7 **Abstract**

8 Computational models of classical conditioning have made significant  
9 contributions to the theoretic understanding of associative learning, yet  
10 they still struggle when the temporal aspects of conditioning are taken  
11 into account. Interval timing models have contributed a rich variety of  
12 time representations and provided accurate predictions for the timing of  
13 responses, but they usually have little to say about associative learning.  
14 In this article we present a unified model of conditioning and timing that  
15 is based on the influential Rescorla-Wagner conditioning model and the  
16 more recently developed Timing Drift-Diffusion model. We test the model  
17 by simulating 10 experimental phenomena and show that it can provide  
18 an adequate account for 8, and a partial account for the other 2. We argue  
19 that the model can account for more phenomena in the chosen set than  
20 these other similar in scope models: CSC-TD, MS-TD, Learning to Time  
21 and Modular Theory. A comparison and analysis of the mechanisms in

22 these models is provided, with a focus on the types of time representation  
23 and associative learning rule used.

## 24 **Author Summary**

25 How does the time of events affect the way we learn about associations between  
26 these events? Computational models have made great contributions to our  
27 understanding of associative learning, but they usually do not perform very  
28 well when time is taken into account. Models of timing have reached high levels  
29 of accuracy in describing timed behaviour, but they usually do not have much to  
30 say about associations. A unified approach would involve combining associative  
31 learning and timing models into a single framework. This article takes just this  
32 approach. It combines the influential Rescorla-Wagner associative model with a  
33 timing model based on the Drift-Diffusion process, and shows how the resultant  
34 model can account for a number of learning and timing phenomena. The article  
35 also compares the new model to others that are similar in scope.

## 36 **1 Introduction**

37 Classical conditioning theories aim to understand how associations between  
38 stimuli are learned. Ever since Pavlov (1927) the process of association forma-  
39 tion has been understood to depend crucially on the temporal relations between  
40 stimuli (Savastano and Miller, 1998; Balsam et al., 2006; Kirkpatrick, 2013).  
41 Yet, classical conditioning theories have so far struggled to work when time is  
42 taken into account as an attribute of the stimulus representation. The study of  
43 time as a mental representation is the object of a separate area of study known  
44 as interval timing. Interval timing theories have produced a rich variety of time  
45 representations (Gibbon et al., 1984; Killeen and Fetterman, 1988; Machado,

46 1997; Staddon and Higa, 1999; Matell and Meck, 2004), and therefore are a  
47 natural place to look for ways to integrate time into classical conditioning. In  
48 this paper we first analyse previous efforts in this direction before introducing  
49 a new hybrid classical conditioning and timing model.

50 The process of association formation is understood to be of fundamental sur-  
51 vival value for both human and non-human animals. Prediction, which forms  
52 the core of classical conditioning, allows the organism to adapt to significant  
53 events in its surroundings. A prototypical experiment in classical conditioning,  
54 a type of associative learning, involves a neutral stimulus and an unconditioned  
55 stimulus (US) which is capable of eliciting an unconditioned response (UR).  
56 After repeated pairings of both stimuli in a specified order and temporal dis-  
57 tance, the neutral stimulus comes to elicit a response similar to the UR. This  
58 response is called the conditioned response (CR) and the neutral stimulus is  
59 said to have become a conditioned stimulus (CS). Classical conditioning theo-  
60 ries typically conceptualize this process as the formation of a link (association)  
61 between the internal representations of CS and US. Their basic building blocks  
62 are (Pearce and Bouton, 2001; Brandon et al., 2002): (a) the representations  
63 of stimuli, and (b) a learning rule to update the association weights between  
64 these representations. Although most theories do not attempt to find neuro-  
65 physiological correlates, these constructs are nonetheless commonly assumed to  
66 be instantiated by (a) neural activity in the form of spike rates, and (b) synaptic  
67 plasticity (Moore, 2002; Klopf, 1988; Gallistel and Matzel, 2013). These have  
68 found some support in the neuroscientific literature, particularly studies of the  
69 role of dopamine in reward prediction (Schultz et al., 1997; Dayan and Niv,  
70 2008; Niv, 2009; Eshel, 2016). However it is important to note that there is still  
71 no widely accepted complete neural mechanism for classical conditioning and  
72 that most theories stay at the computational level of explanation.

73 Stimulus representations are generally thought of as neural activation that  
74 is elicited by the stimulus, which may linger for a short time as a ‘trace’ af-  
75 ter stimulus offset. Representations are commonly one of two types: molar or  
76 componential. Molar (or elemental) trace theories treat the stimulus as a single  
77 conceptualized unit whose activity is usually assumed to peak quite early fol-  
78 lowing stimulus onset, and then gradually decrease (Hull, 1943; Wagner, 1981;  
79 Sutton and Barto, 1981; Schmajuk and Moore, 1988; McLaren and Mackintosh,  
80 2000; Harris and Livesey, 2010). In contrast, componential trace theories break  
81 down the CS representation into smaller units, each capable of being associated  
82 with the US, with some units more active early during the CS and others late,  
83 but all leaving a trace after activation (Desmond and Moore, 1988; Grossberg  
84 and Schmajuk, 1989; Vogel et al., 2003; Ludvig et al., 2008).

85 Learning rules may be classified according to different criteria. An important  
86 period in the recent history of the field gave rise to one of these criteria. Prior to  
87 1970’s conditioning used to be rooted in the stimulus-response tradition, which  
88 attributed crucial importance to the temporal pairing, or contiguity, of stimuli  
89 for the development of associations. The linear operator learning rule (Hull,  
90 1943) is one of the products of that period. In the late 1960’s and early 1970’s  
91 important experimental discoveries using compound stimuli, that is, a stimulus  
92 formed by combining other individual stimuli, showed the contiguity view to  
93 be incomplete (Rescorla, 1988; Gallistel and Gibbon, 2001). These compound  
94 experiments indicated that the formation of associations also depended on the  
95 reinforcement history of the individual elements forming the compound stimu-  
96 lus. This led to the development of new learning rules (Rescorla and Wagner,  
97 1972; Mackintosh, 1975; Pearce and Hall, 1980) capable of combining individual  
98 reinforcement histories in compounds, which the linear operator rule cannot.  
99 The first, and arguably still the most influential, of these learning rules is the

100 Rescorla-Wagner (RW, Rescorla and Wagner, 1972). It has become famous for  
101 being the first model able to provide an account for the blocking effect (Kamin,  
102 1968), where a novel CS does not become associated with the US if it is rein-  
103 forced only in compound with a previously conditioned CS.

104 The CR is usually not a single event. Organisms time their responses so  
105 that they emerge gradually during the duration of the CS and reach maximum  
106 frequency or intensity around the time of reinforcement. Interval timing theories  
107 have attempted to provide an account for this *timing* of the CR. One of the  
108 fundamental properties of timing behaviour is that it is approximately timescale  
109 invariant, i.e. the whole response distribution scales with the interval being  
110 timed (Gibbon, 1977; Allman et al., 2014). One of the consequences of timescale  
111 invariance is that the coefficient of variation, that is the standard deviation  
112 divided by the mean, of the dependent measure of timing is approximately  
113 constant. A number of timing models have put forth explanations for timescale  
114 invariance and other timing properties (how time is encoded, how it is stored in  
115 memory and how it gets translated into behaviour) by recourse to an internal  
116 pacemaker. The most influential pacemaker-based timing theory to date is  
117 Scalar Expectancy Theory (SET, Gibbon et al., 1984; Gibbon and Church,  
118 1984). The pacemaker is supposed to mark the passage of time by emitting  
119 pulses. These pulses can be gated to an accumulator via a switch which closes  
120 at the start of a relevant interval and opens when the interval is finished. The  
121 accumulator count is kept in working memory. At the end of the interval the  
122 current count is transferred to a long-term reference memory. Behaviour is  
123 guided by the action of a comparator which actively compares the count in  
124 working memory to the one retrieved from reference memory.

125 In spite of the considerable overlap, interval timing and classical conditioning  
126 are not easily integrated. Most conditioning theories are trial-based, that is they

127 consider the trial as the unit of time. A trial is generally taken to be the state  
128 where a CS is present (or CSs in compound) and which may or may not contain  
129 a US (or USs). The most influential model in this category is the Rescorla-  
130 Wagner (RW, Rescorla and Wagner, 1972). In order to account for different  
131 stimulus durations, trial-based theories like RW must resort to some sort of  
132 time discretization, usually by subdividing the trial into ‘mini-trials’. Each  
133 mini-trial is treated as a trial in its own right, which are then used to update  
134 associative links. This gives rise to the problem of deciding on a particular  
135 discretization. Also, given that humans experience time passing as a continuous  
136 flow, it is unlikely that animals discretize their conditioning experience in such  
137 a way. A more realistic approach to timing is taken by real-time theories. These  
138 theories attempt to formalize the concept of a continuous flow of time.

139 The Temporal Difference model (TD, Sutton and Barto, 1990,9) was one  
140 of the earliest and still most influential real-time classical conditioning model.  
141 It may be thought of as a real-time version of RW. When used with stimulus  
142 representations such as the Complete Serial Compound (CSC, Moore et al.,  
143 1998), Microstimuli (MS, Ludvig et al., 2008,0) and the Simultaneous and Se-  
144 rial Configural-cue Compound (SSCC, Mondragón et al., 2014) it is capable of  
145 reproducing some timing phenomena like the gradual increase in anticipatory  
146 responding that occurs before a signalled reinforcer, and the lower response rates  
147 observed during longer CSs. However, only MS-TD has a time representation  
148 capable of approximating the most fundamental property of timing, timescale  
149 invariance. Another issue with the stimulus representations for TD is that their  
150 approach to timing resembles the strategy used by trial-based models, i.e. they  
151 all split the stimulus into a number of smaller units or states, the number of  
152 which being directly proportional to the duration of the stimulus. Given that  
153 conditioning is observed in a timescale that ranges from milliseconds to hours

154 (Kehoe and Macrae, 2002, p. 189) this can lead to a very high number of units  
155 being required. The stimulus as a whole no doubt is a complex entity, and the  
156 brain may be employing a large number of neurons to represent it, but to ded-  
157 icate so many resources only for timing might not be the most energy-efficient  
158 strategy. Also, TD and its stimulus representations do not usually account for a  
159 change in timing that is not tied to reinforcement. Animals time the occurrence  
160 of different events, such as onset and offset of stimuli (see for example Meck and  
161 Church, 1984), but TD usually only allows for the timing of rewards.

162 On the other hand, timing models have made even fewer attempts at inte-  
163 grating aspects of classical conditioning. A notable exception is the Learning  
164 to Time (LeT, Machado, 1997; Machado et al., 2009) model. It represents the  
165 passage of time by transitioning between internal states according to a stochas-  
166 tic pacemaker, an idea borrowed from an earlier timing model called the Be-  
167 havioural Theory of Time (Killeen and Fetterman, 1988). Learning takes place  
168 by associating reinforcement presentation with the current internal state accord-  
169 ing to the linear operator, a standard classical conditioning rule. LeT offers an  
170 account of the basic dynamics of association formation, but it cannot explain  
171 cue-competition phenomena like blocking. In a blocking procedure, a CS is first  
172 paired with a US until a CR is acquired. The same CS is then presented together  
173 with a novel CS and both are paired with the US for a few trials. If the novel  
174 CS is now presented alone it elicits little or no responding, and so it is said to be  
175 blocked by the first CS. LeT’s learning rule, the linear operator, has largely been  
176 supplanted by RW in classical conditioning modelling because it cannot explain  
177 cue-competition phenomena. Like TD, LeT also employs a representation that  
178 requires as many units as time-steps, making it a resource-intense model.

179 Modular Theory (MoT, Guilhardi et al., 2007; Kirkpatrick, 2002) is a timing  
180 model which because of its explicit goal of integrating timing and learning may

181 be called a hybrid theory. MoT has introduced novelties that allow it to account  
182 for some aspects of the dynamics of classical conditioning that LeT cannot. Its  
183 architecture is different than the connectionist one (states or units connected  
184 by modifiable links) assumed by RW, TD and LeT. Instead, it uses a more cog-  
185 nitive architecture, with separate information processing stages that deal with  
186 perception, memory and decision. It postulates two separate memories: a pat-  
187 tern memory which stores CS durations, and a strength memory which stores  
188 the associative strength between each pattern memory and the US. This sepa-  
189 ration allows MoT to deal with more complex situations involving the dynamics  
190 of learning during acquisition and extinction. However, MoT also relies on the  
191 linear operator to update its strength memory, which, like LeT, prevents it from  
192 accounting for cue-competition phenomena.

193     Although the models mentioned above, namely TD, LeT and MoT, have  
194 accomplished a great deal in terms of bringing together timing and conditioning,  
195 they each have their different strengths and weaknesses as we have touched  
196 above. In this paper we introduce a model that tries to address some of these  
197 weaknesses while preserving the strengths. More specifically, the model has the  
198 following strengths. It represents time in real-time. Like MoT and unlike LeT  
199 and TD, its time representation does not require an arbitrary large number of  
200 units or states. Similarly to TD but unlike LeT and MoT, it uses a learning rule  
201 that preserves the main features of RW which allow it to account for compound  
202 phenomena. It can time the onset and offset of all stimuli, not only of rewards,  
203 and store a memory for each. It includes two update rules: one for timing that  
204 is updated by time-markers, and another for associations that is updated by  
205 the US. Hence, simple stimulus exposure causes the model to learn and store  
206 its duration. This capability is not present in models that depend only on an  
207 associative learning rule to also learn about time, such as TD and LeT.

208 This new model is essentially a way to connect one of the most influen-  
209 tial classical conditioning theories, the Rescorla-Wagner model (Rescorla and  
210 Wagner, 1972), with a recently developed timing theory called Timing Drift-  
211 Diffusion Model (TDDM, Rivest and Bengio, 2011; Simen et al., 2011). The  
212 TDDM is based on the drift-diffusion model, widely used in decision making  
213 theory, and it provides an adaptive time representation that has commonalities  
214 with pacemaker-based models like SET and LeT (Simen et al., 2013). These  
215 models postulate the existence of a pacemaker that emits pulses at a regular  
216 rate, which are then counted to mark the passage of time. To preserve timescale  
217 invariance they either postulate a specific type of noise in the memory saved for  
218 intervals and a ratio-based decision process (SET) or adapt the rate of pulses  
219 (LeT). The TDDM takes the latter route but sets a fixed threshold on pulse  
220 counting. To emphasize the unification of these two theories we call our pro-  
221 posal the Rescorla-Wagner Drift-Diffusion Model (RWDDM).

222 We evaluate RWDDM based on how well it can simulate the behaviour of  
223 animals in a number of experimental procedures. Many classical conditioning  
224 phenomena have been identified which collectively represent a significant chal-  
225 lenge for any single model to explain. A recent list (Alonso and Schmajuk, 2012)  
226 has compiled 12 categories, which include acquisition, extinction, conditioned in-  
227 hibition, stimulus competition, preexposure effects, temporal properties, among  
228 others. Of particular interest to a theory of timing and conditioning are phe-  
229 nomena that involve elements of both timing and conditioning. As we detail  
230 later, we have searched the literature for documented effects that can challenge  
231 the main mechanisms embodied in RWDDM.

232 We proceed by first introducing the new model. We compare its formalism  
233 with four models that have similar scope, namely CSC-TD, MS-TD, MoT and  
234 LeT. In the results section we present the phenomena we will simulate, followed

235 by the results of our simulations, and compare them to the current explanations  
236 given by LeT, MoT and TD.

## 237 **2 Model**

238 We follow most classical conditioning theories in conceptualizing the condition-  
239 ing process as the formation of an association between the internal representa-  
240 tions of CS and US. Arguably, one of the most influential rules describing the  
241 evolution of this association through training is the Rescorla-Wagner (Rescorla  
242 and Wagner, 1972) rule. As mentioned previously, other models exist which  
243 have a similar scope to RW, both trial based (Mackintosh, 1975; Pearce and  
244 Hall, 1980) and real-time (Buhusi and Schmajuk, 1999; McLaren and Mack-  
245 intosh, 2000,0). However, our goal was to take advantage of TDDM’s time  
246 representation, so we sought a theoretical associative framework that could in-  
247 corporate such a representation. Since trial-based conditioning theories lack  
248 any time representation, they are a natural place to start. Out of those theories  
249 the RW is perhaps the simplest whilst also retaining the greatest possible ex-  
250 planatory power. Its basic formalism consists of the following rule for updating  
251 associative strength:

$$\Delta V_i(n) = \alpha\beta \left( \lambda - \sum_{j=1}^l V_j(n)x_j(n) \right) x_i(n) \quad (1)$$

252 where  $V_i(n)$  denotes associative strength for  $CS_i$  at trial  $n$ ,  $\lambda$  the asymptote of  
253 learning which is set by the US representation,  $x_i(n)$  which marks the presence  
254 ( $x_i = 1$ ) or absence ( $x_i = 0$ ) of the  $i$ -th CS representation at trial  $n$ ,  $0 <$   
255  $\alpha < 1$  a learning rate set by the CS and  $0 < \beta < 1$  a learning rate set by  
256 the US. The summation term in the equation (1) sums over all CSs present  
257 in the trial. The top panel of figure 1 shows a diagram of a basic neural net

258 for classical conditioning which serves as the architectural framework for both  
 259 RW and RWDDM. The RW rule is used to update the links  $V_1, \dots, V_l$  that  
 260 connect the CS input nodes  $CS_1, \dots, CS_l$ . The summation term in the RW rule  
 261 is represented in the diagram as a summation unit or junction  $\Sigma$ , that sums  
 262 the inputs it receives from the CSs  $j = 1, \dots, l$  present in the trial. This sum  
 263 allows RW to combine (additively) the reinforcement history of each individual  
 264 CS present in a compound trial. In the neural network literature, equation (1)  
 265 is also referred to as the Widrow-Hoff rule (Widrow and Hoff, 1960) and the  
 266 Least-Means-Square (LMS; Sutton, 1992). The relationship to the LMS rule  
 267 is easier to see if we let  $y(n) = \sum_{j=1}^l V_j(n)x_j(n)$  be the output of a learning  
 268 unit that aims to predict a target  $\lambda$  given inputs  $x_i$  by adapting the weights  
 269  $V_i$ . In classical conditioning,  $\lambda$  represents the maximum learning driven by a  
 270 given outcome (the US),  $x_i$  is the CS and  $V_i$  the associative strength. If we  
 271 let  $\delta(n) = \lambda - y(n)$  be the error between output and US, equation (1) can be  
 272 obtained with the method of gradient descent by minimizing the squared error  
 273  $\delta^2(n)$  with respect to the weight  $V_i$ .

274 In spite of the relative success in explaining a wide range of conditioning  
 275 phenomena (for a list of successes, and failures, see Miller et al., 1995), the  
 276 Rescorla-Wagner rule lacks a mechanism to account for the microstructure of  
 277 real-time responding during conditioning procedures. In terms of the order of  
 278 CS-US presentation conditioning procedures may be either forward (CS followed  
 279 by US) or backward (US followed by CS). Two common types of forward condi-  
 280 tioning are delay and trace. In delay conditioning the US always occurs a fixed  
 281 time after CS onset. In trace conditioning the US occurs at a fixed duration after  
 282 CS offset. After sufficient training with delay or trace conditioning, responding  
 283 begins some time after CS onset, increases rapidly in frequency until it reaches  
 284 a maximum level where it stays until US onset (Gormezano et al., 1983). The

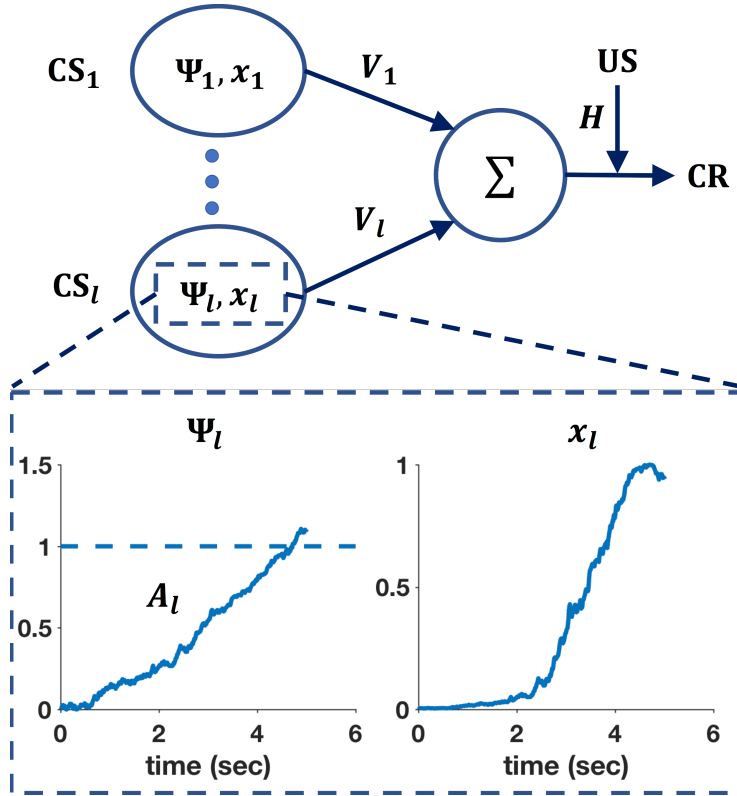

Figure 1: Connectionist diagram of RWDDM. Each CS unit is connected to a summing junction (labelled  $\Sigma$ ) via a modifiable link  $V$ . The output of the summing junction is the CR. The US is represented as a teaching signal with a fixed weight  $H$ . Each CS unit has its own timer  $\Psi$  and representation  $x$ . The bottom panel shows a zoomed-in view of the timer  $\Psi_l$  and CS representation  $x_l$  associated with  $CS_l$ . The timer slope  $A_l$  is tuned to a 5-second CS duration.

285 RW rule alone does not account for CR level as a function of time. This role  
 286 is usually fulfilled by the choice of CS representation. We base our choice on a  
 287 timing model called Timing Drift-Diffusion Model (TDDM, Simen et al., 2011;  
 288 Rivest and Bengio, 2011; Luzardo et al., 2013; Balci and Simen, 2016). We chose  
 289 the TDDM because it possesses a number of interesting features. It is part of a  
 290 family of pacemaker based models like SET and LeT (Simen et al., 2013) which  
 291 are arguably two of the most successful timing theories to date. The TDDM  
 292 is a modified version of the drift-diffusion models that have been extremely

293 successful at modelling reaction time in decision making tasks (Ratcliff, 1978;  
 294 Voss et al., 2013). Evidence of climbing neural activity related to timing that  
 295 resembles the TDDM has been extensively reported (Komura et al., 2001; Leon  
 296 and Shadlen, 2003; Brody et al., 2003; Wittmann, 2013; Jazayeri and Shadlen,  
 297 2015). The TDDM consists of a drift-diffusion process with an adaptive drift or  
 298 rate. The drift-diffusion process is defined by a continuous random walk called  
 299 Wiener diffusion process. The two main components of Wiener diffusion are  
 300 the drift and the normally distributed noise. The Wiener diffusion process may  
 301 be visualized by imagining a two-dimensional grid with time in the horizontal  
 302 axis and displacement on the vertical axis. If we imagine a purely linear and  
 303 non-random walk that starts at the origin and moves up at a constant rate then  
 304 the resulting walk would be a straight line and the drift would be equal to the  
 305 slope of the line. With normally distributed noise, the walk becomes a random  
 306 walk and it looks like a jagged curve, since at each time step there is now only  
 307 a probability that the displacement will be up or down. For the purposes of  
 308 timing, the slope is always positive and the random walk can be interpreted as  
 309 a noisy accumulator (or timer)  $\Psi(t)$ , which starts at the beginning of a salient  
 310 stimulus and stops (and resets) at the end. In a conditioning experiment the CS  
 311 is usually the most salient stimulus in the uneventful context of the conditioning  
 312 chamber, so it is well placed to serve as a time marker. When timing starts,  
 313 accumulator increments are performed at each time-step according to

$$\Delta\Psi_i(t) = A_i(n) \cdot \Delta t + m \cdot \sqrt{A_i(n) \cdot \Delta t} \cdot \mathcal{N}(0, 1), \quad (2)$$

314 where  $A_i(n)$  is the rate (slope) of accumulation for  $\text{CS}_i$  in trial  $n$ ,  $m$  is a noise  
 315 factor,  $\Delta t$  is the time-step size and  $\mathcal{N}(0, 1)$  denotes a sampling from the standard  
 316 normal distribution. An interval is timed by the rise in the accumulator to a  
 317 certain fixed threshold, say  $\Psi_i(t) = \theta$ . The TDDM adjusts to new intervals by

318 keeping the threshold fixed but adapting the rate of accumulation  $A_i(n)$ . The  
 319 bottom left panel of figure 1 shows a typical trajectory (or realization) of a CS’s  
 320 TDDM timer after one 5-second trial.

321 In its original formulation (Rivest and Bengio, 2011; Simen et al., 2011) the  
 322 accumulation process was not allowed to continue beyond the threshold value  $\theta$ ,  
 323 a constraint that gave rise to two distinct rules for rate adaptation, one for when  
 324 the US arrived earlier than expected and another for when it arrived later. The  
 325 constraint fixing a maximum level of accumulation was driven by the neurophys-  
 326 iological assumption that a linear neural accumulator is not likely to continue  
 327 to perform effectively beyond a certain level. The neural implementation so far  
 328 proposed for TDDM’s linear accumulator (Simen et al., 2011) is based on a feed-  
 329 back control mechanism that is tuned to balance excitation and inhibition in a  
 330 neuron population. Tuning of this kind requires great computational precision,  
 331 which may not be easily kept for very long in a biological system. Neurophysiol-  
 332 ogy notwithstanding, we will drop that requirement here for simplicity and use  
 333 instead only one update rule. We demonstrate how this single update rule can  
 334 be derived by the method of gradient descent. The model learns a new interval  
 335 by adapting its slope  $A_i$  so that the accumulator  $\Psi_i$  reaches the threshold value  
 336  $\theta$  at the target time  $t^*$ , which may be the time of reinforcement for example.  
 337 The target slope will therefore be  $\theta/t^*$ . The error  $\delta(n)$  between the target slope  
 338 and the current slope is  $\delta(n) = \theta/t^* - A_i(n)$ . By minimizing the squared error  
 339  $\delta^2(n)$  using gradient descent we can derive the slope update rule. The squared  
 340 error as a function of  $A_i$  forms a curve. Moving in the direction opposite the  
 341 slope of this curve and taking a step of size  $\alpha_t/2$  we form the equation:

$$A_i(n+1) = A_i(n) - \frac{\alpha_t}{2} \frac{d\delta^2(n)}{dA_i(n)}. \quad (3)$$

342 Solving the derivative yields

$$\begin{aligned} A_i(n+1) &= A_i(n) - \frac{\alpha_t}{2} 2\delta(n)(-1) \\ &= A_i(n) + \alpha_t (\theta/t^* - A_i(n)). \end{aligned} \quad (4)$$

343 Since the organism only has access to the psychological time given by its internal  
344 timing mechanism, and not the physical time  $t$ , we assume that an internal  
345 estimate for  $t$  is formed by dividing the current pacemaker count by the current  
346 slope,  $t = \Psi_i(t)/A_i(n)$ . Substituting this estimate into equation (4) we get:

$$\begin{aligned} A_i(n+1) &= A_i(n) + \alpha_t \left( \frac{\theta A_i(n)}{\Psi_i(t^*)} - A_i(n) \right) \\ &= A_i(n) + \alpha_t A_i(n) \left( \frac{\theta}{\Psi_i(t^*)} - 1 \right) \\ &= A_i(n) + \alpha_t A_i(n) \frac{(\theta - \Psi_i(t^*))}{\Psi_i(t^*)}. \end{aligned} \quad (5)$$

347 Hence, the update rule for slope  $A_i$  to be applied at target time  $t^*$  (the end of  
348 the trial or of the interval being timed) is

$$\Delta A_i(n) = \alpha_t A_i(n) \frac{(\theta - \Psi_i(t^*))}{\Psi_i(t^*)}. \quad (6)$$

349 Equation (6) is the slope update rule we use. Note that  $n$  above is indexing  
350 the number of occurrences of a specific interval that the timer is timing. These  
351 intervals may be the duration between CS onset and US onset (the usual ‘trial’ in  
352 delay conditioning for example), but they may be any other salient time interval  
353 such as CS or intertrial duration. Figure 2 shows timer slope adaptation during  
354 three timing scenarios: timing a novel stimulus (row 1), timing a long-short  
355 change in stimulus duration (row 3), and timing a short-long change in stimulus  
356 duration (row 5).

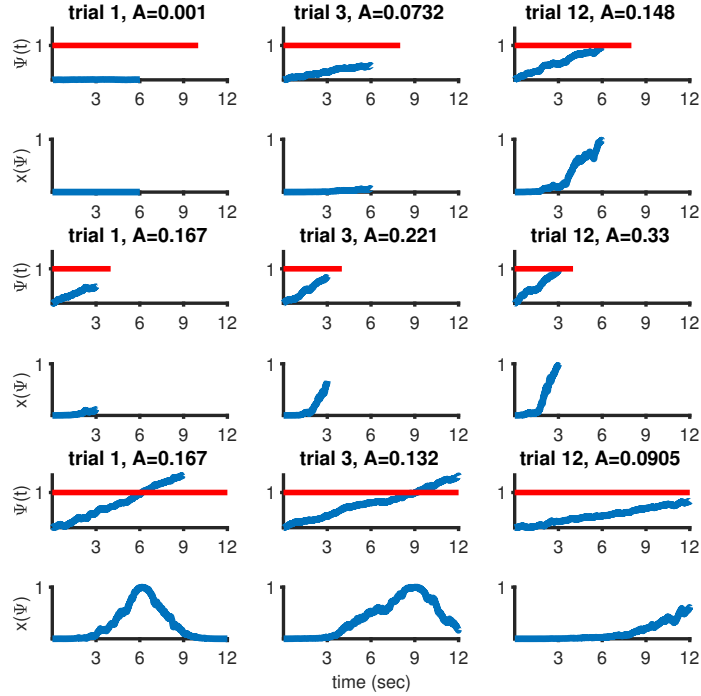

Figure 2: RWDDM timer and CS representation during three 12-trial timing scenarios. Top two rows: timing a novel 6 second stimulus. Timer starts with a low baseline slope ( $A = 0.001$ ) on trial 1 and gradually adapts over training to reach approximately the required slope. Middle two rows: stimulus duration change from 6 to 3 seconds. Bottom two rows: stimulus duration change from 6 to 12 seconds. Parameters:  $\alpha_t = 0.215$ ,  $\theta = 1$ ,  $\sigma = 0.25$ ,  $m = 0.15$ .

357 In the top row of figure 2 and throughout the paper we assume that the initial  
358 value of slope  $A$  for a novel stimulus is so low as to overestimate the stimulus  
359 duration. This overestimation will only last for a few trials, the number of  
360 which can be made arbitrarily small by choosing a high adaptation rate  $\alpha_t$ .  
361 Alternatively, it would be possible to use a very high initial value for  $A$  so as to  
362 underestimate the stimulus duration. However this alternative does not seem  
363 neurophysiologically plausible as the brain would need to keep a pool of neurons  
364 firing very rapidly as its ‘standby’ timer.

365 In TDDM, timescale invariance arises from the nature of the noise in the  
 366 accumulator. After repeated training, say in delay conditioning with a CS of  
 367 fixed duration, equation (6) will converge to a value of  $A_i$  which will make the  
 368 accumulator reach the threshold value  $\theta$  at the time of stimulus offset, but only  
 369 on average. In some trials the accumulator will reach the threshold sooner, in  
 370 which case the organism will underestimate the stimulus duration. In other trials  
 371 the accumulator will reach the threshold later, causing overestimation. The  
 372 variability of this time estimate relative to the mean is given by the coefficient  
 373 of variation (CV). It has been well established experimentally that the CV of  
 374 time estimates in humans and other animals is approximately constant over a  
 375 wide timescale (Gibbon, 1977; Gallistel and Gibbon, 2000; Allman et al., 2014).  
 376 The CV of TDDM’s time estimate is (see equation 3 in Luzardo et al., 2017)

$$\text{CV} = \frac{m}{\sqrt{\theta}}, \quad (7)$$

377 which depends only on the choice of threshold  $\theta$  and noise factor  $m$ . As these  
 378 are constant, the CV of TDDM’s time estimate is also constant. Note that  
 379 because the timer adapts its slope gradually, if the duration of a CS is changed,  
 380 CV measurements will only match the one given by equation (7) after the slope  
 381 has finished adapting. The number of trials to adaptation will vary depending  
 382 on the adaptation rate  $\alpha_t$ .

383 We substitute the presence representation used in the original RW model by a  
 384 Gaussian radial basis function. Its input is provided by the TDDM accumulator:

$$x_i(\Psi_i) = \exp\left(-\frac{(\Psi_i(t) - \theta)^2}{2\sigma^2}\right). \quad (8)$$

385 This representation may be interpreted as the receptive field of time-sensitive  
 386 neurons that read the signal coming from the accumulator neurons. Their re-

387 ceptive fields are tuned to the accumulator threshold value  $\theta$ . The bottom right  
 388 panel in figure 1 shows the representation for  $CS_l$  generated from the input  
 389 provided by the timer on the left. Note how  $x_l$  reaches its maximum value at  
 390 the same time that  $\Psi_l$  crosses the threshold at 1. Figure 2 shows  $x(\Psi)$  adapting  
 391 in the three different timing scenarios explained previously. As can be seen,  
 392  $x_i$  is a dynamic representation of  $CS_i$  that adapts to the temporal information  
 393 conveyed by the stimulus. Other representation shapes could be used, like a  
 394 sigmoid for example, but a Gaussian is mathematically simple and has been  
 395 used before by at least one other timing model (MS-TD, Ludvig et al., 2008).

396 We follow Gibbon (1977) and Gibbon and Balsam (1981) in assuming that  
 397 time sets the asymptote of learning,  $\lambda$ , in equation (1). They were led to this  
 398 hypothesis by investigating CR timing in fixed interval conditioning schedules,  
 399 a type of delay conditioning. After enough training in this procedure, subjects  
 400 begin responding some time after CS onset, with a slow rate at first which then  
 401 increases rapidly until it reaches asymptotic level some time before reinforcement  
 402 delivery. Gibbon (1977) proposed that subjects make an estimate of time to  
 403 reinforcement which is used to generate an expectancy of reinforcement. The  
 404 expectancy for a particular  $CS_i$  with duration  $t^*$ ,  $h_i$ , was hypothesised to be  
 405  $h_i = H/t^*$ , where  $H$  was a motivational parameter which was assumed to depend  
 406 on the reinforcing properties of the US. The reinforcing value of the US is  
 407 thus spread evenly over the CS length. It was assumed that this expectancy  
 408 would be updated as time elapsed during the CS, such that  $h_i(t) = H/(t^* -$   
 409  $t)$ . Hence, expectancy would increase hyperbolically until the estimated time  
 410 to reinforcement  $t = t^*$ . Responding would reach asymptotic level when the  
 411 expectancy crossed a threshold value  $h_i(t) = b$ .

412 Here we will not use Gibbon’s concept of expectancy update. A similar role  
 413 is fulfilled by the TDDM accumulator in our formalization. But we hold on to

414 his argument that the reinforcing value of the US is spread over the CS length.  
415 Within the Rescorla-Wagner modelling framework, Gibbon’s expectancy value  
416 may be interpreted as setting the asymptotic level of learning in equation (1),  
417 namely  $\lambda = H/t^*$ . Under this interpretation,  $\lambda$  may be said to implement  
418 hyperbolic delay discounting of rewards. Similarly to the argument used above  
419 in the derivation of the slope update rule, we use the psychological time estimate  
420 from TDDM in place of the physical time  $t^*$ , such that  $t^* = \Psi_i(t^*)/A_i(n)$ .  
421 The value we use is then  $\lambda = \frac{HA_i(n)}{\Psi_i(t^*)}$ . Another possibility would be simply  
422  $\lambda = HA_i(n)$ . Both alternatives yield the same asymptotic value, but  $HA_i(n)$   
423 converges gradually (with the rate set by  $\alpha_t$ ) whilst  $\frac{HA_i(n)}{\Psi_i(t^*)}$  immediately. Our  
424 version of equation (1) for updating associative strength then becomes:

$$\Delta V_i(n) = \alpha_V \left( \frac{HA_i(n)}{\Psi_i(t^*)} - \sum_{j=1}^l V_j(n)x_j(\Psi_j) \right) x_i(\Psi_i). \quad (9)$$

425 In the trial-based RW model, equation (1) is applied at the end of a ‘trial’, which  
426 is usually taken to be the event starting at CS onset and ending at US delivery.  
427 We follow the same practice here and apply equation (9) at the end of a trial,  
428 i.e. at US delivery. Note that because  $x_i(\Psi_i)$  is a dynamic CS representation,  
429 its activation (or strength) level at the end of the trial will vary from trial to  
430 trial, as can be seen in figure 2. Equation (9) is applied using the activation  
431 level of  $x_i(\Psi_i)$  current at the end of the trial.

432 We assume that real-time responses to a  $CS_i$  are emitted according to the  
433 product of its associative strength  $V_i(n)$  and representation  $x_i(\Psi_i)$ , that is, it is  
434 the output of the summing junction in figure 1:

$$CR_i(t) = V_i(n)x_i(\Psi_i). \quad (10)$$

435 Equations (2), (6), (8), (9), (10) fully define the basic model. Its six free

436 parameters are:  $m, \alpha_t, \theta, \sigma, \alpha_V, H$ .

## 437 2.1 Relationship with Other Models

438 Among the theories capable of providing an account of both timing and condi-  
439 tioning, arguably four stand out for their scope or influence. They are CSC-TD,  
440 MS-TD, LeT and MoT.

441 TD has been developed primarily as a learning model, without the explicit  
442 intention of addressing timing. It may be visualized as a real-time rendition of  
443 the RW rule. Its basic learning algorithm, is given by:

$$V_t(\mathbf{x}_t) = \sum_i w_t(i)x_t(i), \quad (11)$$

$$\delta_t = \lambda_t - (V_t(\mathbf{x}_{t-1}) - \gamma V_t(\mathbf{x}_t)), \quad (12)$$

$$\mathbf{w}_{t+1} = \mathbf{w}_t + \alpha \delta_t \mathbf{e}_t \quad (13)$$

444 where  $V_t$  is the US prediction at time  $t$ , formed by a linear combination of  
445 the weights  $w(i)$  and the CS representation values  $x(i)$ . This update algorithm  
446 is performed at each time step, and not only at the end of a trial like RW  
447 and RWDDM. Another important difference is that equation (12) computes a  
448 difference between the current US value and the temporal difference between  
449 predictions. Hence,  $\delta_t > 0$  if the US is higher than this temporal difference in  
450 prediction, and  $\delta_t < 0$  if the US is lower. The constant  $0 < \gamma < 1$  is termed a  
451 discount factor. Equation (13) updates the weights for the next time step. The  
452 vector  $\mathbf{e}_t$  stores *eligibility traces*, which are functions describing the activation  
453 and decay of representations  $\mathbf{x}_t$ . The three most common eligibility traces used  
454 are: accumulating traces, bounded accumulating and replacing traces. These  
455 three types accumulate activation in the presence of the CS and discharge slowly  
456 in its absence, the first accumulates with no upper bound, the second only until

457 the upper bound and the third is always at the upper bound whilst the CS is  
458 present (Sutton and Barto, 1998, pp. 162-192).

459 The richness of TD’s timing account relies on the choice of CS representation  
460 **x**. The Complete Serial Compound representation (CSC, Moore et al., 1998)  
461 postulates one CS element  $x(i)$  per time unit of CS duration. Each element is  
462 only switched on at its activation time unit, and then decays afterwards following  
463 its choice of eligibility trace  $e(i)$  (usually an exponential decay function). This  
464 componential representation, which increases in size linearly with CS duration,  
465 should be contrasted with RWDDM’s molar representation (equation (8)) which  
466 requires only one element. CSC may be called a time-static representation,  
467 whilst RWDDM is a time-adaptive representation, with a rule to change its  
468 structure based on a change in time (equations (6) and (8)). CSC-TD also lacks  
469 any mechanism to explain timescale invariance of the response curve, which is  
470 present in RWDDM. A modification of CSC has recently been developed, the  
471 Simultaneous and Serial Configural-Cue Compound (SSCC, Mondragón et al.,  
472 2014). SSCC-TD formalizes the idea that when multiple stimuli are presented  
473 together in time, a configural cue—a novel stimulus that is unique to the current  
474 set of present stimuli—is formed. SSCC follows on the CSC representation, but,  
475 unlike any other TD model, it allows for the representation of compounds and  
476 configurations of stimuli. Because SSCC-TD is a real-time model, it also allows  
477 for the simulation of CR timing during compounds and configurations. However,  
478 its approach to timing is still the same as CSC, i.e. it breaks down the stimuli  
479 into a series of elemental units which are activated in series. Therefore, with  
480 respect to timing only we will consider SSCC to belong to the family of CSC  
481 representations.

482 The Microstimuli representation (Ludvig et al., 2008,0) introduced a more  
483 realistic description of time. Unlike CSC, it uses a fixed number of elements

484  $x(i)$  per stimulus. The  $i$ th microstimulus is given by:

$$x_t(i) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{(y_t - i/m)^2}{2\sigma^2}\right) \cdot y_t \quad (14)$$

485 where  $m$  is the total number of microstimuli,  $y$  is an exponentially decaying time  
486 trace set at 1 at CS onset. It will be noted that a microstimulus is a Gaussian  
487 curve modulated by the decaying trace  $y_t$ . The set of microstimuli generated by  
488 the CS will then give rise to partially overlapping Gaussians, with decreasing  
489 heights and increasing widths across time. The fact that only a fixed number  
490 of microstimuli are required per CS is an improvement to the potentially large  
491 numbers of elements in CSC. The MS representation tries to capture the idea  
492 that as time elapses, the stimulus leaves a more diffuse and faint impression.  
493 However, even though it is more realistic than CSC, it still lacks a mechanism  
494 to produce exact timescale invariance.

495 Learning to Time is primarily a theory of interval timing which can also  
496 account for some aspects of conditioning. Here we will deal with its most recent  
497 version in Machado et al. (2009), which differs somewhat from the earlier version  
498 in Machado (1997). Its CS representation resembles CSC in postulating a long  
499 series of elements (or states) that span the whole stimulus duration. Unlike  
500 CSC, it transitions from state to state at a rate that varies from trial to trial,  
501 and that is normally distributed. Hence, time during a trial is represented as  
502 a noiseless linear increase from states  $n = 1, 2, 3, \dots$  (one per time-step) at a  
503 fixed rate. This linear time representation resembles the linear accumulator in  
504 RWDDM, except that the latter has noise built into the linear accumulator,  
505 whilst LeT assumes noise only at the intertrial level. Each state  $n$  is associated  
506 with the US via an associative link. At the end of a trial, the strength  $w$  of  
507 these links are updated as follows:

508 • For the active state at reinforcement,  $n^*$ , the update rule is

$$\Delta w(n^*) = \beta(1 - w(n^*)), \quad (15)$$

509 where  $\beta$  is a constant.

510 • For inactive states,  $n < n^*$ , the update rule is

$$\Delta w(n) = -\frac{\alpha}{n^*}w(n), \quad (16)$$

511 where  $\alpha$  is a constant.

512 • For states that did not become active during the trial,  $n > n^*$ , the rule is

$$\Delta w(n) = 0. \quad (17)$$

513 Note that unlike RWDDM’s associative update rule, equations (15) to (17) do  
514 not include a summation term. This places a severe limitation on the ability  
515 of LeT to deal with compound conditioned stimuli. LeT’s strength lies on its  
516 being able to explain timescale invariance of the response curve. Machado et al.  
517 (2009) showed that it is possible to derive timescale invariance using only the  
518 assumption of intertrial normality of state transition rate. Finally, LeT assumes  
519 that responses are emitted at a constant rate if the current active state has  
520 associative strength  $w(n)$  greater than a threshold  $\theta$ . The fact that responding  
521 depends on the associative strength of the current state, and that this strength  
522 only changes with US associations, prevents LeT from accounting for changes  
523 in timing that are not related to US occurrence. For example, there is evidence  
524 that animals learn the timing of a preexposed CS (Bonardi et al., 2016) and are  
525 sensitive to changes in timing during extinction (Guilhardi and Church, 2006),  
526 two situations that do not involve the occurrence of a US.

527 Modular Theory is another primarily timing theory that can also deal with  
528 some aspects of conditioning. It treats the onset of a stimulus as signalling a  
529 time expectation to reinforcement. Its time representation  $T$  is, like LeT, an  
530 accumulator that increases linearly with time  $t$ ,  $T = ct$ , where  $c$  is a constant.  
531 When reinforcement is delivered the current reading from the accumulator is  
532 stored in what is called *pattern memory*. Pattern memory is updated at each  
533 trial  $n$  according to

$$m(n) = m(n - 1) + \alpha(T^* - m(n - 1)) \quad (18)$$

534 where  $\alpha$  is a learning rate and  $T^*$  is reinforcement time. Equation (18) may be  
535 contrasted to (6) from RWDDM. The main difference is that pattern memory  
536 in MoT stores a moving exponential average of intervals, whilst the slope in  
537 RWDDM stores a moving exponential harmonic average of intervals. However,  
538 both models are similar in that they can potentially time the occurrence of any  
539 event, not only rewards. MoT's pattern memory and RWDDM's slope can be  
540 made, for example, to adapt to mark the end of stimuli that are not necessarily  
541 paired with a reward.

542 A stochastic threshold  $b$  is used to mark response initiation. The threshold  
543 distribution is set so as to yield timescale invariance of the response curve.  
544 Its mean,  $B$ , is a fixed proportion of the value in pattern memory,  $B = km(n)$ ,  
545 where  $k$  is the proportionality constant, and its standard deviation is  $\gamma B$ , where  
546  $\gamma$  is the coefficient of variation of  $B$ . Hence, the coefficient of variation of  
547 the threshold, i.e. of response initiation, is constant for all intervals, which  
548 is the timescale invariance of the response curve. RWDDM derives timescale  
549 invariance of response curve from noise in the accumulator (equation (2), not  
550 from the threshold.

551 This account of time from MoT is an instantiation of Scalar Expectancy

552 Theory, arguably one of the most successful timing models to date. Being a  
 553 purely timing theory, SET does not address associative learning directly, so it  
 554 does not have a rule for changes in association between stimuli. MoT bridges this  
 555 gap by adding a rule to update what is termed *strength memory*,  $w(n)$ . Strength  
 556 memory holds the associative strength between stimulus and reinforcement. The  
 557 rule consists of a linear operator:

$$\Delta w(n) = \begin{cases} \beta_e(0 - w(n-1)) & \text{if US is absent,} \\ \beta_r(1 - w(n-1)) & \text{if US is present,} \end{cases} \quad (19)$$

558 with  $\beta$  a constant that can determine different rates of update for acquisition  
 559 ( $\beta_r$ ) and extinction ( $\beta_e$ ). Equation (19) may be compared with (9). Note that,  
 560 unlike RWDDM, equation (19) does not contain the summation term from RW  
 561 based rules.

562 MoT also includes a rule for response rate that is more realistic than RWDDM's  
 563 given by (10). It is partly derived from an empirical analysis of real-time re-  
 564 sponding in animals. We refer the interested reader to Guilhardi et al. (2007) for  
 565 a fuller description. We will only mention here that MoT generates a two-state  
 566 response pattern, low and high. The transition between states is determined  
 567 by the crossing of threshold  $B$ , and the high state is proportional to strength  
 568 memory  $w(n)$ .

569 Other theories exist which are similar in scope to CSC-TD, MS-TD, LeT and  
 570 MoT. Two notable examples are the Componential version of the Sometimes  
 571 Opponent Process model (C-SOP, Brandon et al., 2003) and the Adaptive Res-  
 572 onance Theory - Spectral Timing Model (ART-STM Grossberg and Schmajuk,  
 573 1989). C-SOP builds a CS representation based on two sets of elements, or com-  
 574 ponents, one that includes elements activated as a function of time and another  
 575 whose elements are randomly activated. Associative strength for each element is

576 updated using the standard trial-based RW rule. Simulations in Brandon et al.  
577 (2003) have demonstrated that C-SOP can produce some degree of timescale  
578 invariance. ART-STM is a neural net with an input layer and one hidden layer,  
579 which allows it to explain nonlinear conditioning phenomena (such as negative  
580 pattern) that a single-layer RW neural net cannot. It employs a CS represen-  
581 tation that is very similar to the microstimuli used in MS-TD, so it also shows  
582 a degree of timescale invariance. Other theories could be mentioned (for two  
583 influential examples see Buhusi and Schmajuk, 1999; McLaren and Mackintosh,  
584 2000,0) but we will limit the analysis to CSC-TD, MS-TD, LeT and MoT for  
585 two reasons: a) these four models collectively embody most of the conditioning  
586 and timing mechanisms used in modelling these areas, and b) our goal here is  
587 not to provide a comprehensive review, but rather focus on the mechanisms that  
588 are shared by our proposed model and the others.

589 Table 1 summarizes the main mechanisms/features of the models described  
590 above. In terms of the type of time representation, it may be observed that  
591 the models fall roughly into two categories: (a) those that employ a chain of  
592 units or states activated sequentially (CSC-TD, MS-TD, LeT), and (b) those  
593 that employ an accumulator (MoT and RWDDM). Those in category (b) may  
594 be considered more economical both computationally and biologically, as they  
595 don't require a number of units that increase with time. In terms of what  
596 the representations can time, two categories may be discerned: (a) those that  
597 time only rewards (CSC-TD, MS-TD and LeT), and (b) those that can time  
598 any stimuli (MoT and RWDDM). Models in category (b) have more flexibil-  
599 ity to create a temporal map involving all stimuli present, including those not  
600 signalling reward. In terms of timescale invariance, the models are basically di-  
601 vided between those that can account for it (MS-TD, LeT, MoT and RWDDM)  
602 and the one that cannot (CSC-TD). Finally, in terms of the type of associative

Table 1: Summary of the main features of the models.

model	type of time representation	what it can time	timescale in-variant	associative learning rule
CSC-TD	units/states, one per time step	only rewards	no	TD/RW, cue competition
MS-TD	units/states, fewer than one per time step	only rewards	approximately	TD/RW, cue competition
LeT	units/states, one per time step	only rewards	yes	linear operator, no cue competition
MoT	linear accumulator	any stimuli, not only rewards	yes	linear operator, no cue competition
RWDDM	noisy linear accumulator	any stimuli, not only rewards	yes	RW, cue competition

603 learning rule used, models are divided between those that use a RW-type rule  
604 (CSC-TD, MS-TD, RWDDM) and those that use the linear operator (LeT and  
605 MoT). The ones that use RW are wider in scope, being able to account for  
606 cue-competition phenomena, which form the core of classical conditioning.

607 The main innovation of RWDDM over its predecessors is the combination of  
608 a noisy linear accumulator for timing with the RW rule for associative learning.  
609 As table 1 shows, linear accumulator theories are the only ones in our sample  
610 of the models that can fully account for timescale invariance. But because  
611 they rely on the linear operator rule, they cannot account for cue-competition  
612 and other compound stimuli phenomena in conditioning. Therefore RWDDM  
613 extends the application of the linear accumulator to compound stimuli, covering  
614 a wider range of conditioning phenomena.

615 In summary, the model we propose is, to the best of our knowledge, the only  
616 one that unites the flexibility, computational economy and timescale invari-  
617 ance of the linear accumulator as a time representation, to the RW associative

Table 2: Model features and the experimental findings they can explain.

RWDDM feature	phenomenon for which it can account
independent update rules for time and associative strength	faster reacquisition, time change in extinction, latent inhibition and timing
RW rule for associative strength	blocking with different durations, time specificity of conditioned inhibition
intertrial variability in time estimation asymptote of associative strength set by time	compound peak procedure ISI effect, mixed FI
a memory that learns the rate of reinforcement	VI and FI, temporal averaging

618 learning rule, which accounts for many more conditioning phenomena than the  
 619 linear operator. In the next section we evaluate the models against a number  
 620 of phenomena in conditioning and timing.

### 621 **3 Results**

622 The long history of experimental work in classical conditioning has allowed the  
 623 discovery of a rich variety of phenomena—a recent review (Alonso and Schma-  
 624 juk, 2012) has catalogued approximately 87. This forces theorists to be selective  
 625 when deciding which phenomena to simulate when presenting a new model. We  
 626 searched the literature for phenomena that could test each feature of the model.  
 627 Table 2 lists the main RWDDM features, together with the corresponding phe-  
 628 nomena found in the literature that can test each.

629 Table 3 contains the design for each simulation performed with the model.  
 630 The model parameters used in all simulations were kept almost constant but in  
 631 some cases a few adjustments were found necessary to obtain a better agreement  
 632 between model and data. We report their values in each simulation below. The

633 time-step was the same for all simulations:  $\Delta t = 10$  msec. Simulations were  
634 performed using MATLAB version R2016b. The code to generate the figures in  
635 each result section is available as supplementary material.

### 636 3.1 Faster reacquisition

637 A conditioned response emerges gradually over the course of several trials where  
638 the CS signals the arrival of a US. If a measure of CR strength (such as rate or  
639 magnitude) is plotted against the number of trials, the shape and rate of this  
640 acquisition curve will depend largely on the CR and organism, but it usually  
641 follows a negatively accelerated curve (Pavlov, 1927; Kehoe and Macrae, 2002).  
642 Pavlov (1927) believed timing of the CR would emerge only later in acquisition,  
643 through a process he described as *inhibition of delay* whereby the initial part  
644 of the CS would become inhibitory. Recent and more detailed analyses suggest  
645 that an estimate for the time to reinforcement is acquired very early in training,  
646 possibly even after one or two trials, although the expression of such estimation  
647 may not be observable until later in training (Holland, 2000; Ohyama and Mauk,  
648 2001; Balsam et al., 2002; Drew et al., 2005).

649 If the CS no longer signals reinforcement, CR strength gradually decreases  
650 over the course of these extinction trials, until it finally disappears. If the CS  
651 is made to signal the US again, the CR returns, a process that is called reac-  
652 quisition. It is a consistent finding that reacquisition is faster than acquisition  
653 (Ricker and Bouton, 1996; Guilhardi et al., 2007; Kehoe and Macrae, 2002, p.  
654 185).

655 Learning is loosely defined as an enduring change in behaviour as a result of  
656 experience. Acquisition of a CR is the most basic demonstration that classical  
657 conditioning is a form of learning. As such, all classical conditioning models  
658 provide an account of it.

659 **3.1.1 Simulations**

660 Figure 3 (top left panel) shows a plot of RWDDM’s associative strength as  
 661 given by equation (9), in a simulation of acquisition and extinction. Acquisition  
 662 consisted of 80 presentations of a 5-sec CS followed by reinforcement, after which  
 663 there were 100 extinction trials where  $H$  was set to zero. The simulations match  
 664 with experimental data from acquisition and extinction (bottom left panel of  
 665 figure 3). The simulated acquisition curve asymptotes around the theoretical  
 666 value given by setting  $\Delta V(n) = 0$  in equation (9) and solving for  $V$ , yielding

$$V_\infty = \frac{HA_\infty}{x(\Psi_{t^*})\Psi(t^*)}, \quad (20)$$

667 which in this particular case is  $V_\infty \approx 1$ , since  $H = 5$ ,  $A_\infty \approx 1/5$ ,  $\Psi_{t^*} = \Psi(t^*) \approx$   
 668  $1$ ,  $x(\Psi_{t^*}) \approx 1$ , where  $t^*$  is the time of reinforcement. Because  $\Psi(t^*)$  is a random  
 669 variable,  $x(\Psi_{t^*})$  and  $V_\infty$  are also random variables and their values are reported  
 670 as approximations to their expected values (but not the actual expected values).

671 Figure 3 (top middle panel) shows the adaptation of timer slope  $A$  given by  
 672 equation (6). This equation precludes the initial value of  $A$  from being zero,  
 673 so we set it to the very low value of  $A(1) = 10^{-6}$ . We also set the threshold  
 674  $\theta = 1$ , which by equation (6) means that  $A_i(n)$  encodes the exponential moving  
 675 average of the rate of reinforcement signalled by  $CS_i$ . Or, equivalently,  $1/A_i(n)$   
 676 encodes the moving harmonic average of the intervals since last reinforcement  
 677 during  $CS_i$ . In this simulation, since there is only one US which is delivered  
 678 always at the same time at CS offset (5000 msec),  $A$  converges to  $A_\infty = 1/5000$ .  
 679 Note that the value of  $A$  does not decline after extinction begins at trial 80. It  
 680 continues to be updated since the stimulus is still present, even if its presence  
 681 no longer signals reinforcement.

682 The top right panel of figure 3 shows the acquisition and reacquisition curves  
 683 using RWDDM. Reacquisition produced by the model is evidently faster than

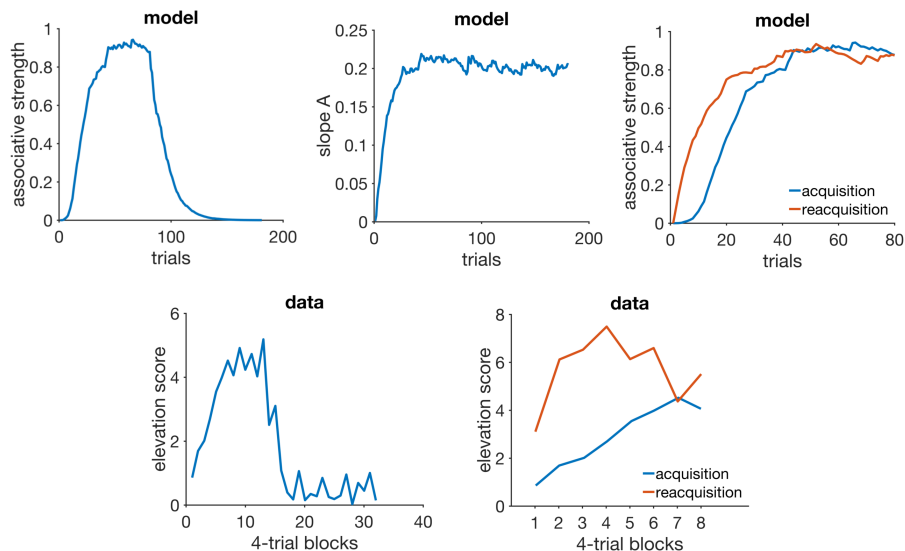

Figure 3: Acquisition and reacquisition. Top left: simulated associative strength  $V$  in acquisition and extinction. Top middle: adaptation of RWDDM slope  $A$ . CR extinction began at trial 80 but has no effect on the RWDDM slope. Top right panel: simulated  $V$  curves in acquisition and reacquisition. Bottom left panel: response strength data from an experiment in acquisition and extinction, redrawn from figure 1 in Ricker and Bouton (1996). Bottom right panel: data from an experiment in acquisition and reacquisition, redrawn from the top panel of figure 3 in Ricker and Bouton (1996). Model parameters:  $m = 0.15$ ,  $\theta = 1$ ,  $\sigma = 0.3$ ,  $\alpha_t = 0.1$ ,  $\alpha_V = 0.1$ ,  $H = 4$  in acquisition and  $H = 0$  in extinction.

684 the simulated acquisition, but not as fast as the reacquisition seen in the data  
 685 on the bottom left of figure 3.

### 686 3.1.2 Discussion

687 In RWDDM acquisition and extinction of associative strength follow from the  
 688 same mechanism as RW. The only difference is the noisy stimulus representation  
 689  $x(\Psi_{t^*})$ , which induces noise into the acquisition curve. Changes in associative  
 690 strength and timing are treated independently. In particular, the memory for  
 691 time encoded by the slope  $A$  is not affected by extinction. This leads to a faster  
 692 reacquisition following extinction. This is because RWDDM’s time-adaptive

693 CS representation  $x(\Psi_{t^*})$  reaches its maximum activation value right from the  
694 beginning of reacquisition, since the timer slope  $A$  is already tuned to the current  
695 CS duration (see equation (8)).

696 Modular theory (Guilhardi et al., 2007) is another model that treats timing  
697 and associative strength separately. It postulates two memories, one for the  
698 pattern of reinforcement and another for the strength of the association between  
699 CS and US. The pattern memory stores an exponential moving average of the  
700 intervals to reinforcement which, like RWDDM, does not change with extinction.  
701 However, its strength memory  $w(n)$  is updated according to the linear operator  
702 rule,

$$w(n+1) = w(n) + \beta(\lambda - w(n)) \quad (21)$$

703 which, unlike RWDDM, does not include a term for a time-adaptive CS rep-  
704 resentation. Thus, the way MoT accounts for rapid reacquisition is by using  
705 different learning rates  $\beta$  for acquisition and reacquisition. The same strategy  
706 may be employed with the TD and LeT models.

707 In summary, RWDDM explains reacquisition as the persistence of a memory  
708 for time, whilst TD, LeT and MoT explain it as a permanent change in the  
709 learning rate for associative strength.

### 710 **3.2 Time change in extinction**

711 When a previously conditioned stimulus is no longer followed by reinforcement,  
712 the conditioned response gradually decreases. An important theoretical question  
713 for hybrid timing/conditioning models concerns what happens to the timing of  
714 responses in extinction. Using the peak procedure Ohyama et al. (1999) found  
715 that although the maximum (peak) response rate decreased in extinction, peak  
716 time and sensitivity (measured by the coefficient of variation) remained virtu-

717 ally unchanged. Drew et al. (2004) investigated the behaviour on extinction by  
718 changing CS duration between acquisition and extinction. Groups where the  
719 CS changed to a shorter or longer duration were compared to another where  
720 the duration did not change. They found that CS duration had little effect on  
721 the rate of extinction, with all groups taking about the same number of tri-  
722 als to achieve CR extinction. However, when the CS used in extinction was  
723 considerably longer (4 times) than the one acquired, extinction was facilitated.  
724 Guilhaudi and Church (2006) performed a similar experiment (experiment 2)  
725 and observed that when stimulus duration is changed from acquisition to ex-  
726 tinction, the pattern of responding during extinction gradually shifts to the new  
727 duration over extinction trials. Following the same procedure, Drew et al. (2017)  
728 also used partial reinforcement to slow down the rate of acquisition, and thus  
729 observe if response patterns really do shift gradually to the new duration. They  
730 confirmed that when CS duration was increased from acquisition to extinction,  
731 the within-trial response peak shifted gradually to the right over the course of  
732 extinction. When the CS was shortened, the results were not conclusive. Also,  
733 when CS duration was changed from training to extinction, the speed of extinc-  
734 tion increased, but this appeared to be explained at least in part by the shifting  
735 of response patterns.

736 In summary: a) peak timing and CV are not altered in extinction when using  
737 a peak procedure, b) changing the CS duration from training to extinction causes  
738 the within-trial response peak to shift to the new duration, and c) changing the  
739 CS duration in extinction can speed up extinction, but this may be due to the  
740 shifting of the response peak and not to changes in associative strength. These  
741 results pose a challenge to the models analysed here. Out of CSC-TD, MS-TD,  
742 LeT and MoT, only MoT has a mechanism that would allow it to account for  
743 time change in extinction.

### 744 3.2.1 Simulations

745 RWDDM provides an account for these findings as follows. In the case of the  
746 peak procedure, the occurrence of the longer peak trials may be considered too  
747 infrequent to cause a shift to the longer time. In this case, equation (6) is not  
748 applied in peak trials so RWDDM predicts that both slope  $A$  and CV will remain  
749 unaltered in extinction. In the case of a permanent change in CS duration from  
750 acquisition to extinction, the slope update rule is applied and the response peak  
751 will shift gradually to the new duration.

752 We have simulated RWDDM in two extinction conditions, one where the  
753 CS presented in extinction was longer than the one acquired (20 sec to 40 sec,  
754 short-long) and another where the extinction CS was shorter than the acquired  
755 CS (20 sec to 10 sec, long-short). Figure 4 summarizes the main results.

756 The panels on the left column show response strength during a trial in condi-  
757 tions short-long (top) and long-short (bottom). In the early stages of extinction  
758 (early) the response curves peak around the time of US arrival in acquisition  
759 (20 sec). This is more evident in the condition short-long (top left) because in  
760 the other condition (bottom left) the trial ends 10 seconds before the peak at 20  
761 seconds occurs. Had the stimulus remained on for a full 20 seconds, the response  
762 curve in the early stages of long-short would have continued to increase until the  
763 20 second mark. In middle and late extinction the response peak slowly shifts  
764 to the new duration in both conditions, and their heights decrease. Compare  
765 the simulated curves in the left column of figure 4 to the actual experimental  
766 data in the right column. The panels on the middle row of figure 4 show the  
767 adaptation of time estimate  $1/A$  in conditions short-long (top) and long-short  
768 (bottom). They demonstrate that RWDDM adapts exactly to time change in  
769 extinction.

770 To investigate if the rate of acquisition changes with CS duration, we have

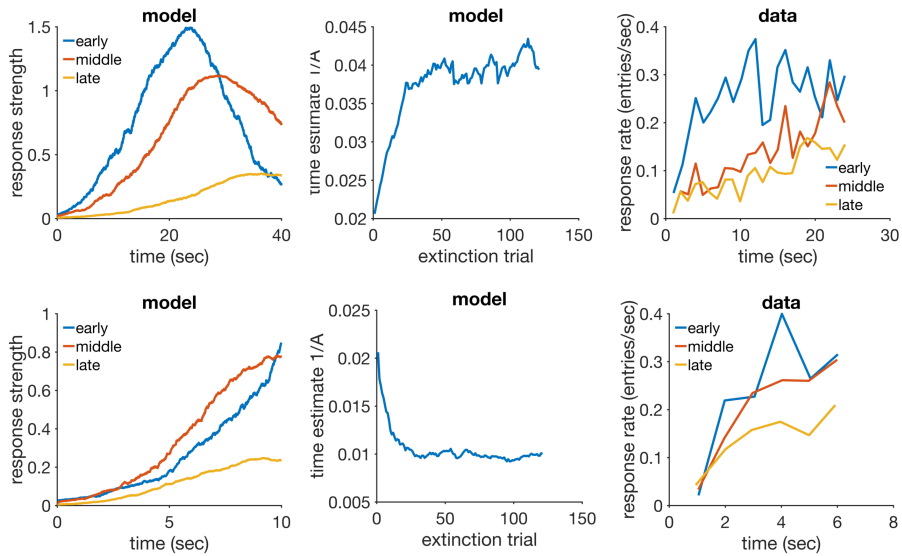

Figure 4: Time change in extinction. Left column: simulated response strength averaged over trials in extinction short-long (top) and long-short (bottom). Middle column: time estimate adaptation of the model during extinction short-long (top) and long-short (bottom). Right column: experimental data from an experiment where the CS duration changed from 12-sec in acquisition to either 24-sec (top) or 6-sec (bottom) in extinction. Data plots redrawn from figure 10 in Drew et al. (2017). Model parameters:  $m = 0.25$ ,  $\theta = 1$ ,  $\sigma = 0.35$ ,  $\alpha_t = 0.08$ ,  $\alpha_V = 0.09$ ,  $H = 30$ .

771 plotted the extinction curves for each CS duration in the left panel of figure  
 772 5. Decreasing CS duration from acquisition to extinction slightly facilitates  
 773 extinction, but increasing CS duration markedly delays extinction. However,  
 774 these are only the  $V$  values, a theoretical construct that accounts for the as-  
 775 sociative strength of the stimulus as a whole. Actual behaviour measurements  
 776 of extinction are based on how much response frequency changes from trial to  
 777 trial. But response frequency also changes within the trial. As pointed out by  
 778 Drew et al. (2017), the value obtained for the rate of extinction may be affected  
 779 by which portion of the CS was measured. To analyse this, Drew et al. (2017)  
 780 measured response frequency only during the first 6-sec (half the duration of  
 781 the CS in acquisition) of each CS duration in extinction. We have followed the

782 same procedure and the results can be seen on the middle panel of figure 5.  
 783 They show a marked delay on extinction when the CS duration was shortened,  
 784 but not when it was lengthened. Compare these curves with the actual data  
 785 analysed by Drew et al. (2017) and displayed in the rightmost panel of figure 5.  
 786 The simulations conflict in part with the same analysis in Drew et al. (2017),  
 787 which showed no delay on extinction, only facilitation in the case of extending  
 788 CS duration.

Figure 5: Extinction curves. Left panel: model  $V$  values for each CS duration in extinction. Middle panel: simulated CR values calculated only for the first 10 seconds of the CS. Each data point is calculated by summing the output of equation (10) over the first 10 sec of each trial, then averaging these trial values two by two, and dividing by 100 to rescale. Right panel: actual CR data for the first 6 sec of the CS in extinction, redrawn from figure 8 (C) in Drew et al. (2017)

### 789 3.2.2 Discussion

790 RWDDM predicts that a change in CS duration from acquisition to extinction  
 791 will always cause a rescaling of the response curves in extinction. This is largely  
 792 in agreement with the data. However, RWDDM seems to predict a degree of  
 793 delay on extinction, whilst the data seems to point to a facilitation of extinction  
 794 when the CS changes duration. When only the first half of the CS response  
 795 curves are analysed, the data suggests that extending CS duration in extinction  
 796 can speed up extinction, whilst RWDDM predicts that shortening CS duration  
 797 will delay extinction.

798 RWDDM's prediction for a delay in extinction following a change in CS  
799 duration is due to the shifting of the response curve. At the beginning of  
800 extinction, a trial ends either before the CS representation has reached its peak  
801 (CS shortening) or after its peak (CS lengthening). This makes equation (9)  
802 update with a small value for  $x(\Psi)$ , resulting in a smaller update than with the  
803 higher  $x(\Psi)$  value of the unchanged CS.

804 As mentioned above, time change in extinction is a difficult phenomenon for  
805 the current models to explain. CSC-TD does not have a mechanism to change  
806 the peak of responding when a US is not present. Neither does MS-TD or LeT.  
807 These models assume that extinction can only weaken existing links between CS  
808 and US representations. Because in these models timing usually depends on the  
809 sequential activation of these links, changing the CS duration in extinction would  
810 not alter the timing but only the magnitude of responding. RWDDM explains  
811 time change in extinction because its rule for time adaptation is independent of a  
812 change in associative strength. Thus, when the duration changes in extinction,  
813 RWDDM's accumulator slope tracks this change, whilst associative strength  
814 decays as a function of US absence. Regarding the extinction facilitation caused  
815 by a change in CS duration, none of the models analysed here currently have a  
816 mechanism to explain this either.

817 It would be possible to allow the average rate of state transition in LeT  
818 to vary as a function of CS duration, which would cause timing to adapt to  
819 the new time in extinction. However, in its latest formulation (Machado et al.,  
820 2009) LeT relies on a fixed average rate of state transition to explain timescale  
821 invariance. Thus, if the rate is made to change as a function of CS duration,  
822 this would break timescale invariance.

823 As for MS-TD, one interesting modification that would likely allow it to  
824 explain time change in extinction is to make the microstimuli themselves time-

825 adaptive. Like RWDDM's time-adaptive CS representation, the microstimuli  
826 could be made to 'stretch' or 'compress' when stimulus duration shortens or  
827 lengthens.

828 Modular Theory is likely to account for time change in extinction, since  
829 its pattern memory for time could be made to update even in extinction. That  
830 would shift the response pattern to the new time whilst strength memory, which  
831 depends only on US presentation, would decay.

### 832 **3.3 Latent inhibition and timing**

833 When a subject is exposed to repeated and non-reinforced presentations of a  
834 stimulus it has never encountered before, this procedure is called preexposure.  
835 If reinforcement is subsequently paired with the preexposed CS, the initial rate  
836 of CR acquisition is usually lower compared to acquisition to a nonpreexposed  
837 stimulus, a phenomenon called latent inhibition (Lubow and Moore, 1959). The  
838 asymptotic level of conditioning, however, is not normally affected by preexpo-  
839 sure (Lubow, 1989). Latent inhibition is an important representative of a class  
840 of phenomena involving latent effects. Collectively, these phenomena demon-  
841 strate that something is learned about the stimulus even when it does not sig-  
842 nal reinforcement. Therefore, latent inhibition cannot be accounted by the  
843 Rescorla-Wagner model, since the theory only applies when there are changes  
844 in associative strength.

845 A question relevant for real-time conditioning models is what happens to  
846 timing when a preexposed stimulus is conditioned. To answer this question,  
847 Bonardi et al. (2016) used CSs of variable and fixed durations (the variable  
848 duration CS had the same mean as the duration of the fixed CS) to vary the  
849 temporal conditions between preexposure and conditioning phases. Latent in-  
850 hibition was observed even when the temporal information from the two phases

851 was different. Crucially, timing, as measured by the response gradient within  
 852 a trial, appeared to improve in the preexposed CS even when the temporal  
 853 information was different between the two phases.

854 As alluded to above, latent inhibition cannot be accounted by the associative  
 855 learning update rule used in RWDDM, the Rescorla-Wagner. However, we show  
 856 here that RWDDM is compatible with the Pearce-Hall rule (Pearce and Hall,  
 857 1980; Pearce et al., 1982), one of the most widely used models for explaining  
 858 latent inhibition and other latent learning effects. We demonstrate that this  
 859 modification maintains the basic framework of the RWDDM, and that it can  
 860 account for latent inhibition and improved timing with preexposure. None of  
 861 the other models analysed here can account for latent inhibition without mod-  
 862 ifications. Improved timing with preexposure could be accounted by Modular  
 863 Theory, but not by the the current version of the other models.

### 864 3.3.1 Simulations

865 The Pearce-Hall model is basically a rule for adapting the learning rate  $\alpha_V$  based  
 866 on the error  $\delta$  between the predicted US outcome and the actual US outcome.  
 867 It was originally formulated by Pearce and Hall (1980) and updated by Pearce  
 868 et al. (1982). We have maintained equation (9) for associative strength, but  
 869 changed  $\alpha_V$  on every trial  $n$  according to

$$\alpha_V(n+1) = \alpha_V(n) + \gamma(|\delta| - \alpha_V(n)), \quad (22)$$

$$\delta = \left( \frac{HA(n)}{\Psi(t^*)} - V(n)x(\Psi) \right) \quad (23)$$

870 where  $0 < \gamma < 1$  is a parameter that sets the rate of learning rate adaptation.  
 871 Equation (22) is basically the Pearce-Hall rule, except that instead of using 1  
 872 as the asymptote of learning we use  $\frac{HA(n)}{\Psi(t^*)}$ .

873 We simulated latent inhibition with a 5-sec CS. Preexposure consisted of

874 80 trials of the CS without reinforcement ( $H = 0$ ). The preexposed CS was  
 875 then reinforced for 250 trials. Figure 6 (top left panel) compares the acquisition  
 876 curves for the preexposed CS and a control CS in the reinforced trials. The  
 877 preexposed CS acquisition curve increases at a lower rate than the control CS,  
 878 the latent inhibition effect (see data from a corresponding experiment at the  
 879 bottom left panel of figure 6).

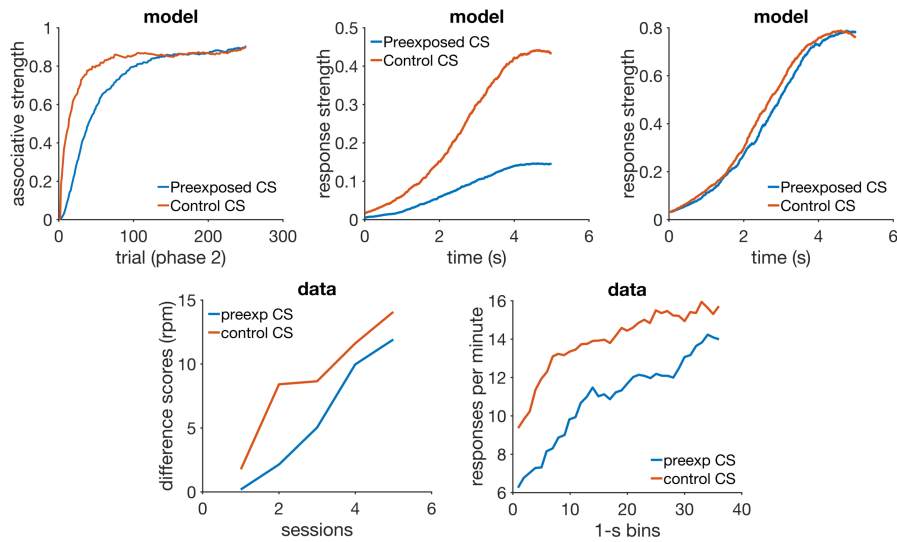

Figure 6: Latent Inhibition. Top row: simulated associative strength in latent inhibition (left), simulated CR averaged over the first 30 trials of conditioning phase (middle), and simulated CR averaged over the last 30 trials of conditioning phase (right). Bottom row: acquisition curves from an actual experiment in latent inhibition (left), and response rate data during the CS (right). Data plots redrawn from figures 1 and 2 respectively in Bonardi et al. (2016). Model parameters:  $\alpha_t = 0.1$ ,  $\alpha_V = 0.08$ ,  $\mu = 1$ ,  $\sigma = [0.6 - 0.35]$ ,  $m = 0.2$ ,  $H = 4$ ,  $\alpha_{PH} = 0.4$ ,  $\gamma = 0.03$ .

880 Improved timing with preexposure follows directly from the fact that RWDDM  
 881 adapts its accumulator slope  $A$  to the CS duration during preexposure. How-  
 882 ever, our choice of a Gaussian for stimulus representation does not allow for this  
 883 change to become visible. Bonardi et al. (2016) demonstrated improved timing  
 884 by showing that the slope of the response curve from the preexposed CS was

885 higher in the first few trials of acquisition than the one from the control CS  
 886 (see bottom right panel of figure 6). In general, animal response curves tend  
 887 to be quite flat during the beginning of acquisition. There is evidence that the  
 888 response curves appear to change from negatively accelerated to a sigmoidal  
 889 shape over the course of training (see figure 1 in Meck and Church, 1984, for  
 890 an example). This means that in the early stages of acquisition, within-trial  
 891 response frequency increases very early in the trial and then stays at a constant  
 892 level until the end. As training progresses, the increase in frequency moves  
 893 slowly to the right, giving rise to the sigmoidal shape that peaks just before  
 894 the end of the trial. In these cases a higher slope of the response curve would  
 895 indicate improved timing. But in our model the curves are sigmoidal from start  
 896 of acquisition, so they will always peak at the end of the trial, even if the timer  
 897 slope has not adapted to the interval yet, as is the case with a novel stimulus.  
 898 Therefore, during the acquisition phase of latent inhibition, RWDDM predicts  
 899 that only the peaks of the response curves will gradually increase over the tri-  
 900 als. Because of the learning decrement caused by preexposure, the peak of the  
 901 control CS will increase faster than the preexposed CS, as the top middle panel  
 902 of figure 6 demonstrates. The response curve of the control CS will have a  
 903 higher slope than the preexposed CS, even though the preexposed CS's timer  
 904 rate has been adapted to its duration. Hence, the improved timing found in the  
 905 data is explained by adaptation of RWDDM's timer slope, but RWDDM's CS  
 906 representation cannot make this visible.

907 We have tried adding an adaptable  $\sigma$  in equation (8) so as to decrease the  
 908 width of the gaussian curve gradually over trials. We chose a simple linear  
 909 operator rule to adapt the Gaussian width:

$$\sigma(n + 1) = \sigma(n) + \alpha_\sigma(0.35 - \sigma(n)), \quad (24)$$

910 and set  $\sigma(1) = 0.6$  and  $\alpha_\sigma = 0.025$ .

911 Figure 6 (top middle panel) shows response strength of control and preex-  
912 posed CSs averaged over the first 30 trials of the conditioning phase. The pre-  
913 exposed CS already shows a clear sigmoidal shape, whilst the control is slightly  
914 wider and linear. But the effect is too small to be able to account for the one  
915 seen in the data from Bonardi et al. (2016). Towards the end of the conditioning  
916 phase the two curves converge (figure 6, top right panel).

### 917 **3.3.2 Discussion**

918 The simulations show that the model can account for latent inhibition ade-  
919 quately if the Pearce-Hall rule is used (in which case the model would be more  
920 appropriately named PHDDM). The PH rule adapts the learning rate  $\alpha_V$  based  
921 on the level of associative learning between stimulus and reward. When the  
922 subject encounters a novel stimulus, it is assumed that  $\alpha_V$  has some non-zero  
923 starting value  $\alpha_V^{\text{novel}}$ , which allows learning in equation (9) to take place. If this  
924 novel stimulus does not signal reward, as is the case in the preexposure phase  
925 of latent inhibition,  $\sigma = 0$  and equation (22) will simply decay the value of the  
926 learning rate across trials until it reaches zero. If at this point the stimulus  
927 begins to be followed by reward,  $\sigma > 0$  and equation (22) will begin to raise  
928 the value of the learning rate, which in turn will allow equation (9) to begin  
929 increasing the value of  $V$ . Since the increase in the value of the learning rate  
930 is gradual, determined by the rate  $\gamma$ , there will be a number of trials in the  
931 beginning of the conditioning phase where  $\alpha_V < \alpha_V^{\text{novel}}$ , which leads to the ini-  
932 tial impairment in the learning curve when compared to the learning curve of a  
933 non-preexposed CS, as seen in the top left panel of figure 6.

934 The separate rule for time adaptation allows the model to account for im-  
935 proved timing after preexposure, but the model cannot make this effect visible  
936 even if we allow for Gaussian width adaptation. In view of this it seems more

937 likely that a two-state CS representation may be a better solution. As men-  
938 tioned above, figure 1 in Meck and Church (1984) suggests that during the  
939 initial stages of training a CS representation may be modelled by the following  
940 leaky integrator

$$x_i(t+1) = x_i(t) + \frac{1}{\tau}(I_i - x_i(t)) \quad (25)$$

941 where  $I_i$  is the indicator function marking the presence of  $CS_i$ , and  $\tau$  a time  
942 constant. In the latter stages of training, when timing is expressed, the organism  
943 switches to the Gaussian representation given by equation (8). When the switch  
944 between representations is made and how abruptly remains to be investigated.

945 Latent inhibition cannot be accounted by any of the other models analysed  
946 here without modifications. Also, models that rely on the US for time adap-  
947 tation, like CSC-TD, MS-TD and LeT, cannot account for improved timing by  
948 preexposure. Modular Theory is the only one that can time any stimulus like  
949 RWDDM, so it could account for the improved timing. But it would also need a  
950 modification like (22) to adapt its learning rate to account for latent inhibition.

### 951 **3.4 Blocking with different durations**

952 Arguably, the most important compound conditioning phenomenon is blocking.  
953 It is part of a class of cue competition and compound phenomena discovered in  
954 the late 1960s which challenged the view that conditioning was driven by the  
955 pairing, or contiguity, of CS-US. These results suggested that conditioning with  
956 compound stimuli was influenced by the reinforcement histories of the elements  
957 forming the compound (Rescorla, 1988; Gallistel and Gibbon, 2001). This led  
958 to the development of a new generation of models that could account for those  
959 findings (Rescorla and Wagner, 1972; Mackintosh, 1975; Pearce and Hall, 1980).  
960 The rule we use, the Rescorla-Wagner, provides an explanation for blocking that

961 is based on the summation term in equation (1).

962 In a blocking procedure a CS is first paired with a US in phase 1 of training.  
963 During phase 2 a novel CS is presented in compound with phase 1 CS and paired  
964 with the US for just a few trials. Subsequently, when tested alone the novel CS  
965 elicits less responding than if it had been trained in compound with another  
966 novel stimulus (Kamin, 1968). The previously reinforced CS is said to block  
967 the novel CS. The temporal information encoded by each CS has an effect on  
968 the amount of blocking observed. Schreurs and Westbrook (1982) varied the ISI  
969 in the pre-training and compound phases, and observed less blocking when the  
970 durations were different in both phases than when they were the same. Barnett  
971 et al. (1993) performed a similar experiment but with forward and simultaneous  
972 conditioning varying between phases, and also found that blocking was stronger  
973 when blocked and blocking CSs had the same temporal history. Jennings and  
974 Kirkpatrick (2006) used compounds where the elements had different durations.  
975 They observed that a long blocking CS could block a co-terminating short Cs,  
976 but a short blocking CS failed to block a co-terminating long CS (see rows 1 and  
977 3 in figure 7). Amundson and Miller (2008) performed four blocking experiments  
978 using trace conditioning. In two of them the blocking CS trace duration changed  
979 between phases, and blocking was not observed. In the other two experiments  
980 the trace duration was held fixed between phases, and the blocking and blocked  
981 CSs were presented serially and not in a compound (see rows 2 and 4 of figure  
982 7). Blocking was observed when the blocking CS followed the blocked CS, but  
983 not in the reverse condition.

984 The studies reviewed above appear to show that changing the ISI of the  
985 blocking CS between phases may attenuate blocking. Another finding is the  
986 apparent asymmetry of blocking when the ISI of the blocking CS is kept constant  
987 between phases. Rows 1 and 2 of figure 7 suggest that a long blocking ISI can

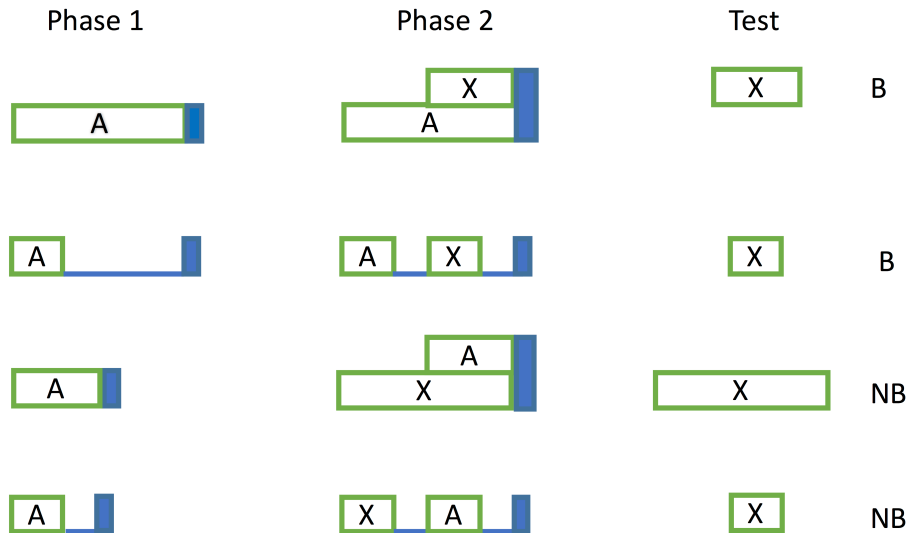

Figure 7: Experimental designs from two blocking experiments. CS X was blocked (B) in rows 1 and 2, and not blocked (NB) in rows 3 and 4. Blue bar indicates US presence.

988 block a short blocked ISI. Rows 3 and 4 suggest that a short blocking ISI does  
 989 not block a long blocked ISI.

990 As mentioned above, RWDDM can account for blocking because it uses the  
 991 RW rule. The summation term in equation (1) formalizes the widely held view  
 992 that a given US can only confer a limited amount of associative strength which  
 993 CSs must compete for. Different theories exist that take other approaches to  
 994 blocking (see for example Mackintosh, 1975; Harris, 2006; Stout and Miller,  
 995 2007) but among the ones analysed here (for their ability to handle timing also)  
 996 only CSC-TD and MS-TD are equipped to deal with it. We show next that  
 997 RWDDM can account for the blocking of a short CS by a long CS, and that  
 998 by making the reasonable assumption of second-order conditioning it can also  
 999 account for the lack of blocking of a long CS by a short CS. CSC-TD and MS-TD  
 1000 are also capable of providing an account of both blocking conditions.

1001 **3.4.1 Simulations**

1002 Because RWDDM is based on the RW rule, it produces virtually the same results  
1003 as the latter when the CSs have the same duration. Our interest here is to test  
1004 whether it can reproduce the finding that a long CS can block a shorter CS but  
1005 a shorter CS does not block a longer one. We performed a simulation following  
1006 the design in rows 1 and 3 of figure 7. In the first phase a CSA (blocking  
1007 CS) of duration either 10 or 15 seconds was followed by reinforcement until its  
1008 associative strength  $V$  reached asymptote. In phase 2 CSA was joined with a  
1009 CSX (blocked CS), of either 15 or 10 seconds, in a coterminating compound and  
1010 followed by US. The top left panel of figure 8 shows the acquisition of associative  
1011 strength for CSX and its control during phase 2 for the condition CSA-15sec  
1012 and CSX-10sec. A considerable amount of blocking is observed, matching with  
1013 the data (bottom left panel).

1014 The top right panel of figure 8 shows the results for condition CSA-10sec  
1015 and CSX-15sec. In this condition the model diverges considerably from the data  
1016 (bottom right panel) and predicts that CSX should actually become inhibitory.

1017 **3.4.2 Discussion**

1018 The blocking and inhibition seen in figure 8 is a result of a discrepancy in the  
1019 asymptote of learning between the CSs. After phase 1, CSA has associative  
1020 strength  $V_A \approx HA_A$ . During phase 2, CSX's associative strength changes ac-  
1021 cording to:

$$\begin{aligned}\Delta V_X &\approx \alpha(HA_X - (V_A + V_X)) \\ &= \alpha(HA_X - (HA_A + V_X)) \\ &= \alpha(H(A_X - A_A) - V_X)\end{aligned}$$

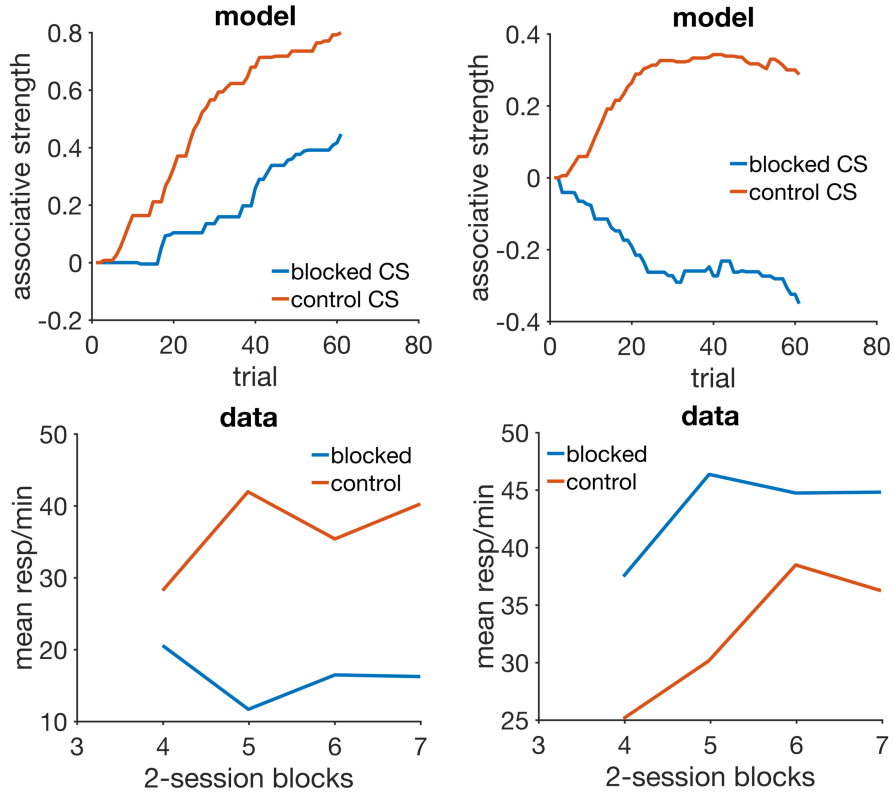

Figure 8: Blocking with different durations. Left column: simulation (top) with a 15 sec blocking CS and 10 sec blocked CS, and animal data (bottom) from an experiment with the same design. Right column: simulation (top) with a 10 sec blocking CS and 15 sec blocked CS, and animal data (bottom) from an experiment with the same design. Data panels redrawn from the top right panel in figure 5 in Jennings and Kirkpatrick (2006). Model parameters:  $\alpha_t = 0.2$ ,  $\alpha_V = 0.1$ ,  $\mu = 1$ ,  $\sigma = 0.35$ ,  $m = 0.2$ ,  $H = 10$ .

1022 and since  $(A_X - A_A) < 0$ ,  $V_X$  becomes negative.

1023 However, it could be argued that the short CSA becomes a secondary rein-  
 1024 forcer which is signalled by the onset of the long CSX. In this case, the onset of  
 1025 CSX would serve as the time marker for the onset of CSA, and not for the onset  
 1026 of US. Hence, during the first 5 seconds of CSX responding would be under  
 1027 the control of this 5-sec stimulus representation which would not overlap, thus  
 1028 not compete, with CSA's later representation. It would follow from this account

1029 that no blocking would be observed, and that responding during test phase with  
1030 CSX would peak at the 5-sec mark. This is a testable prediction that, if shown  
1031 to be the case, could validate RWDDM's account.

1032 Also note that the time-dependent associative strength asymptote assumed  
1033 by RWDDM implies that learning during a compound where the elements are  
1034 of different durations is not stable. In particular, if CSA and CSX are the  
1035 two elements of the compound phase of blocking, their associative strengths are  
1036 updated by RWDDM as

$$\begin{aligned}\Delta V_A &= \alpha_V(HA_A - (V_A + V_B)) \\ \Delta V_B &= \alpha_V(HA_B - (V_A + V_B)),\end{aligned}$$

1037 which in the steady state form an inconsistent system of linear equations,

$$\begin{aligned}V_A + V_B &= HA_A \\ V_A + V_B &= HA_B.\end{aligned}$$

1038 Since the compound phase of blocking only lasts for a few trials, RWDDM  
1039 could produce the blocking seen on the left panel of figure 8. But if training  
1040 with the compound was carried out for longer, the  $V$  values would grow without  
1041 bound. However, there is evidence that in compounds formed by elements with  
1042 asynchronous onsets, like in the compound phase of the blocking experiments  
1043 here, the shorter stimulus comes to control CR timing and there is no summation  
1044 of associative strengths (Fairhurst et al., 2003). Hence, it appears that with  
1045 compounded asynchronous CSs, the shorter CS, more proximal relative to the  
1046 US, comes to dominate and a summation rule like RW would not be applicable  
1047 beyond the first few trials of training.

1048 A model that is well placed to explain these results is CSC-TD. A long

1049 blocking CS will completely overlap a short blocked CS, blocking all units in the  
1050 blocked CS. But in the case of a short blocking CS, there will be free units in the  
1051 beginning of the blocked CS which will acquire associative strength, attenuating  
1052 blocking. Given its similarity, MS-TD would likely produce comparable results.  
1053 MoT and Let would not be able to account for any type of blocking given their  
1054 current choice of rule for associative strength. Unlike RWDDM and the TD  
1055 models, they both rely on the linear operator rule, which antedates the transition  
1056 to the rules that sum associative strengths in the compounds as mentioned  
1057 previously. MoT and LeT would need, at the very least, to replace the linear  
1058 operator by the RW or other equivalent rule to be able to account for blocking  
1059 and other compound phenomena.

### 1060 **3.5 Time specificity of conditioned inhibition**

1061 Learning occurs not only when a CS signals the occurrence of a US, but also  
1062 when a CS signals the omission of a US. It is commonly assumed that the ex-  
1063 citation caused by the former is counteracted by an inhibition produced by the  
1064 latter. This is again formalized by the summation term in the RW rule. Con-  
1065 ditioned inhibition is thus one of the phenomena that, together with blocking  
1066 and other compound phenomena, challenged the contiguity interpretation of  
1067 classical conditioning.

1068 A conditioned inhibition procedure involves reinforced trials with a CS, say  
1069 A+, intermixed with non-reinforced trials with a compound AB-. Conditioned  
1070 responding develops during A+ trials but not during AB-. Hence, conditioned  
1071 inhibition is a key conditioning phenomenon since it is also a form of discrimi-  
1072 nation learning.

1073 Conditioned inhibition poses higher technical challenges for a model of learn-  
1074 ing and timing as responses cannot be directly observed. To assess conditioned

1075 inhibition two types of measures are used (Denniston and Miller, 2007): sum-  
1076 mation and retardation tests. There are different procedures that can generate  
1077 inhibition, so we refer here specifically to the inhibition produced by alternating  
1078 A+ with AB- trials. CSA is called a training excitator, and CSB an inhibitor.  
1079 In summation tests, this inhibitor is then presented together with a different  
1080 excitator, and the inhibitor is said to pass the test if there is a decrement in re-  
1081 sponding compared to the excitator alone. In retardation tests, the inhibitor by  
1082 itself is now paired with the US, and it is said to pass the test if acquisition  
1083 is slower than with a neutral stimulus. Denniston and Miller (2007) reviewed  
1084 a series of studies that varied the durations of the training excitator and that  
1085 between the inhibitor and the training excitator. The studies showed that condi-  
1086 tioned inhibition is observed when the temporal relations between training and  
1087 testing are preserved, and not otherwise.

1088       However, the studies reviewed by Denniston and Miller (2007) used as mea-  
1089 sure of conditioned inhibition the time to resume drinking (licking suppression)  
1090 when presented with the inhibitor. Williams et al. (2008) investigated inhibi-  
1091 tion caused by reinforcement omission in excitatory conditioning, a more direct  
1092 measure than licking suppression. In their experiments the inhibitor stimulus  
1093 signalled the omission of one of two USs (at 10 or 30 seconds) that had been as-  
1094 sociated with the excitator stimulus. Using summation tests they found that the  
1095 inhibitor would suppress responding only at the specific time of predicted US  
1096 omission. Retardation tests confirmed that the time of US omission is encoded  
1097 by the inhibitor.

1098       We show here that RWDDM can account for inhibition and its time speci-  
1099 ficity. CSC-TD and MS-TD are also equipped to deal with these results. MoT  
1100 and LeT do not currently have the necessary mechanisms to explain inhibition.

### 1101 **3.5.1 Simulations**

1102 We demonstrate time specificity of inhibition with simulations of Williams et al.  
1103 (2008) experiment. Exciters E1 and E2 signalled reinforcement after 10 and 30  
1104 seconds respectively, and inhibitors I1 and I2 signalled US omission after 10  
1105 and 30 seconds respectively. During phase 1, E1 and E2 were always reinforced,  
1106 whilst the compounds E1I1 and E2I2 were never reinforced (see table 3). In  
1107 phase 2 a transfer excitor E3 was trained on a mixed FI schedule, where in  
1108 half the trials E3 lasted 10 seconds and in the other half 30 seconds. Phase 3  
1109 consisted of nonreinforced peak trials that lasted 90 seconds, a third with E3  
1110 compounded with I1, a third with E3I2, and a third with E3 alone. Figure 9  
1111 summarizes the results. Responding during E3 alone shows the two peaks char-  
1112 acteristic of mixed FIs. As figure 9 shows, the compound excitor and inhibitor  
1113 inhibits responding only at the time encoded by the inhibitor.

### 1114 **3.5.2 Discussion**

1115 The account provided of inhibition by RWDDM relies on the traditional summa-  
1116 tion term inherited from the RW rule. Time specificity comes from the inhibitor  
1117 CS timer being treated just like any other CS timer, except that instead of tim-  
1118 ing the arrival of the US it times the arrival of US omission.

1119 RWDDM predicts that the representation of an inhibitor CS has the same  
1120 shape as of an excitor CS. This implies that inhibition is the exact opposite  
1121 of excitation. This is a testable prediction which the empirical results above  
1122 provide some validation.

1123 The TD models provide a similar account of these data. Both CSC and  
1124 MS TD have CS representations that allow for time specificity of US omission.  
1125 Because the TD relies on the RW summation term, they can account for inhi-  
1126 bition. LeT and MoT can also represent such time specificity, but because they

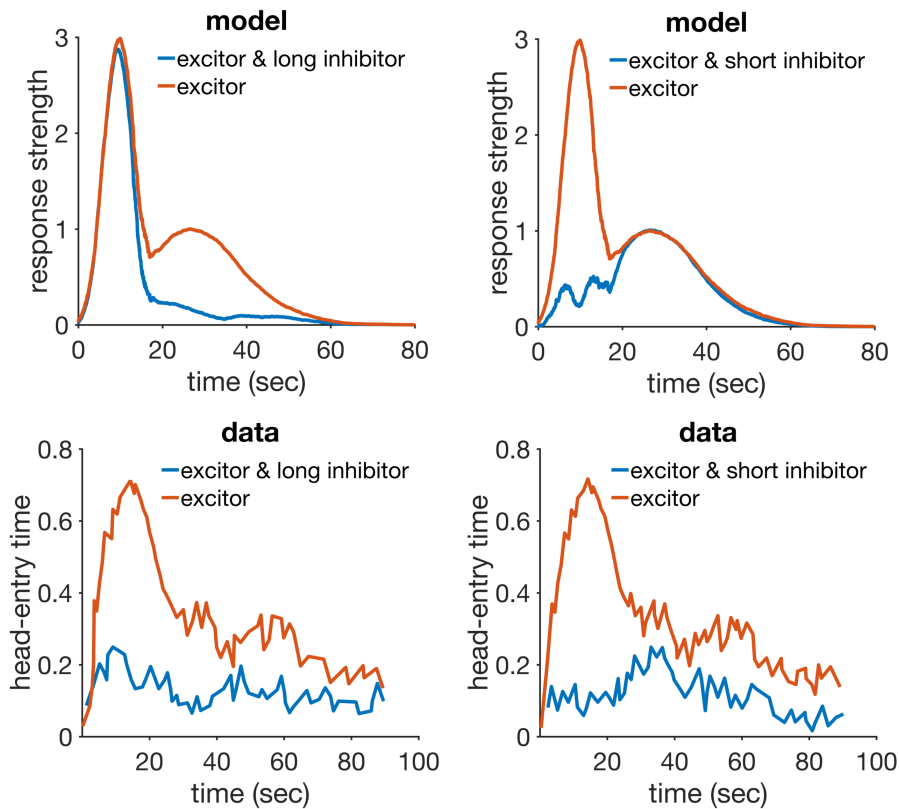

Figure 9: Conditioned inhibition. Left column: simulation (top) and data (bottom) from conditioned inhibition with a long inhibitor. Right column: simulation (top) and data (bottom) from conditioned inhibition with a short inhibitor. Data plots redrawn from figure 4 Williams et al. (2008). Model parameters:  $\alpha_t = 0.09$ ,  $\alpha_V = 0.06$ ,  $\mu = 1$ ,  $\sigma = 0.35$ ,  $m = 0.16$ ,  $H = 30$ .

1127 rely on the older linear operator rule, they do not have a mechanism to account  
 1128 for inhibition.

### 1129 3.6 Disinhibition of delay and compound peak procedure

1130 The two related phenomena described here are important in that they appear  
 1131 to challenge the summation effect. A common observation is that a compound  
 1132 of two previously conditioned CSs usually produces more responding than its  
 1133 individual components (Rescorla, 1997; Kehoe and Macrae, 2002, p. 204). How-

1134 ever, failure to obtain summation is also common (Rescorla and Coldwell, 1995;  
1135 Pearce et al., 2002), and the precise conditions when it is observed or not is still  
1136 a current topic of debate (see Harris and Livesey, 2010, for a discussion). Here  
1137 we consider two cases in which summation was not observed and that RWDDM  
1138 can offer a possible explanation.

1139     Aydin and Pearce (1995) used an autoshaping procedure to condition pigeons  
1140 to stimuli of 30 second duration. They observed little or no summation in  
1141 compound trials, but a response curve with a consistent shift to the left. This  
1142 earlier start of responding was observed even when one of the components was  
1143 a neutral preexposed CS. The shift of the response curve to the left was termed  
1144 disinhibition of delay.

1145     Meck and Church (1984) performed an analogue experiment using the peak  
1146 procedure. They trained rats to associate a light and a sound (both of 50 second  
1147 duration) individually to a reinforcement, and then used a peak procedure to  
1148 investigate what happens to timing in their compound. Like Aydin and Pearce  
1149 (1995) they also found no summation and a shift to the left in the compound.  
1150 Furthermore, rats also stopped responding earlier in the compound peak trials.

1151     Taken together, these results appear to show that in some cases summation  
1152 is not observed, and responding in the compound starts earlier than in the com-  
1153 ponent CSs. One possible explanation for this effect is that the subject fails  
1154 to recognize the two individual components of the compound, what is known  
1155 as generalisation decrement. If this is the case then it would be a performance  
1156 effect, and not a learning phenomenon. We cannot rule this out, but we show  
1157 that RWDDM's trial variability in time estimation provides a plausible mecha-  
1158 nism to explain this effect. The only other models in our analysis set that can  
1159 account for this are MoT and LeT.

### 1160 3.6.1 Simulations

1161 RWDDM is capable of accounting for the earlier responding in compounds by  
1162 noise in the timer. When a compound formed by CSA and CSB is presented,  
1163 its two timers  $\Psi_A(t)$  and  $\Psi_B(t)$  will run in parallel. However, their rates  $A_A$   
1164 and  $A_B$  will have slightly different values due to noise. This implies that on  
1165 every compound trial, one timer will be running slightly faster than the other.  
1166 In contrast, on trials where only one CS is present, the timer will run faster in  
1167 some trials and slower in others. Therefore, if on compound trials responding  
1168 is guided by the faster timer, the average response curve for compounds will be  
1169 shifted to the left when compared to the averaged response curve for a single  
1170 CS.

1171 Figure 10 shows simulations of disinhibition of delay and compound peak  
1172 procedure. The figures were constructed by averaging the responses produced  
1173 by equation (10) over 50 trials. The simulations reproduce in part the an-  
1174 ticipation in responding during the compound that is observed in the data in  
1175 both experiments (see top right and bottom left panels of figure 10). Meck and  
1176 Church (1984) reported a median peak time of  $40 \pm 4$  seconds for the response  
1177 curves in compound trials, and  $50 \pm 3.5$  seconds in the individual trials. We ran  
1178 15 simulations as the one shown at the bottom row of figure 10, and analysed  
1179 the peak times produced by each. We found an average peak time of  $42 \pm 3$  sec-  
1180 onds in the compound trials, and  $47 \pm 4$  in the individual trials. Both results are  
1181 within the error bounds in Meck and Church (1984). Aydin and Pearce (1995)  
1182 did not analyse peak times or shift in the response curves, so we cannot make  
1183 a quantitative comparison with our simulations.

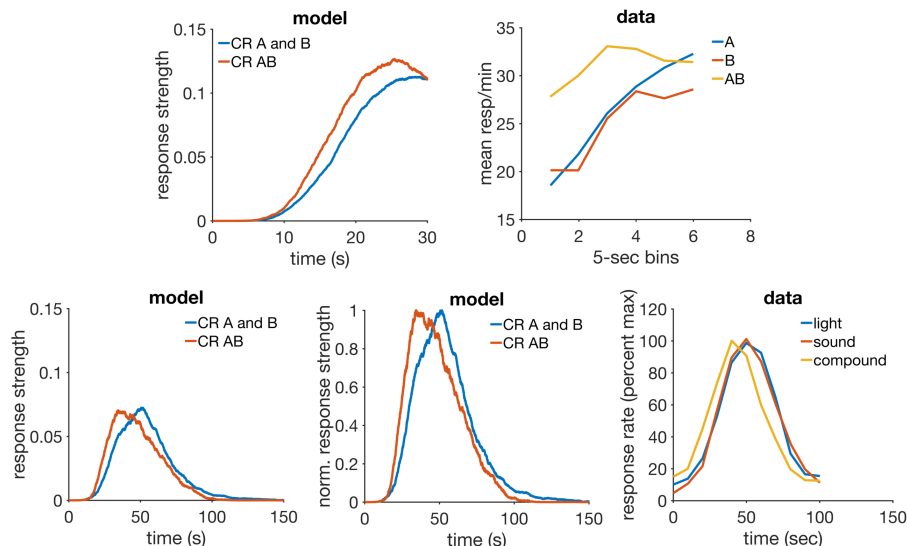

Figure 10: Disinhibition of delay and compound peak procedure. Top row: simulation (left) and data (right) of disinhibition of delay. Bottom row: simulation (left and middle) and data (right) of a compound peak procedure. The middle panel is a normalized (proportion of maximum response strength) version of the left panel. Data plot redrawn from figure 13 in Meck and Church (1984). Model parameters:  $m = 0.25$ ,  $\theta = 1$ ,  $\sigma = 0.18$ ,  $\alpha_t = 0.75$ ,  $\alpha_V = 0.1$ ,  $H = 5$ .

### 1184 3.6.2 Discussion

1185 RWDDM can offer a good account for the lack of summation and earlier re-  
 1186 sponding in compound trials in the two cases analysed here. It does so by  
 1187 having trial to trial variability in time estimation. However, the model shows a  
 1188 slightly higher maximum response frequency in compounds than in their com-  
 1189 ponents (top and bottom left of figure 10) something not observed in the data.  
 1190 This is not the product of summation, but of the slightly different asymptotes of  
 1191 learning in the faster and slower timers in the reinforced trial immediately pre-  
 1192 ceding the peak trial. Our assumption was that in compound trials the timer  
 1193 running faster, with a higher slope  $A$ , would be the one guiding responding.  
 1194 When timing adaptation has reached asymptotic levels, the updates on slope  
 1195  $A$  are due to noise in the value of the timer at reinforcement time,  $\Psi(t^*)$ . The

1196 two slopes,  $A_A$  and  $A_B$ , will have very similar values. In the reinforced trial  
1197 preceding the compound peak trial, whichever timer produces a value of  $\Psi(t^*)$   
1198 lower than the threshold will have its slope  $A$  adjusted up by the the slope  
1199 update rule, likely causing it to overtake the other slope. This slightly higher  
1200 slope will then be chosen in the peak trial that follows. But the corresponding  
1201  $V$  associated with that timer will have been updated on the previous reinforced  
1202 trial based on the lower  $\Psi(t^*) < \theta$  value. Because that is the denominator in  
1203  $HA/\Psi(t^*)$ , the  $V$  value of the chosen timer will be consistently slightly higher  
1204 on the compound peak trials.

1205 Other theories that might account for the data in this phenomenon are LeT  
1206 and MoT. Both theories postulate intertrial variability in timer rate, the same  
1207 mechanism used by RWDDM to explain this data. TD in any of its current  
1208 versions lacks a mechanism to explain these data.

### 1209 **3.7 ISI effect**

1210 The interval between CS onset and US onset is called *Inter Stimulus Interval*  
1211 (ISI). In general, measures of CR strength such as response frequency and ampli-  
1212 tude decrease with longer ISIs (Smith, 1968; Gormezano et al., 1983; Kehoe and  
1213 Macrae, 2002). Response timing is commonly analysed by using fixed interval  
1214 (FI) schedules of reinforcement, which rely on a fixed ISI. It is a well established  
1215 result that the peak in the response curve decreases with longer FIs (Catania  
1216 and Reynolds, 1968; Gibbon et al., 1997). However, the entire response curve  
1217 approximately scales with FI. This is obtained by plotting different FI response  
1218 curves as the proportion of maximum response strength versus the proportion  
1219 to FI, a normalization procedure. The resultant normalized curves roughly su-  
1220 perimpose (Rakitin et al., 1998; Matell and Meck, 2000,0; Allman et al., 2014).  
1221 This is sometimes called scalar timing, and it is one of the manifestations of the

1222 more general property of timescale invariance.

1223 CSC-TD does not have a mechanism to explain either timescale invariance  
1224 or the ISI effect. Its more recent development, MS-TD, can approximately  
1225 reproduce both timescale invariance and the ISI effect. LeT is also a timescale  
1226 invariant model, but does not appear to show the decrease in response peak as  
1227 a function of FI. MoT, at least in its earlier version (Kirkpatrick, 2002), can  
1228 reproduce both the ISI effect and timescale invariance.

### 1229 **3.7.1 Simulations**

1230 To demonstrate how RWDDM can reproduce the ISI effect we have simulated a  
1231 delay conditioning procedure using three fixed interval stimuli. Figure 11 shows  
1232 RWDDM simulations with FIs 5, 10 and 20 seconds. The top left panel shows  
1233 within-trial response rate (given by equation (10)) averaged over 50 trials for  
1234 each FI. The response curves show the same pattern as the data (bottom panel)  
1235 from the ISI effect: a sigmoidal shape with a maximum that decreases as a  
1236 function of FI duration. Note that because the curves are averages of 50 trials,  
1237 the noise is averaged out.

1238 The top middle panel of figure 11 shows the associative strength acquisition  
1239 curves for each FI. Their asymptotic levels are given by equation (20).  $V_\infty$  is ap-  
1240 proximately a linear function of  $A_\infty$ , the TDDM slope. The different asymptotic  
1241 levels of associative strength are responsible for the different response peaks in  
1242 the left panel of figure 11.

1243 RWDDM also reproduces the superposition observed when FI response curves  
1244 are normalized by maximum response rate and time to reinforcement (top right  
1245 panel of figure 11).

### 1246 **3.7.2 Discussion**

1247 Gibbon and Balsam (1981) attributed the ISI effect to the expectancy to re-

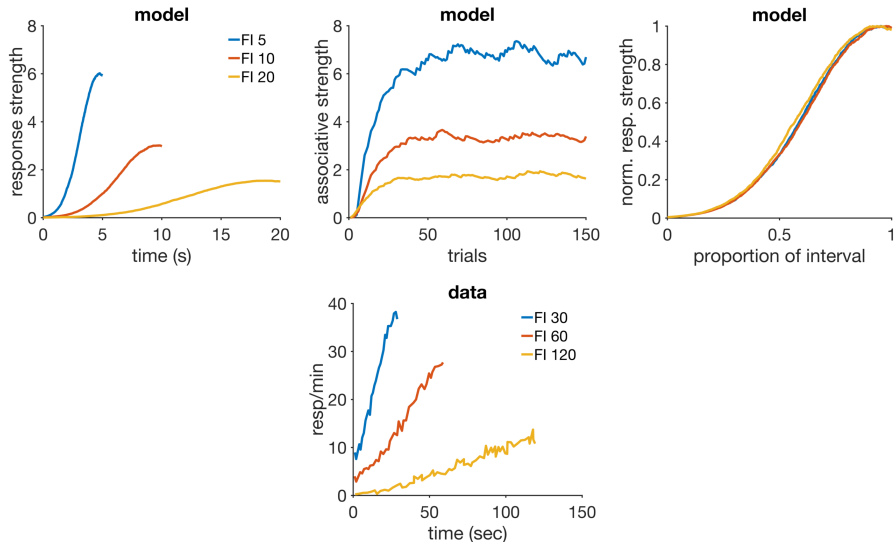

Figure 11: ISI effect. Top row: simulated average response rate during CSs (left), associative strength over trials (middle), and superimposition of response curves (right). Bottom row: average response rate data from an FI experiment, redrawn from bottom right panel of figure 4 in Kirkpatrick and Church (2000). Model parameters:  $m = 0.15$ ,  $\theta = 1$ ,  $\sigma = 0.3$ ,  $\alpha_t = 0.2$ ,  $\alpha_V = 0.1$ ,  $H = 5$ .

1248 enforcement. A specific reinforcer carries, according to their view, an amount  
 1249 of expectancy  $H$ . This expectancy is spread back in time over the stimulus  
 1250 that signals US occurrence. Hence, for a CS of fixed duration  $T$  and US with  
 1251 expectancy amount  $H$ , the total expectancy during the CS is  $h_T = H/T$ . Our  
 1252 RWDDM account follows the same principles. The time to reinforcement  $T$  is  
 1253 computed by the ratio between the accumulation height at time of reinforcement  
 1254  $\Psi(t^*)$  and the timer slope at the current trial  $A(n)$ . This leads to the asymptote  
 1255 of learning in equation 9 being set to  $HA_i(n)/\Psi_i(t^*)$ . Superimposition of the  
 1256 response curves follows directly in RWDDM from the nature of noise in the  
 1257 linear accumulator. This noise guarantees that the time estimate produced by  
 1258 the model is timescale invariant (Simen et al., 2013).

1259 The ISI effect can also be explained by the TD model with the Presence  
 1260 representation (Sutton and Barto, 1990) and with the more recently developed

1261 Microstimuli representation (Ludvig et al., 2012). The Presence representation  
1262 consists of a single element  $x$  which has the value 1 when the CS is present,  
1263 and 0 otherwise. Its associative strength  $V$  is updated by the TD rule at every  
1264 time step within a trial. In longer trials (longer FIs) the strength  $V$  will decay  
1265 more, since it is updated more times in the absence of the US. This will lead to  
1266 a lower asymptotic value for  $V$ . However, Presence TD cannot account for the  
1267 superimposition of intratrial response curves. The CSC-TD fares even worse,  
1268 unable to account for either ISI effect or superimposition (see Ludvig et al.,  
1269 2012, for a comparison between MS, CSC and Presence TD). The Microstimuli  
1270 representation treats the stimulus as if it were composed of many units activated  
1271 in sequence. Their activations follow a Gaussian shape which partially overlap.  
1272 Later units have lower peaks and are wider than earlier ones. Because the  
1273 number of Microstimuli are fixed, in longer FIs there is less temporal resolution  
1274 which causes the US prediction to be lower than in shorter FIs, so it can explain  
1275 the ISI effect. MS-TD's account of superimposition is only partial, although  
1276 clearly better than CSC and Presence-TD.

1277 LeT in its current version lacks a mechanism to produce decreasing response  
1278 peaks with increasing FIs. But it can account very well for superimposition,  
1279 since its time representation is timescale invariant. The earlier version of Mod-  
1280 ular Theory, called Packet Theory, has been shown to produce the ISI effect (see  
1281 top row of figure 3 in Kirkpatrick, 2002). This prediction comes from longer in-  
1282 terval durations decreasing the probability of response packet generation in the  
1283 model. MoT is also timescale invariant, so it generates superimposition quite  
1284 easily.

1285 To summarise, the ISI effect is explained either by time setting the asymptote  
1286 of learning (RWDDM) or by a time representation that gets more diffuse with  
1287 time, lowering the US prediction (MS-TD). Superimposition is explained either

1288 by the type of noise in the linear accumulator (RWDDM, LeT) or by stimulus  
1289 units which have an approximately timescale invariant activation profile (MS-  
1290 TD).

### 1291 **3.8 Mixed FI**

1292 Procedures where a stimulus signals reinforcement at more than one location in  
1293 time are called mixed FI or two-valued interval schedules. A mixed FI involves  
1294 only one CS which could be of short or long duration, and the subject has no way  
1295 of knowing which duration it is currently experiencing until the US is delivered.  
1296 Catania and Reynolds (1968) conditioned pigeons in a mixed FI and reported  
1297 a pattern of responding during the long CS that resembles a combination of  
1298 two distinct FIs (with two peaks) when the separation between the intervals  
1299 was in the ratio 8:1 but not at smaller proportions. Cheng et al. (1993) found  
1300 a similar result (experiment 2) when the intervals were in 5:1 proportion and  
1301 Leak and Gibbon (1995) showed that with intervals in the 8:1 proportion the  
1302 scalar property (measured by the CV) holds approximately even for three-valued  
1303 interval schedules. Whitaker et al. (2003) ran three experiments with Mixed FIs  
1304 in rats and found two peaks with the same CV when the proportion between  
1305 the durations was greater than 4:1, but not for smaller proportions. They also  
1306 found that the peak height at the short duration was higher than at the long  
1307 duration in most cases. Whitaker et al. (2008) used intervals in the very small  
1308 proportion 2:1 and still found two peaks that became more distinct when the  
1309 short interval was presented more often than the long.

1310 These results are interesting because they challenge in particular models of  
1311 timing. They have served to provide evidence in favour of SET, and against  
1312 BeT and the first version of LeT (Leak and Gibbon, 1995). Subsequently, they  
1313 provided motivation for the development of the current version of LeT Machado

1314 et al. (2009). LeT can now account for the multiple response peaks in Mixed FIs,  
1315 and their superimposition, but it cannot produce peaks with decreasing heights.  
1316 Modular Theory has the necessary mechanisms to account for all the features of  
1317 the data above. The TD models, MS and CSC, could both account for multiple  
1318 peaks, but their account of superimposition would vary, with MS being superior  
1319 than CSC. We show next that RWDDM can account for all features of the data  
1320 in Mixed FIs.

### 1321 **3.8.1 Simulations**

1322 In this simulation one CS was used which was followed by reinforcement either  
1323 after 15 or 75 seconds randomly chosen, a proportion of 5:1. Our assumption  
1324 was that in Mixed FI experiments subjects form two independent stimulus rep-  
1325 resentations, one for the short interval  $x_S$ , and another for the long interval  $x_L$ ,  
1326 each with its respective associative strength ( $V_S, V_L$ ) and timer ( $\Psi_S, \Psi_L$ ). At  
1327 CS onset, both timers begin timing, generating the two representations  $x_S$  and  
1328  $x_L$ , and at each point in time behaviour is guided by the representation with the  
1329 highest activation value. When a reinforcement occurs, the CS representation  
1330 with the highest activation value is the one to which credit is assigned.

1331 The left panel of figure 12 shows the simulated responses averaged over 50  
1332 trials of the long 75-second duration. Two peaks, centred roughly at 15 and 75  
1333 seconds, of decreasing heights and increasing widths are clearly seen, matching  
1334 roughly with the data (right panel).

### 1335 **3.8.2 Discussion**

1336 RWDDM's mechanism for dealing with mixed FIs is in essence the same as for  
1337 single FIs. The only difference is that instead of only one timer (and CS repre-  
1338 sentation) in Mixed FIs RWDDM uses as many timers (and CS representations)  
1339 as rewards. We have not however addressed explicitly how one CS can give rise

Figure 12: Mixed FI. Left: simulated response strength during long trials. Right: response strength data from a mixed FI experiment, redrawn from figure 3 in Leak and Gibbon (1995). Model parameters:  $\alpha_t = 0.2$ ,  $\alpha_V = 0.1$ ,  $\mu = 1$ ,  $\sigma = 0.425$ ,  $m = 0.2$ ,  $H = 30$ .

1340 to two distinct representations. One possible explanation is that the slope adap-  
 1341 tation rule (equation (6)) is only applied when the difference between the two  
 1342 intervals is below a certain amount. If the difference is above this amount, then  
 1343 the model would create a new representation. In fact, the data reviewed here  
 1344 suggests that animals may not be able to distinguish two intervals if they are  
 1345 in proportion below 2:1.

1346 To the best of our knowledge, the only other model from our analysis set  
 1347 that has tried to address the behaviour in mixed FIs is LeT. Machado et al.  
 1348 (2009) have succeeded in obtaining the two peaks with the same CV using LeT.  
 1349 Their account relies on a single accumulator in the form of a series of states  
 1350 activated at a fixed rate. This rate is fixed within a trial, but varies from  
 1351 trial to trial. After repeated training with a mixed FI, the states around the  
 1352 reinforced times receive on average more associative strength than the ones away  
 1353 from them. This activation pattern generates the response peaks seen in the  
 1354 data. However, as the authors note, ‘in mixed-FI schedules, the response rate  
 1355 [produced by LeT] at the first peak is equal to or lower than the response rate

1356 at the second peak, but never higher,' which is the opposite of what the data  
1357 shows. The authors suggest that a decaying arousal function might need to be  
1358 added to the model so as to allow response rate to decay with interval duration.

1359 Modular Theory is capable of accounting for the behaviour in Mixed FIs  
1360 since its pattern memory for time is based on SET, which has been shown to  
1361 account for these data (Leak and Gibbon, 1995). MoT's account is similar to  
1362 RWDDM's in that both rely on a separate accumulator (and memory) for each  
1363 time of reinforcement. CSC-TD would likely produce two peaks, since it relies  
1364 on a perfect discretization of time into as many units as time-steps. But the  
1365 curves would not superimpose when scaled as there is no mechanism to account  
1366 for timescale invariance. MS-TD would also account for the two peaks but  
1367 superimposition would likely not be fully obtained as its simulations of the ISI  
1368 effect have only partially reproduced it (see section 3.7 and Ludvig et al., 2012).

### 1369 **3.9 VI and FI**

1370 Schedules of reinforcement specify the conditions of reinforcement delivery. There  
1371 are a number of different types of schedules, some are based on the time elapsed  
1372 between reinforcements, some on the number of responses emitted between re-  
1373 inforcements, but there can be other possibilities. Of particular interest for a  
1374 timing and conditioning model are the two most commonly used time-based  
1375 schedules: variable and fixed interval. Variable Interval schedules of reinforce-  
1376 ment (VI) consist in the delivery of a US following a CS that varies in duration  
1377 from trial to trial. The CS durations are usually derived from an arithmetic or  
1378 geometric sequence. In contrast, Fixed Interval schedules of reinforcement (FI)  
1379 use a CS of fixed duration in all trials. Skinner and Ferster (2015) reported that  
1380 VIs tend to produce behaviour with a constant rate throughout the trial, whilst  
1381 FIs produce scalloped curves with a pause following each reinforcement and a

1382 rapid increase in rate until the next reinforcement.

1383     Catania and Reynolds (1968) performed a detailed analysis of behaviour un-  
1384 der VIs and found that response rate declined with the average reinforcement  
1385 rate. Within a trial response frequency increased with time, following approxi-  
1386 mately a negatively accelerated curve. When normalized by maximum response  
1387 rate and time to reinforcement, these curves showed a considerable degree of  
1388 superimposition.

1389     Matell et al. (2014) trained rats on a VI in which intervals were sampled from  
1390 an uniform distribution  $\mathcal{U}(15, 45)$ , and then tested using a peak procedure. They  
1391 compared the VI response peak curve to the peak curve from a control group  
1392 trained on an FI 30 (the mean of the VI distribution). Although the two curves  
1393 were not significantly different statistically, the VI response peak curve peaked  
1394 slightly earlier and was slightly higher than the control group.

1395     Jennings et al. (2013) compared timing performance between VI and FI in  
1396 three experiments, but found VI timing only in a VI where the average interval  
1397 was 30 seconds. The other experiments from the same paper produced results  
1398 more in agreement with the earlier work by Skinner and Ferster (2015) showing  
1399 a constant rate of responding during VI trials.

1400     Taken together, these studies appear to show that timing may sometimes  
1401 be present during VI schedules. In this case, animals appear to be learning the  
1402 average of the interval distribution. Here we demonstrate with simulations that  
1403 RWDDM can account for such findings. The only other model in our analysis  
1404 set that can account for this result is Modular Theory.

### 1405 **3.9.1 Simulations**

1406 In this simulation a random VI was produced by sampling intervals from a  
1407 discrete uniform distribution  $\mathcal{U}(15, 45)$ . Non-reinforced peak trials of duration  
1408 135 seconds were interspersed during the VI, with a probability of 0.25. Our

1409 assumption here is that subjects will keep adapting the timer rate  $A$  over trials.  
1410 In this case, equation (6) calculates the exponential moving harmonic average  
1411 of the CS durations. Since it is a moving average, the predicted peak time will  
1412 depend on the actual intervals used and their presentation order, but the non-  
1413 moving harmonic average of all intervals is 27.1 seconds. This is earlier than  
1414 the arithmetic average (30 seconds), which is in line with the trend observed in  
1415 the data by Matell et al. (2014).

1416 Figure 13 (top left panel) compares the response strength averaged over peak  
1417 trials in the VI and in a regular peak procedure with FI 30. The VI peak is  
1418 higher and slightly earlier (at roughly 29.68 sec) than the FI peak, matching  
1419 roughly with the data (bottom row). When normalized both by peak height  
1420 and time the curves show the superimposition (top right panel) also seen in the  
1421 data.

### 1422 3.9.2 Discussion

1423 The model predicts a harmonic mean value for the position of the response peak,  
1424 which is always less than the arithmetic mean, but because it is a weighted  
1425 moving average the actual value may vary. As we saw in the simulations, the VI  
1426 response curve peaked at a value (29.68 sec) very near the arithmetic mean of the  
1427 intervals (30 sec). This may explain the trend observed in the data by Matell  
1428 et al. (2014). However, because that trend was not statistically significant,  
1429 further experiments would be needed to establish if the response peak during  
1430 VIs is nearer to the harmonic or the arithmetic mean.

1431 Taken together, these results are more easily accommodated by theories that  
1432 can store an average of CS durations like RWDDM. Modular Theory is such  
1433 an example, since it also stores an average of intervals in its pattern memory.  
1434 Other models such as LeT and MS or CSC-TD would struggle with this result.  
1435 The CS representation in these models break down the CS into a sequence of

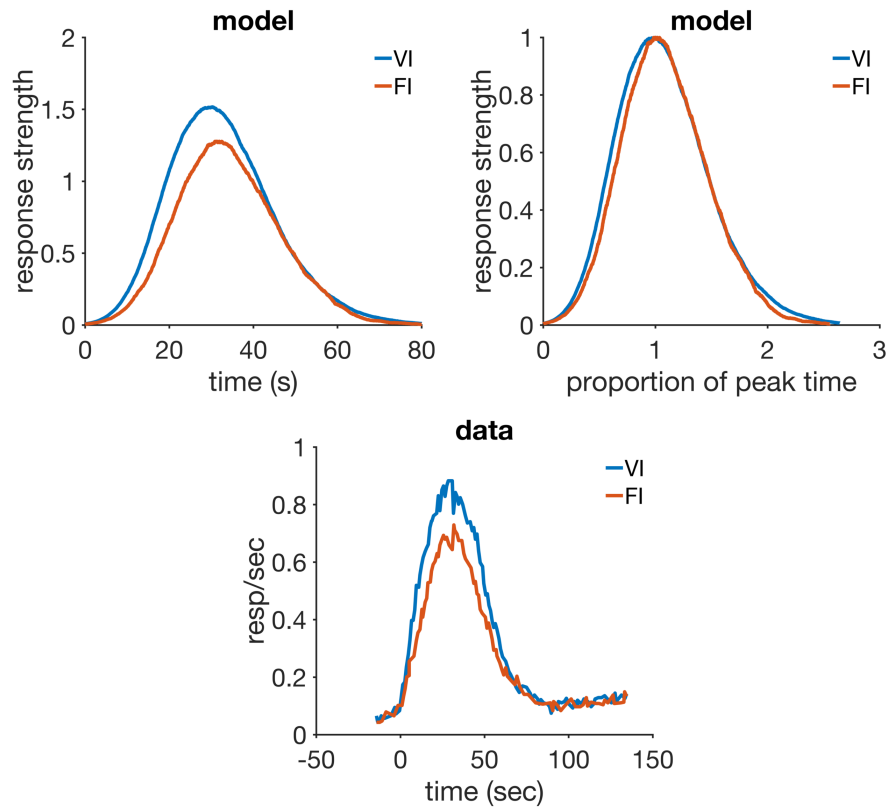

Figure 13: VI and FI. Top row: simulated average response strength during peak trials (left), and the same data plotted after both axes are normalized (right). Bottom row: average response strength data from an experiment in VI and FI, redrawn from figure 1 in Matell et al. (2014). Model parameters:  $\alpha_t = 0.1$ ,  $\alpha_V = 0.1$ ,  $\mu = 1$ ,  $\sigma = 0.3$ ,  $m = 0.2$ ,  $H = 40$ .

1436 units activated serially in time. With a uniform distribution of CS durations  
 1437 associative strength would likely be spread broadly over the weights that cover  
 1438 the interval, generating a broader pattern of responses that would not be centred  
 1439 on the mean.

### 1440 3.10 Temporal Averaging

1441 Although animals are able to time different durations simultaneously, as seen  
 1442 in mixed FIs, paradoxically under certain circumstances a type of temporal

1443 averaging can be observed. This is a relatively new and important phenomenon,  
1444 which challenges in particular theories of timing to propose a mechanism that  
1445 can explain such averaging.

1446 When rats are trained using two distinct stimulus modalities, a visual stimu-  
1447 lus (a light) and an auditory (a tone), each signalling reinforcement at a different  
1448 time, responding during compound presentations of both stimuli peaks roughly  
1449 in the middle of both durations (Swanton et al., 2009). This intermediate re-  
1450 sponse curve to the compound superimposes with the two other single stimulus  
1451 curves when normalized, suggesting that the animal is timing only one aver-  
1452 age duration. The type of average being computed appears to be modulated by  
1453 the reinforcement probabilities associated with each stimulus duration, with the  
1454 weighted geometric average fitting the data better than a weighted arithmetic  
1455 average or a non-weighted average (Swanton and Matell, 2011; Matell and Hen-  
1456 ning, 2013; Matell and Kurti, 2014). Significantly, temporal averaging in rats  
1457 is only consistently observed when the auditory stimulus signals the short in-  
1458 terval and the visual stimulus signals the long interval (Swanton and Matell,  
1459 2011; Delamater and Nicolas, 2015). Even when each stimulus is associated  
1460 with a different response option (light reinforced with a left nosepoke, tone with  
1461 a right) rats still tend to mix the temporal information during compound trials  
1462 (De Corte and Matell, 2016).

1463 We do not make a strong claim about RWDDM's ability to explain this data.  
1464 Rather, we show that it has the necessary elements from which an account can  
1465 begin to be formulated. MoT also has similar elements from which an account  
1466 can be built. CSC-TD, MS-TD and LeT do not appear to be equipped to deal  
1467 with this phenomenon.

### 1468 3.10.1 Simulations

1469 In RWDDM the accumulator is the mechanism that marks the passage of time.  
1470 The temporal proximity to an event is determined by how close the level of  
1471 accumulation is to a fixed threshold value. A CS that signals reward later than  
1472 another CS, will have a lower rate ( $A_{\text{low}}$ ) of accumulation than the shorter CS  
1473 ( $A_{\text{high}}$ ). Because in RWDDM associative strength is set by time to reward, the  
1474 two CSs will also have different associative strengths,  $V_{\text{low}}$  and  $V_{\text{high}}$  respectively.  
1475 We may assume that under temporal averaging circumstances the stimuli are  
1476 of such nature that they cause the subject to integrate their information. At  
1477 the start of the compound trials, the ambiguity presented by the compound  
1478 stimulus may cause the representations of the two component stimuli to be only  
1479 partially retrieved. If the subject fails to represent the two stimuli separately,  
1480 the result may be the formation of a single representation composed by only  
1481 a fraction of the timing rate  $A$  and associative strength  $V$  of each individual  
1482 stimulus. The fractions are then added into one single rate and one single  
1483 associative strength, and processed as if they were the components of a single  
1484 stimulus representation. For the simulation below, we assume that the fractions  
1485 added are exactly half of their individual values:  $A_{\text{compound}} = A_{\text{low}}/2 + A_{\text{high}}/2$ ,  
1486 and  $V_{\text{compound}} = V_{\text{low}}/2 + V_{\text{high}}/2$ .

1487 We used a long CS of duration 20 seconds and a short CS of duration 10.  
1488 We simulated a peak procedure with each CS and with the compound. A plot  
1489 of the response strength averaged over peak trials is shown in the top left panel  
1490 of figure 14. The three peaks scale when normalized (top right panel).

1491 The peak of the compound is roughly at 13.33 sec, which would be the  
1492 expected value for an averaged rate  $A = (1/10 + 1/20)/2$ , the harmonic average  
1493 of the intervals. The height of the compound peak is also at an intermediate  
1494 level between the two end peaks. The simulations match roughly with the data

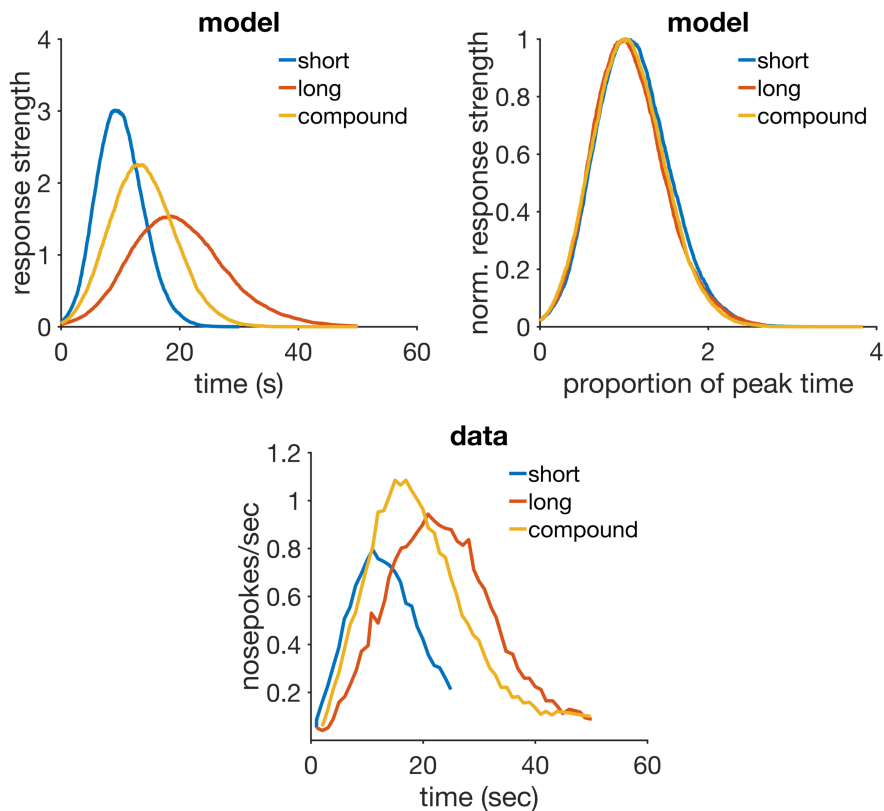

Figure 14: Temporal averaging. Top row: simulated response strength averaged over peak trials in temporal averaging (left), and the same data normalized by maximum response strength and peak time (right). Bottom row: peak trial response strength data from an experiment in temporal averaging, redrawn from figure 1 in Swanton et al. (2009). Model parameters:  $\alpha_t = 0.2$ ,  $\alpha_V = 0.1$ ,  $\mu = 1$ ,  $\sigma = 0.35$ ,  $m = 0.2$ ,  $H = 30$ .

1495 (bottom row of figure 14)

### 1496 3.10.2 Discussion

1497 The assumption we made here, that temporal averaging is the result of only  
 1498 one accumulator being active during the compounds and fed with half the rate  
 1499 for each of the stimuli, is plausible and can accommodate the main features of  
 1500 the data. However, given the evidence from mixed FIs it seems animals are

1501 capable of keeping multiple timers running in parallel, without averaging their  
1502 rates. Also, if averaging of rates always happened during compounds, then  
1503 the explanation provided by RWDDM for the left shift in the response curve  
1504 in the compound peak procedure would not hold. We suggest one possible  
1505 way of interpreting these three phenomena based on a failure of representation  
1506 selection caused by the ambiguity of the signal. In mixed FIs there is one  
1507 single CS that signals two rewards at very different times. There is not much  
1508 ambiguity in how to interpret the signal, so the subject keeps two timers running  
1509 in parallel. In the case of compounds formed by individual CSs that signal  
1510 reward at the same time, as in the compound peak procedure, there is also  
1511 not much ambiguity. There's very little difference between the time memories  
1512 evoked by the CSs, so choosing only one, the faster one, leaves no ambiguity as  
1513 to which CS is signalling reward. In the case of compounds formed by individual  
1514 CSs of different modalities that signal reward at different times, the ambiguity  
1515 might be such that cannot be resolved easily. The information from each CS  
1516 may then be only partially retrieved and added into one representation, resulting  
1517 in temporal averaging.

1518 As mentioned previously, this is not a strong account of the conditions that  
1519 generate temporal averaging. But whatever the final word on this may be,  
1520 RWDDM has components that allow it to generate averaging and timescale  
1521 invariance. However, RWDDM predicts this average to be the harmonic mean,  
1522 and not the geometric mean weighted by reinforcement probabilities that has  
1523 been frequently found (Swanton and Matell, 2011; Matell and Henning, 2013;  
1524 Matell and Kurti, 2014). Also, Matell and Henning (2013) reported evidence  
1525 of summation of response rates during the compound trials. In our simulations  
1526 here we assumed that equal fractions were taken of the rates of each CS, resulting  
1527 in a combined non-weighted harmonic average of rates, but different fractions

1528 (or weights) may be taken. In particular, the data indicates that the weights  
 1529 are set by the reinforcement probabilities of each individual stimulus. Since this  
 1530 information is stored in the associative strength  $V$ , we could assume the subject  
 1531 integrates the two timer rates as follows:

$$A_{\text{compound}} = \left( \frac{V_{\text{low}}}{V_{\text{low}} + V_{\text{high}}} \right) A_{\text{low}} + \left( \frac{V_{\text{high}}}{V_{\text{low}} + V_{\text{high}}} \right) A_{\text{high}}.$$

1532 Although this would produce a weighted average, it is still a weighted harmonic  
 1533 average of the intervals and not a weighted geometric average found in the data,  
 1534 so the account given by RWDDM would still be partial. As for the summation  
 1535 of response rates observed in the compound trials, this could be explained by  
 1536 RWDDM if instead of taking a fraction of the  $V$  values for each stimulus to  
 1537 form the  $V_{\text{compound}}$ , the subject simply summed, or partially summed, both  
 1538  $V$  values.

1539 Another model that is equipped to deal with averaging is Modular Theory.  
 1540 If we allow for one single accumulator fed by one half of each time memory,  
 1541 then MoT would predict a peak of responding at the arithmetic mean of the two  
 1542 intervals. A weighted average could also be obtained following the procedure we  
 1543 sketched above for RWDDM. However, this would yield a weighted arithmetic  
 1544 mean, and not the weighted geometric mean obtained in the data. As for  
 1545 timescale invariance, MoT relies on a noisy timer threshold whose mean is always  
 1546 a fixed proportion of the time memory, with a standard deviation proportional to  
 1547 this mean. Therefore, timescale invariance is guaranteed for all time memories,  
 1548 averaged or not.

1549 LeT would not be able to explain temporal averaging without modifications.  
 1550 It cannot change its average transition rate between states without compromis-  
 1551 ing timescale invariance. Without changing the transition rate it is difficult to  
 1552 see how else LeT could account for a different timing in the presence of the

1553 compound. CSC-TD and MS-TD also lack any mechanism that could be used  
1554 to account for temporal averaging.

### 1555 **3.11 Summary of Results and Analysis**

1556 Table 4 summarizes the results from the simulations. RWDDM was able to  
1557 reproduce the main features of the data in 8 out of the 10 experiments. In the  
1558 other 2 the model was able to partially account for the data.

1559 To allow for comparison we have offered qualitative predictions for the other  
1560 4 models in table 4. It is important to note that for most of the 10 phenomena  
1561 analysed here simulations using these models are not available in the literature.  
1562 Although we have tried our best to provide predictions based on our under-  
1563 standing of these models, we have not actually simulated them. Therefore it is  
1564 possible that in some cases a model may produce results that we did not foresee  
1565 if the right set of parameters is found or some of the assumptions are relaxed.  
1566 It is also possible that some simple modifications might allow the models to  
1567 explain the data. We endeavoured to point out some such modifications that  
1568 seem likely to work when discussing the simulation results above, but we do not  
1569 make predictions based on them because the purpose here is only to provide a  
1570 comparison of the current mechanisms of each model and therefore encourage  
1571 future work on model improvement. With that in mind, Modular Theory has  
1572 fared best after RWDDM, being able to account for 7 out of the 10 experiments.  
1573 MS-TD and CSC-TD shared the second place with 3 out of 10. LeT came in  
1574 last, able to account for 2 experiments. The last column of table 4 identifies the  
1575 main mechanisms responsible for successfully accounting for each phenomenon.

## 1576 4 General Discussion

1577 RWDDM was able to reproduce faster reacquisition due to its memory for time  
1578 being conserved during extinction. This memory is used to activate the stimulus  
1579 representation. Learning is slower in acquisition because RWDDM increases the  
1580 activation in the stimulus representation gradually over the trials. The stimulus  
1581 representation needs to be ‘built up’ first, and this process depends on learning  
1582 the timing of the US. Extinction eliminates associative strength but leaves the  
1583 time memory, hence the stimulus representation, intact. Reacquisition proceeds  
1584 faster because the stimulus representation does not need to be built up again.  
1585 Other models explain this by allowing the associative strength learning rate to  
1586 be faster in reacquisition.

1587 Time change in extinction was accounted for because of RWDDM’s ability to  
1588 time CS duration independently from US associations. Time is learned entirely  
1589 by time markers. The TD models and LeT do not make this separation. These  
1590 models do not have a mechanism to time stimuli without the US stamping in  
1591 the changes.

1592 Improved timing in latent inhibition was also accounted by RWDDM’s abil-  
1593 ity to learn timing independently of associations. Preexposure allows the model  
1594 to build its time representation, which is later expressed by behaviour during  
1595 the acquisition phase. The only other model that learns to time independently  
1596 of associations is MoT, but it does not have a mechanism to explain the latent  
1597 inhibition effect. The latent inhibition effect alone, i.e. the initial decrement in  
1598 the acquisition curve of a preexposed stimulus, was made possible in RWDDM  
1599 by using the P-H rule to change the learning rate for associative strength. The  
1600 use of the P-H rule instead of the RW would certainly have other theoretical  
1601 implications for the general theory we are introducing in this paper, but we  
1602 have used it only in this case. We will make further comments in the conclu-

1603 sion. Blocking with different durations was easily accounted in one condition,  
1604 the short blocked and long blocking CS. The blocking effect in this condition  
1605 followed from the summation term in the RW rule. For the other condition, long  
1606 blocked and short blocking CS, a straight application of the model did not yield  
1607 the results expected. But the experimental results leave open the possibility  
1608 that this might be a case of second-order conditioning, where the summation  
1609 term in RW does not play a role. In this case, RWDDM is well placed to ex-  
1610 plain the results, since it can time the whole sequence of stimuli. The only other  
1611 models capable of explaining these results were the TD models.

1612 The time specificity in conditioned inhibition was very well accounted for  
1613 by the combination of the summation term in the RW rule, which allowed for  
1614 inhibition to develop, and the independent timing mechanism in RWDDM that  
1615 allowed it to time US omission. However, the alternative account provided by  
1616 the different time representation in the TD models was also successful. The  
1617 other theories failed here for the same reason as in blocking, they lack a rule  
1618 like RW that can deal with compound stimuli effects.

1619 The response curves centred at the mean of intervals in the VI procedure  
1620 was well accounted by the ability of RWDDM to learn the average of intervals.  
1621 This ability is only present in Modular Theory, making it the only other model  
1622 able to account for the results here.

1623 In the case of temporal averaging, RWDDM was able to account for the  
1624 general features of the phenomenon, namely a response curve that peaks at the  
1625 average of the intervals signalled by the compound stimulus. However, RWDDM  
1626 predicts the peak to be at the harmonic mean, whilst some experimental results  
1627 suggest it happens at the geometric mean. RWDDM's account of temporal  
1628 averaging was hypothesised as the result of ambiguity in the signal. In trying  
1629 to resolve whether the compound should be treated as a single stimulus or as

1630 two separate stimuli, the subject settles on using one accumulator that is fed  
1631 partial timing information from both stimuli. Other hypothesis might turn out  
1632 to be more adequate, but this is one possibility that fits well with the RWDDM  
1633 framework. The only other model that would produce averaging under the same  
1634 hypothesis is MoT.

1635     The classic ISI effect followed from two mechanisms in RWDDM. The lower  
1636 response curves during longer stimuli were explained by time setting the asymp-  
1637 tote of associative learning by hyperbolic delay discounting. The larger spread  
1638 of response curves during longer stimuli and the superimposition of normalised  
1639 curves follows from RWDDM’s timescale invariant time representation. The  
1640 noise in RWDDM’s accumulator decreases with the interval being timed in such  
1641 a way that it results in timescale invariance of the response curves. Modular  
1642 Theory can also reproduce all features in the data. This is because it relies on  
1643 a timescale invariant response rule function that generates less responding in  
1644 longer intervals. LeT can account for superimposition, but it does not have a  
1645 mechanism to account for the lower curves in longer stimuli. MS-TD can ac-  
1646 count for both elements because of the form of its microstimuli representation.

1647     The double peaks observed in the response curves during mixed FIs is ex-  
1648 plained by RWDDM using simultaneous timing. It generates two different repre-  
1649 sentations, one for each reward. Thus, it can account for mixed FIs by the same  
1650 principles used to account for the ISI effect and simple FI schedules. Modular  
1651 Theory takes the same approach of simultaneous timing and is also successful.  
1652 The TD models and LeT can provide a partial account due to their distributed  
1653 time representation. But timescale invariance of the peaks is not observed in  
1654 CSC-TD and only approximately in MS-TD. LeT produces the timescale invari-  
1655 ance but not the decrease in peak height with time.

1656     The left shift of response curves seen in compound peak procedure and dis-

1657 inhibition of delay was well accounted for by RWDDM. It did so because of  
1658 intertrial variability in noise estimation. By choosing in every compound trial  
1659 the time memory that predicts reward sooner, RWDDM produces the left shift  
1660 in response. The only other models that can appeal to the same principle to  
1661 explain it are LeT and MoT.

1662 The superiority of RWDDM and MoT in explaining the majority of the phe-  
1663 nomena analysed highlights the importance of some of their shared mechanisms.  
1664 Both models have separate rules for updating time and associative strength.  
1665 This makes them capable of timing any stimuli, independent of changes in asso-  
1666 ciative strength. Both models represent psychological time as linearly related to  
1667 physical time through the theoretical construct of the accumulator. Their mem-  
1668 ory for time stores a moving average of the experienced intervals. They both  
1669 allow for intertrial variability in time estimation. Among their differences, only  
1670 one proved crucial in discriminating the two models in the experiments anal-  
1671 ysed here: the lack of a mechanism in MoT to account for stimulus compounds.  
1672 RWDDM uses the RW rule, which was developed to deal with phenomena such  
1673 as blocking and inhibition, whilst MoT uses the linear operator, a historically  
1674 earlier association rule that cannot handle compounds. This was the single dif-  
1675 ference that caused the difference between MoT and RWDDM in number of  
1676 phenomena explained.

1677 MS-TD came in third place in number of phenomena successfully explained,  
1678 but the gap between it and MoT was comparatively high, with MoT being  
1679 almost twice more successful than MS-TD. CSC-TD came just half a point be-  
1680 low MS-TD. This is certainly a result of their similarities. The only difference  
1681 between these two TD models is in their time representation. However, this  
1682 different representation allowed MS-TD to explain only one more phenomenon  
1683 than CSC-TD, the ISI effect. Therefore, in the set of experiments analysed

1684 here MS-TD did not show a significant improvement on CSC-TD. This does  
1685 not mean that MS-TD is not a significant improvement on CSC-TD overall.  
1686 Its superior account of timing is significant. But the set of experiments chosen  
1687 here are particularly challenging even for a dedicated timing theory, so they  
1688 raise the bar even higher. The strength of the TD models was in account-  
1689 ing for compound phenomena of blocking and inhibition, due to their RW rule  
1690 for association. Their weaknesses was that they rely on changes in associative  
1691 strength to express changes in timing. This prevented them from explaining  
1692 time change in extinction and improved timing in latent inhibition. They both  
1693 lack a memory to store the average of intervals, so they could not explain be-  
1694 haviour in VI schedules. Finally, their lack of trial to trial variability in time  
1695 estimation prevented them from accounting for the left-shift in the compound  
1696 peak procedure.

1697 With respect to the number of successes only, LeT came in last. The results  
1698 allowed us to identify at least four limitations in LeT's current formulation. The  
1699 first is that it ties its time representation to changes in associative strength.  
1700 This prevented it to explain time change in extinction and improved timing in  
1701 latent inhibition. The second limitation is that it relies on the linear operator  
1702 rule for associative strength, which prevented it from accounting for blocking  
1703 and time specificity in conditioned inhibition. Thirdly, its distributed memory  
1704 for time does not store the average of the intervals seen. This prevented it  
1705 from accounting for the behaviour in VI. Lastly, it doesn't have a mechanism  
1706 to explain the decrease in peak height of the response curves with longer ISIs.  
1707 However, as a timing model, LeT's strength is in explaining timescale invariance.  
1708 If it can be made to overcome at least the weakness of its associative learning  
1709 rule, for example by also adopting the RW to update associative strength, LeT  
1710 could be on a par with the TD models.

1711 RWDDM faced a few problems in explaining the set of phenomena analysed  
1712 here. In latent inhibition the model was able to learn the timing for the pre-  
1713 exposed CS, but our choice of CS representation translates this into a response  
1714 curve that does not fully match the data. A better solution might involve a  
1715 two-state CS representation, one state for the early stages of training and the  
1716 other for the latter stages. RWDDM could not account for the lack of blocking  
1717 with a long blocked CS and a short blocking CS. One possible solution that  
1718 does not require changing the model is to treat the blocking CS as a secondary  
1719 reinforcer. A more difficult problem related to asynchronous co-terminating  
1720 CSs such as the ones used in the blocking experiment analysed here, is that  
1721 in its current formulation RWDDM cannot produce a stable solution. Because  
1722 RWDDM assigns a different learning asymptote for each CS in the compound,  
1723 it generates an inconsistent system of equations for  $V$ . How to fix this remains  
1724 an open problem. Finally, in temporal averaging RWDDM predicts a peak in  
1725 CR at the harmonic mean of the intervals, not at the geometric mean as has  
1726 been observed in the data. More experiments might help to determine if the  
1727 harmonic average should indeed be ruled out as an explanation.

1728 One relevant phenomenon that we did not explore here is the peak procedure.  
1729 In particular, Balci et al. (2009) have produced evidence that in the long peak  
1730 trials animals don't stop responding immediately after the expected reward  
1731 time, but instead take a number of peak trials to learn to stop. The Gaussian  
1732 function  $x_i(\Psi_i)$  used as the CS representation in RWDDM ensures that CR  
1733 levels will begin to decrease after  $\Psi_i(t)$  crosses threshold  $\theta$  without any learning.  
1734 To address the findings in Balci et al. (2009) the RWDDM CS representation  
1735 could be changed to a sigmoid, saturating after the timer  $\Psi(t)$  crosses a first  
1736 threshold. A second threshold could then be introduced to mark the time to stop  
1737 responding. When the timer crosses this stop threshold the saturation process

1738 in the CS representation would stop and a decay process would begin. This  
1739 however would still be an incomplete account, as a mechanism would be needed  
1740 to explain the learning of the second threshold. But if such a CS representation  
1741 was used, the model would also fit a larger body of data coming from studies that  
1742 analyse responding during individual trials of the peak procedure. Schneider  
1743 (1969) and subsequently Gibbon and Church (1990) and others (Cheng and  
1744 Westwood, 1993; Matell et al., 2006) have argued that the pattern of responding  
1745 is better characterized not by a Gaussian but instead by an approximate square-  
1746 wave function, with a low-high-low response frequency pattern. It can be shown  
1747 that by introducing a stop threshold to the timer  $\Psi_i(t)$ , the TDDM timer (used  
1748 in RWDDM) can fit the data on times of start and stop responding (Luzardo  
1749 et al., 2017). Alternatively, the accumulator  $\Psi_i(t)$  itself could be used as the  
1750 CS representation, replacing  $x_i$  in equations (9) and (10). In this case, an  
1751 upper absorbing boundary would need to be set on the accumulator to prevent  
1752 response strength increasing considerably in the first few trials following a CS  
1753 duration increase for example. Also, such a choice of CS representation would  
1754 cause within-trial responding to become linear, rather than the more commonly  
1755 observed sigmoidal pattern. If a sigmoidal response curve is to be preserved, a  
1756 different choice of response function would be required.

1757 Another phenomenon that we did not address but deserves mention is the  
1758 timescale invariance of the acquisition process (Gallistel and Gibbon, 2000). It  
1759 refers to the general finding that the number of trials required until an acqui-  
1760 sition criterion is met depends on the ratio of intertrial (or context) and trial  
1761 durations, the I/T ratio (Gibbon, 1977; Lattal, 1999; Holland, 2000). Gibbon  
1762 and Balsam (1981) provided an account for this that postulates a decision pro-  
1763 cess based on the reward expectancy signalled by the stimulus versus the one  
1764 signalled by the context. A ratio between the two expectancies is calculated, and

1765 once the ratio exceeds a certain value, acquisition starts. If the same postulate  
1766 of a decision ratio of reward expectancies is made, RWDDM may account for  
1767 the I/T ratio in a similar manner. If we assume that animals time the interval  
1768 between USs (the context or I duration) with rate  $A_I(n)$  and also the CS dura-  
1769 tion as usual with rate  $A_T(n)$ , then we can form the ratio  $r(n) = A_T(n)/A_I(n)$ .  
1770 As the number of trials  $n$  increases, the  $A$  rates converge to their asymptotic  
1771 values, and the ratio  $r$  will converge to  $A_T/A_I = (1/T)/(1/I) = I/T$ . This  
1772 is essentially the same account given by Gibbon and Balsam (1981), with the  
1773 timer rates  $A_T$  and  $A_I$  substituting Gibbon and Balsam's expectancies  $H/T$   
1774 and  $H/C$ .

1775 At least three testable RWDDM predictions came out from the simulations  
1776 reported here. The first concerns blocking with different durations. A long  
1777 blocked CS will not be blocked by a short co-terminating blocking CS, and two  
1778 peaks in responding will be observed during test trials with the blocked CS: one  
1779 at the time the short blocking CS would normally start, and another at the end of  
1780 the blocked CS. The second prediction is that conditioned inhibition is the exact  
1781 opposite of excitation. This means that the behaviour produced by inhibition is  
1782 timed in the same manner as in excitation. Finally, in temporal averaging the  
1783 response peak in the compound stimulus should be at the harmonic average,  
1784 or weighted harmonic average. One prediction that did not come out of the  
1785 simulations but that is worth mentioning concerns time estimation during very  
1786 early trials. Our assumption of a low initial value for the accumulator rate  
1787  $A$  implies that in the initial trials durations will be overestimated. A new  
1788 experiment testing this prediction could help validate, or invalidate, the model.

1789 RWDDM is, to the best of our knowledge, the first time the RW associative  
1790 learning rule is coupled with a accumulator-based timing theory. An important  
1791 implication of this effort for associative learning is that it allows for a richer

1792 analysis of the effects of timing in compound stimuli experiments. Here we have  
1793 analysed blocking and conditioned inhibition, but there is evidence suggesting  
1794 time may have important effects in other cue-competition phenomena such as  
1795 overshadowing (Kehoe and James, 1983; Jennings et al., 2007). Timing effects  
1796 in compounds has until now received somewhat little attention, with many pub-  
1797 lished experimental studies reporting only aggregate response measures. This is  
1798 perhaps to be expected, since most associative learning models that can handle  
1799 compounds do not have any, or a rich enough, time representation. RWDDM  
1800 is an attempt at filling this theoretical gap.

1801 Another limitation of associative learning models is that they tend to simply  
1802 postulate the timing features of the stimulus representation, without a detailed  
1803 account of how these can mechanistically arise and evolve. This is the case with  
1804 the CS representations of CSC-TD, MS-TD and others like C-SOP (Brandon  
1805 et al., 2003). RWDDM’s adaptive timer and time-adaptive CS representation  
1806 provide a fuller account of the timing mechanism and its dynamics. Another  
1807 recent model that provides this level of detail is the Timing from Inverse Laplace  
1808 Transform (TILT, Shankar and Howard, 2012; Howard et al., 2015). It can  
1809 dynamically develop a timescale invariant representation of stimulus history  
1810 using a two-layer neural network. It can also reproduce the important I/T ratio  
1811 conditioning phenomenon, but so far it has only been implemented with the  
1812 linear operator rule for associative learning, which precludes it from accounting  
1813 for cue competition phenomena.

1814 The RWDDM architecture suggests that timing is largely independent of  
1815 the process of association formation and maintenance. Associations however,  
1816 according to RWDDM, depend on timing both to set the asymptote of asso-  
1817 ciative strength and to build the CS representation so that it can enter into  
1818 association with the US. Thus, RWDDM implies that interactions between tim-

1819 ing and associative learning are mainly one-directional. This appears to match  
1820 roughly with experimental findings. In a review Kirkpatrick (2013) found that  
1821 prediction error influenced measures of time estimation only through changes in  
1822 reward magnitude and devaluation, whilst effects in the other direction included  
1823 the appropriate timing of CRs from start of conditioning, trial and intertrial  
1824 durations affecting strength and probability of CR occurrence, and cues with  
1825 different temporal information affecting cue competition.

## 1826 **5 Conclusion**

1827 In this paper we introduced a new real-time model for classical conditioning and  
1828 timing. The model combines elements from two theories, the Rescorla-Wagner  
1829 conditioning model and the TDDM interval timing theory.

1830 We have simulated the model on 10 conditioning phenomena selected from  
1831 the literature, which collectively represent a particular challenge for any single  
1832 model to explain. The model was successful in accounting for 9, and can be  
1833 made to account for the rest if simple modifications are made. The mechanisms  
1834 used by other models of similar scope were evaluated to see if they could also  
1835 account for the data. The model that got closer to this level of success in this set  
1836 of phenomena was Modular Theory. This was due to MoT and RWDDM having  
1837 a significant overlap in terms of mechanisms. Both models use an accumulator  
1838 to mark the passage of time. Both models require only a single associative  
1839 unit per stimulus that adapts to the temporal information conveyed by the  
1840 stimulus. Their main difference is that MoT still uses the linear operator rule  
1841 which precludes it from explaining blocking and other compound phenomena,  
1842 whilst RWDDM uses the RW which can account for those phenomena. The  
1843 same limitation is faced by TILT, a recent model that we did not analyse but  
1844 that shows promising results and has desirable timing properties.

1845 RWDDM may be improved in several ways. It is quite likely that the asymp-  
1846 tote of learning may not be described by the simple inverse relationship to re-  
1847 inforcement time that we assumed. In some of the experiments modelled here,  
1848 response peak seemed to decrease slower with ISI than our inverse relation-  
1849 ship predicted. Functions other than Gaussians might be used to represent the  
1850 CS, which could better fit the data in the case of latent inhibition for example.  
1851 These and other theoretical issues may be better elucidated by new experiments  
1852 involving compound stimuli and a manipulation of their durations, such as the  
1853 experiments with blocking, compound peak procedure and temporal averaging  
1854 analysed here.

1855 We have also adopted the P-H rule in one experiment, but have not explored  
1856 its application in the others. Making the P-H rule an integral part of RWDDM  
1857 would add one more parameter but it would also allow RWDDM to account for  
1858 other preexposure and attentional effects that the rule is designed to account.  
1859 This is not a difficult modification, and we have already shown it to be feasible.

1860 RWDDM may be regarded, like TD, as a real-time extension of RW. Unlike  
1861 TD and LeT, it does not require a number of associative units that grows linearly  
1862 with time. It adds to RW the powerful timing mechanism of TDDM. But also,  
1863 by making a link with a version of DDM, it shows that it may be possible to  
1864 arrive at a unified account of timing, conditioning and decision making.

Simulation	Group	Phase 1	Phase 2	Phase 3
Acquisition, extinction and reacquisition	FI 5	80 CS+	100 CS-	80 CS+
Extinction with diff. duration	FI 20-40	150 CS(20)+	150 CS(40)-	—
	FI 20-10	150 CS(20)+	150 CS(10)-	—
ISI effect	FI 5	—	—	—
	FI 10	150 CS+	—	—
VI vs FI	FI 20	—	—	—
	VI 30	mixed 1500 CS+, 375 peak	—	—
Mixed FI	FI 30	mixed 500 CS+, 125 peak	—	—
	MFI 15-75	mixed 200 A(15)+, 200 A(75)+	—	—
Latent inhibition	Preexposed A	80 A-	120 A+	—
	Control C	—	120 C+	—
Blocking diff. durations	Blocked A	120 A(10 or 15)+	60 A(10)B1(15)+ or 60 A(15)B1(10)+	—
	Blocked B1, B2	—	60 C(10)B2(15)+ or 60 C(15)B2(10)+	—
Disinhibition of delay	Control C	—	mixed 300 A+, 300 B+, 100 AB+	—
	FI 30	100 A+, 100 B-	mixed 300 A+, 300 B+, 100 AB peak	—
Compound peak	FI 50	100 A+, 100 B+	mixed 300 each E3(10)+, E3(30)+	—
	1 group	mixed 300 each E1(10)+, E2(30)+, E1(10)I1(10)-, E2(30)I2(30)-	100 each peak E3I1, E3I2, E3	—
Conditioned inhibition	FI 10-20	700 L(20)+, 700 S(10)+, 154 L peak, 154 S peak	—	—
	Temporal averaging	—	—	—

Table 3: Simulation designs.

Table 4: Summary of main simulation results and comparison with other models.  
Notes: (1) if learning rate is allowed to vary.

phenomenon	RWDDM	CSC-TD	MS-TD	LeT	MoT	explaining mechanism
faster reac- quisition	yes	yes <sup>1</sup>	yes <sup>1</sup>	yes <sup>1</sup>	yes <sup>1</sup>	time-adaptive stimu- lus representation or changes in learning rate
time change in extinction	yes	no	no	no	yes	separate rules for time adaptation and asso- ciative strength
latent inhibi- tion and tim- ing	part.	no	no	no	no	PH rule and separate rules for time adap- tation and associative strength
blocking with diff. dura- tions	part.	yes	yes	no	no	RW rule and ability to time any stimulus or distributed time rep- resentation
time spec. of conditioned inhibition	yes	yes	yes	no	no	RW rule and con- centrated memory for time or distributed time representation
compound peak proce- dure	yes	no	no	yes	yes	intertrial variability in time estimation
ISI effect and superimposi- tion	yes	no	part.	part.	yes	asymptote of assoc. strength set by time and accumulator noise or time representation that gets diffuse with longer time
mixed FI	yes	part.	part.	part.	yes	ability to generate multiple time rep- resentations or a single distributed time representation
VI and FI	yes	no	no	no	yes	memory that stores average of intervals
temporal av- eraging	yes	no	no	no	yes	memory that stores average of intervals and the accumulator
