Figure 2a shows the spatial distribution of

171 the winter mean climatological precipitation over Asia from 1979 to 2013. There is more

172 precipitation over CAWTP and the main areas of precipitation are distributed on the windward

173 slope of the western Tibetan Plateau, in agreement with earlier reports by Schiemann et al.

174 (2008) and Yin et al. (2014). There are two core areas of precipitation centered at 70°E, 42°N

175 and 75°E, 33°N respectively, with the maximum precipitation rate of 8 mm d^{-1}. The winter

176 precipitation over CAWTP accounts for more than 50% of the annual precipitation (Fig. 2b).

177 The distribution of water vapor flux integrated vertically from 950 hPa to 300 hPa (Fig. 2c)

178 suggests that the moisture transport convergence over CAWTP is mainly controlled by mid-

179 tropospheric westerly winds, rather than by lower-tropospheric (below 950 hPa) circulations

180 (not shown). The distribution of WWD frequency (Fig. 2d) shows that more WWDs occur in

181 the Karakoram Himalaya, coincident with the local precipitation maximum there shown in Fig.

182 2a. This is consistent with Cannon et al. (2015a, b) who reported that heavy precipitation

183 occurs when the WWD encountered mountains of the Himalaya. The climatology of

184 precipitation over CAWTP is quite different from that over the monsoon areas. The annual

185 precipitation over CAWTP is much lower than that over Asian monsoon regions and mainly

186 occurs in winter, when the mountains block and lift the strong mid-latitude westerly

187 circulation (e.g., Yin et al 2014, Cannon et al. 2015a, b).

188

189 3.2   Intraseasonal variability in winter daily precipitation and circulation over CAWTP

190   It is possible that the strength and position of westerly circulation determine the forced

9

191 upward motion, frequency of WWDs and the distribution of precipitation on the intraseasonal

192 time scale. The winter daily precipitation was decomposed by EOF analysis after the

193 climatological seasonal cycle was removed and the first two modes are shown in Fig. 3a and

194 3b. The first mode shows the same sign allover CAWTP with explained variance of 24.4% and

195 the second mode shows a seesaw pattern between northern Pamir Plateau and the

196 Karakoram Himalaya with explained variance of 15.6%. These EOF modes suggest the

197 existence of the intraseasonal variability of winter precipitation over CAWTP. Then we

198 composited the 500 hPa zonal wind (U component) during the dominant periods according to

199 the time series of the first mode and the second mode as Fig. 3c and Fig. 3d, which indicated

200 close connection between regional circulation and precipitation. Therefore, the relationship

201 between the regional circulation and precipitation in the study area is explored in the

202 following.

203 The seasonal cycle removed daily precipitation and 700hPa moisture flux fields for 35

204 winters during 1979–2013 were used for the SVD analysis to determine the simultaneous

205 relationship between the precipitation and circulation variability over CAWTP. The first SVD

206 mode shows a dipole pattern of precipitation variability with a positive anomaly over the

207 Karakoram Himalaya (center located at 33°N, 78°E, Fig.4a) and a negative anomaly over the

208 northern Pamir Plateau (center located at 40°N, 68°E), bearing a very similar structure as

209 shown for the second mode of EOF analysis (Fig. 3b). Accompanied with this pattern of

210 precipitation variability is a southerly wind anomaly over the Karakoram Himalaya and a

211 northwesterly wind anomaly (southwesterly wind weakened) over the northern Pamir

212 Plateau(not shown) and anomalous lower tropospheric moisture transport (Fig. 4b). This

213 pattern of precipitation anomaly is closely related to the forced lifting of the westerly

214 airstream on the windward side of the mountains. The explained variance reaches 55.12% and

215 the correlation coefficient between the time coefficients of two fields is 0.65 for the first SVD

216 mode, suggesting the importance of orographic forcing in modulating the regional

217 precipitation at the intraseasonal time scale.

218 We also did the SVD analysis with the seasonal cycle removed daily precipitation and 500

219 hPa geopotential height fields over CAWTP. The explained variance and correlation coefficient

220 corresponding for the first SVD mode are 60.5% and 0.64, respectively (Fig. 4c and d). Figs. 4c

221 and 4d illustrate that a negative center over the southeast of CAWTP in the field of 500 hPa

222 geopotential height anomaly is associated with a precipitation anomaly pattern with the

223 wetter southeast and the drier northwest. Hence, the distribution of winter precipitation

224 anomaly in the study area at the intraseasonal time scale is the result of topography-affected

225 regional atmospheric circulation variability. In the following, a lead-lag linear regression was

226 used to further reveal the relationship between the regional and large-scale circulation

227 variations and the regional precipitation change.

228

229 **4   Correlation of 500hPa geopotential height over CAWTP with the preceding atmospheric**

230 **circulation over the North Atlantic Ocean and Eurasia**

231 The preceding atmospheric circulation over the Atlantic Ocean and Eurasian region may

232 influence the regional circulation over CAWTP, leading to the regional precipitation anomaly

233 via teleconnection. The time series of the 500 hPa geopotential height analyzed by SVD was

234 normalized and then the normalized time series with an absolute value greater than 1.5 and

235 higher than the neighboring 4 other days was chosen for further analysis (a total of 200 time

236 series mixed with both positive and negative values). A linear regression was applied between

237 the chosen 200 time series and the antecedent 500 hPa geopotential height field over the

238 Atlantic Ocean–Eurasian region from lead 16 days to the lag 3 day of the chosen days

239 respectively and results are shown in figure 5. There is a positive geopotential height anomaly

240 over the Azores (center located at 30°W and 40°N) and a negative anomaly over Iceland

241 (center located at 10°W and 60°N) from day −10 to day −8 (10 to 8 days before the regional

242 circulation phase, the same below) (Fig. 5a, 5b). These patterns of the anomalous circulation

243 show a similarity to the positive phase of the NAO (Hurrell 1996). On day −6, the original

244 negative geopotential height anomaly over Iceland moves to the east and a significant positive

245 anomaly occurs over the Eurasian border and northern Asia and meanwhile a negative

246 anomaly over CAWTP develops (Fig. 5c). With time advance, the magnitude of the anomaly

247 over the Atlantic Ocean decrease, whereas the strength of the anomalies over the Eurasian

248 border and over CAWTP enhance on day −4 (Fig. 5d). On day −2 and 0, significant negative

249 geopotential height anomalies occur over CAWTP (Fig. 5e, 5f), similar to the results of the SVD

250 analysis. It is therefore possible that the regional circulation has been affected by the

251 preceding large-scale circulation variability related to NAO.

252 The time evolution of the 500hPa geopotential height anomaly over the North Atlantic

253 was analyzed by lead-lag linear regression and correlation. Areas A (20–40° W, 30–40° N), B

(0–20° W, 54–64° N), C (44–64° E, 54–64° N) and D (60–80° E, 30–40° N) in Fig. 5 were chosen

to calculate the average geopotential height anomaly and the correlation coefficient in

different lead days. The four domains are recognized in consideration of both covering the

centers of 500hPa geopotential height anomaly and the significant at 95% level in Fig. 5.

Otherwise, the numbers   of the grids of the four domains should be the same so they are

comparable. Table 1 lists regression coefficients and correlation coefficients of regionally-

averaged 500 hPa geopotential heights on different lag days for these four areas and the time

coefficients of the first mode of 500 hPa geopotential height field over CAWTP in the above

SVD analysis. From days −15 to −9 (the negative number means the days before the day for

the regional SVD analysis) there is a positive anomaly over area A, a significant increasingly

negative anomaly over area B, and no significant anomaly over area C. From days −8 to −4,

the anomaly over area A decreases and the anomaly over area B increases to a maximum

value. A significant positive anomaly appears over area C on day −5 and increases rapidly

afterwards. From days −3 to 0 there is no significant anomaly over area A, the anomaly over

area B decreases, and the anomaly over areas C and D increases to maximum values. From

days +1 to +3 there is no significant anomaly over area B and the anomaly over areas C and D

decreases. Figure 5 and Table 1 show time evolutions of geopotential height anomaly in

various regions before the maximum height anomaly over CAWTP and suggest that NAO-like

circulation anomaly over the North Atlantic is a precursor for the intraseasonal variation of

precipitation over CAWTP. The lead-lag correlation coefficients between NAO index and time

series of first SVD mode in these chosen days were calculated and they are given in Table 1.

275 These correlation coefficients indicate large correlations when NAO leads the regional

276 geopotential height by about 10 days.

277 Although we found a close connection between the 500 hPa geopotential height over

278 CAWTP and geopotential height over the North Atlantic about 10-8 days before by linear

279 regression and correlation, further analysis was required to elucidate the mechanism for the

280 relationship between the north–south precipitation seesaw over CAWTP during both positive

281 and negative NAO phases respectively. In the following, composite analysis was therefore

282 used to further investigate how the different NAO phases influenced the regional circulation

283 and precipitation over CAWTP.

284

285 **5   Influence of the NAO on spatial and temporal distribution of winter precipitation over**

286 **CAWTP**

287 Based on our definition of NAO events, the 500 hPa geopotential height, the 700 hPa wind

288 flow field were combined to assess the influence of the NAO on the circulation over remote

289 downstream areas. The time evolutions of composited 500hPa geopotential height anomaly

290 and 700 hPa streamlines at different lags for the positive and negative NAO phase cases are

291 illustrated in Fig. 6. In positive NAO phases, the NAO pattern is clearly shown on the 0 day (the

292 peak day of NAO index) with the strong negative 500 hPa geopotential height anomaly over

293 the Iceland and the positive one over the Azores. As time advances, the positive anomaly

294 extends eastward to the Eurasian border. In the following days, NAO pattern is weakening and

295 the east positive anomaly is further extended eastward and is finally separated from the

296 positive anomaly over the Azores. The eastward extension of positive anomaly over the

297 Eurasian border is associated with the intensification of the negative anomaly over the CAWTP

298 (Fig. 6c). The time evolutions of the 700 hPa wind streamlines associated with geopotential

299 height anomaly evolutions offer another view. Associated with positive NAO at day 0 is a single

300 strong westerly jet over the North Atlantic and two branches of strong westerly wind, whose

301 axes locate on 55°N and 30°N along the Eurasian border, resulted from the positive 500 hPa

302 geopotential height anomaly over the Eurasian border (Fig. 6a). Over the Eurasian border, the

303 north branch westerly wind forms a ridge while the south one forms a trough. They both

304 extend eastward in a similar way as the positive 500 hPa geopotential height anomaly. The

305 north branch westerly wind goes around the north CAWTP while the south branch encounters

306 the Karakoram Himalaya. The Figs. 6d, 6e and 6f show time evolutions of composited 500hPa

307 geopotential height anomaly and 700 hPa streamlines at different days for the negative NAO

308 phases. Time evolutions of geopotential height anomaly show similar evolutions as those

309 during the positive NAO phase cases, but with a change in sign of the anomalies. Associated

310 with the negative NAO phases, the north branch of westerly wind encounters the north

311 CAWTP while the south branch goes around the Krakoram-Himalaya at day 10.

312   The time averaged 700 hPa moisture flux anomaly and WWD frequency anomaly from

313 day 5 to day 10 after the peak of NAO phases intuitively show the regulation of regional

314 circulation by the NAO. During the positive NAO phases, northeasterly moisture flux

315 anomalies (decreased southwesterly moisture flux) occur over the Central Asia and northern

316 Pamir Plateau, whereas southerly moisture flux anomalies accompanied with higher

317 frequency of WWD occur over the Karakoram Himalaya (Fig. 7a). During the negative NAO

318 phases, southwesterly moisture flux anomalies occur over the Central Asia and northern

319 Pamir Plateau, whereas northeasterly moisture flux anomalies accompanied with lower

320 frequency of WWD occur over the Karakoram Himalaya (Fig. 7b). The composites of

321 precipitation anomalies of positive and negative NAO phases, as shown in Fig. 7c and 7d, are

322 well matched with the regional circulation and moisture flux anomalies. There is less

323 precipitation over the north east of Iran, Turkmanistan, Tajikistan and Kyrgyzstan (center at ~

324 75°E, 34°N) and more precipitation over the Karakoram Himalaya (center at ~ 70°E, 42°N)

325 during positive NAO phases and vice versa. For the south part, the WWD seems to be more

326 important while the moisture flux takes control of the north part. Compared with the daily

327 average winter precipitation (Fig. 2a), the precipitation anomaly at the intraseasonal time

328 scale reaches 10% of the climatological mean. The precipitation composites during the

329 different NAO phases are similar to the results of the SVD analyses. The two analyses both

330 demonstrate the teleconnection between the NAO over the North Atlantic and the regional

331 circulation and precipitation variability over CAWTP.

332

333 **6   Discussion and conclusions**

334   The climate is characterized by dominant westerly circulation and scarce precipitation

335 over CAWTP. The lowlands of this area are almost rainless due to the lack of moisture and

336 upward motion. By contrast, heavy rains occur on the high mountain areas as a result of the

337 uplifting of the westerly winds by the high topography.

16

338   There have been much published research on precipitation and its interannual variability

339   over the Karakoram Himalaya (Syed et al. 2006, 2010, Filippi et al. 2014, Cannon et al. 2015a,

340   b). For example, Cannon et al. (2015a, b) stressed the importance of the westerly disturbance.

341   Less research has focused on precipitation over the northern Pamir Plateau and mainly

342   focuses on interannual variations (e.g., Chen et al. 2011). Filippi et al. (2014) and Syed et al.

343   (2006) found that the interannual variation in precipitation is connected to the NAO, but they

344   did not discuss the intraseasonal precipitation variations and the contemporaneous opposite

345   variations over the northern Pamir Plateau and over the Karakoram Himalaya.

346   This study focused on the intraseasonal variation in winter daily precipitation over CAWTP.

347   The EOF, SVD, lead-lag linear regression and composite analyses showed that a seesaw pattern

348   of winter intraseasonal precipitation anomaly between the Karakoram Himalaya and the

349   northern Pamir Plateau is connected with the intraseasonal oscillation of the NAO. The main

350   physical processes for the seasaw pattern of precipitation variability are the trough–ridge

351   phase of the two westerly jets rather than the westerly strength at the intraseasonal scale.

352   Multi-method analyses gave similar results, confirming that the NAO is able to influence the

353   intraseasonal precipitation variability in winter over CAWTP.

354   The seesaw pattern of winter intraseasonal precipitation anomaly was found between

355   the southeastern CAWTP (centered in the Karakoram Himalaya) and the northwestern CAWTP

356   (centered in the northern Pamir Plateau) by the SVD analysis and this pattern of precipitation

357   was closely connected to the regional 700 hPa circulation. When there was a northeasterly

358   moisture flux anomaly (southwesterly moisture flux weakened) over the northwestern CAWTP

359 and a southwesterly moisture flux anomaly (southwesterly moisture flux strengthened) over

360 the southwestern CAWTP at 700 hPa, a negative precipitation anomaly occurred over the

361 northern Pamir Plateau and a positive anomaly over the Karakoram Himalaya. Accompanied

362 by the seesaw precipitation pattern, a negative 500 hPa geopotential height anomaly over

363 CAWTP (center located in the central Tibetan Plateau) was also observed, and vice versa.

364   The mechanism for the seesaw precipitation anomaly over CAWTP may be related to the

365 NAO-like circulation at the intraseasonal time scale. The results of both the regression and

366 composite analyses showed that the seesaw precipitation pattern was closely connected with

367 the precursor NAO-like circulation anomalies over the North Atlantic. During the positive NAO

368 phases, the southern branch of the 700 hPa westerly winds formed a ridge over the North

369 Atlantic and combined with the northern branch which formed a trough. The two branches

370 separated around Eurasian border. The southern branch then formed a trough over the Middle

371 East, which increased the transport of moisture and the strength of the westerly winds over

372 the Karakoram Himalaya. By contrast, the northern branch formed a ridge and went around

373 the northwestern Tibetan Plateau, which decreased southwesterly winds, the southwesterly

374 moisture transport, and therefore precipitation over the Central Asia and northern Pamir

375 Plateau. The large scale wind stream pattern can modify the regional circulation. Meanwhile

376 during positive NAO, more WWD occurred over the Karakoram Himalaya since south branch

377 of westerly encounters the Himalaya, which finally increased the precipitation over Karakoram

378 Himalaya. This pattern was reversed during the negative NAO phases. The main physical

379 processes involved and discussed above for the influence of the NAO on the winter

380 precipitation variability at the intraseasonal time scale over CAWTP are illustrated in

381 schematic diagrams of Fig. 8.
