Key words: Depression, DNA methylation, early life adversity, fetal programming, NR3C1, BDNF

Abbreviations: NR3C1: gene encoding the glucocorticoid receptor, BDNF: gene encoding the brain-derived neurotrophic factor protein, HPA: hypothalamic-pituitary adrenal, GR: glucocorticoid receptor, BPA: bisphenol A

Abstract

Prenatal maternal psychological distress increases risk for adverse infant outcomes. However, the biological mechanisms underlying this association remain unclear. Prenatal stress can impact fetal epigenetic regulation that could underlie changes in infant stress responses. It has been suggested that maternal glucocorticoids may mediate this epigenetic effect. We examined this hypothesis by determining the impact of maternal cortisol and depressive symptoms during pregnancy on infant *NR3C1* and *BDNF* DNA methylation. Fifty-seven pregnant women were recruited during the second or third trimester. Participants self-reported depressive symptoms

and salivary cortisol samples were collected diurnally and in response to a stressor. Buccal swabs for DNA extraction and DNA methylation analysis were collected from each infant at two months of age, and mothers were assessed for postnatal depressive symptoms. Prenatal depressive symptoms significantly predicted increased *NR3C1* 1F DNA methylation in male infants ($\beta = 2.147$, $P = 0.044$). Prenatal depressive symptoms also significantly predicted decreased *BDNF* IV DNA methylation in both male and female infants ($\beta = -3.244$, $P = 0.013$). No measure of maternal cortisol during pregnancy predicted infant *NR3C1* 1F or *BDNF* promoter IV DNA methylation. Our findings highlight the susceptibility of males to changes in *NR3C1* DNA methylation and present novel evidence for altered *BDNF* IV DNA methylation in response to maternal depression during pregnancy. The lack of association between maternal cortisol and infant DNA methylation suggests that effects of maternal depression may not be mediated directly by glucocorticoids. Future studies should consider other potential mediating mechanisms in the link between maternal mood and infant outcomes.

Introduction

Psychological wellbeing during pregnancy can have long-term implications for offspring mental and physical health¹⁻⁴. In particular, psychological distress, which encompasses feelings of anxiety, depression, and perceived stress, increases risk for a number of adverse offspring outcomes⁵⁻⁹, including premature birth¹⁰, behavioral difficulties in childhood⁵, and psychiatric disorder in adulthood^{7, 11}. However, the mechanism(s) that account for associations between prenatal distress and health outcomes are unclear.

The prevailing mechanistic theory in perinatal psychiatry to account for mood-associated effects in offspring is via alterations of the maternal hypothalamic-pituitary-adrenal (HPA) axis during pregnancy^{1, 4}. Indeed, symptoms of prenatal depression have been associated with increased diurnal salivary cortisol¹², and exaggerated cortisol responses to an acute stressor¹³. Moreover, enduring changes in fetal DNA methylation have been proposed to be involved in entraining the fetal HPA axis in response to maternal distress^{4, 14}. Epigenetic variation, including DNA methylation changes in brain regions involved in the regulation of HPA activity, have been observed in animal studies following prenatal exposure to stress¹⁵, maternal separation¹⁶, and in response to variation in mother-infant interactions^{17, 18}, with implications for the HPA response to stress. In particular, increased DNA methylation in the promoter region of the gene encoding the glucocorticoid receptor (*Nr3c1*) in the hippocampus has been observed, and may account for heightened glucocorticoid levels in offspring¹⁹.

The glucocorticoid receptor (GR) plays a critical role in HPA responses to stress through negative feedback on glucocorticoid release. Increased DNA methylation within the *Nr3c1* gene results in decreased expression of hippocampal GR, a dampening of negative feedback, and prolonged increase in circulating glucocorticoid levels¹⁹. In rodents, offspring that experience low compared to high levels of postnatal maternal care have increased hippocampal *Nr3c1* DNA methylation and reduced *Nr3c1* expression. Cross-fostering studies have confirmed that these epigenetic changes emerge in response to maternal care during the postnatal period, and pharmacological studies have indicated that shifts in hippocampal *Nr3c1* DNA methylation can modulate the behavioral and physiological response to stress²⁰. Although the epigenetic effects of maternal care are not restricted to *Nr3c1*^{21,22}, this target gene may be particularly relevant to understanding the coordinated biological response observed following exposure to early life adversity.

Translational studies examining the association between exposure to early life stress and *NR3C1* exon 1F DNA methylation in humans have generated findings consistent with animal studies using both post-mortem brain samples and peripheral tissues²³⁻²⁵. Increased *NR3C1* exon 1F methylation and decreased GR mRNA have been detected in the hippocampus of suicide victims with a history of childhood abuse²³. Increased *NR3C1* 1F DNA methylation has also been detected in DNA extracted from whole blood samples from young adolescents exposed to physical abuse in childhood²⁴, and adolescents exposed to stressful life events or trauma²⁵. This susceptibility to alterations in *NR3C1* DNA methylation is also observed in response to prenatal distress. Increased *NR3C1* 1F DNA methylation has been found in cord blood of infants exposed to maternal depressed mood during pregnancy and this altered

epigenetic state was predictive of stress responses in these infants at three months of age²⁶. Increased *NR3C1* 1F DNA methylation has also been observed in whole blood of young adolescents whose mothers had experienced intimate partner violence during pregnancy²⁷.

Although gene targets associated with the HPA response to stress have predominated epigenetic studies of the impact of early life adversity, the complex behavioral phenotypes that emerge suggest the importance of genes involved in brain development and neuroplasticity, such as brain derived neurotrophic factor (*BDNF*). *BDNF* plays an essential role in neurodevelopment and has been linked to psychiatric risk²⁸. In animal studies, maternal stress during pregnancy induces increased *bdnf* promoter IV DNA methylation and decreased *BDNF* expression in the amygdala and hippocampus in offspring that persist into adulthood²⁹. Persistent epigenetic changes in *bdnf*, within the cortex of offspring, are also observed in response to abusive caregiving during the postnatal period²⁹⁻³². We have recently found that increased *BDNF* promoter IV DNA methylation in peripheral blood may be a significant biomarker of prenatal adversity that is relevant for both animals and humans³³. However, the impact of prenatal psychological distress on infant *BDNF* IV DNA methylation has yet to be explored.

The role of epigenetic variation in mediating the effects of early life adversity is an evolving area of study. In the current study, we determine whether exposure to maternal prenatal depression predicts increased infant *NR3C1* 1F DNA methylation in buccal cells. It has been suggested that biological markers of distress in pregnancy may be more reliable predictors of adverse infant outcomes than self-reported

psychological measures³⁴. Here, we assess whether maternal prenatal cortisol may be a more accurate predictor of infant *NR3C1* 1F DNA methylation than a self-reported measure of depression. A further aim of this study is to investigate, for the first time in a human cohort, whether depressed mood during pregnancy may have implications for infant *BDNF* IV DNA methylation.

Results

Sample characteristics

The demographic characteristics of this sample are presented in **Table 1**. All mothers in this study were primiparous; average age was 32.04 (SD 4.35). This primarily Caucasian (89.5%) group of women was highly educated (49.1% had a postgraduate degree). No participants reported smoking cigarettes during pregnancy; however, 21.1% reported consuming 1-5 units of alcohol per week. No participants were using antidepressant or steroid-based medications whilst pregnant. A total of 89.5% of participants reported that their pregnancy had been planned, and 29.8% reported a previous history of mental health disorders. There were no significant differences between the demographic characteristics of the control group (n=37) and depression-symptom group (n=20). The groups only differed on prenatal and postnatal EPDS score; with a significantly higher EPDS score in the depression-symptom group compared to the control group [**Table 1**; ($t_{(55)}=2.297$, $P<0.001$) and ($t_{(55)}=-2.469$, $P<0.05$), respectively]. There were no group differences in prenatal salivary cortisol responses to the infant distress stimulus (**Table 1**; $t_{(55)}=1.097$, $P=0.277$) or log AUC of diurnal cortisol (**Table 1**; $t_{(55)}=-1.471$, $P=0.147$). Days-of-gestation was not correlated with either log AUC of diurnal cortisol ($r=0.224$, $P=0.107$), or mean cortisol change in response to the stressor ($r=0.026$, $P=0.849$).

Of the 57 infants included in this study, 25 (43.9%) were male and 32 (56.1%) were female. Mean birth weight was 3.33 kg (SD=0.64), and 21 mothers (36.8%) reported delivery complications. Mothers who experienced prenatal depressive symptoms reported significantly more delivery complications than controls ($\chi^2_{(1)}=4.0657$, $P<0.05$). Examples of reported delivery complications include the development of preeclampsia resulting in an induced birth, signs of fetal distress leading to an assisted delivery, and a retained placenta. There were no significant differences between women who did and did not report delivery complications on measures of prenatal cortisol or postnatal depression.

Maternal prenatal depressive symptoms and infant NR3C1 1F and BDNF IV DNA methylation

None of the maternal demographic variables, including prenatal depression, significantly correlated with DNA methylation at any CpG site. In the regression analyses, mean DNA methylation of all 10 CpG sites within *NR3C1* 1F was first used as the outcome variable. There was a significant effect of the prenatal depression*gender interaction to predict mean *NR3C1* 1F DNA methylation ($\beta=-0.350$, $P=0.017$); see **Table 2**. To investigate this interaction further, the data was split by gender, and the regression model repeated. For male infants only, prenatal depression significantly predicted mean *NR3C1* DNA methylation ($\beta=2.147$, $P=0.044$), such that those infants exposed to prenatal depressive symptoms had increased *NR3C1* 1F DNA methylation across the 10 CpG sites. These results are shown graphically in **Figure 1**. The regression model was reconstructed using percentage methylation at each individual CpG site as the outcome variable. At CpG

sites 2 and 9, a prenatal group*gender interaction also significantly predicted DNA methylation [(β =-0.285, P <0.05) and (β =-0.330, P <0.05) respectively]. The data was split by gender and the model was repeated for the two sites. At CpG2, the effect of prenatal depression approached significance for males (β =0.395, P =0.067), but not females (β =-0.239, P =0.231). At CpG9 the effect of prenatal depression in predicting DNA methylation in the females approached significance (β =-0.360, P =0.066), but was not significant for the males (β =0.288, P =0.191).

A similar model was constructed using mean *BDNF* IV DNA methylation across the 5 assessed CpG sites as the outcome variable. Here, prenatal depression significantly predicted mean *BDNF* promoter IV DNA methylation (β =-2.590, P =0.013); however, there was no significant effect of gender (β =-1.796, P =0.079) or a prenatal depression*gender interaction (β =0.620, P =0.538); see **Table 2**. This model was reconstructed using % DNA methylation at each CpG site as the outcome variable. Prenatal depression significantly predicted % DNA methylation at CpG3 only (β =-3.244, P =0.002), such that those infants exposed to antenatal depression had decreased methylation at CpG3. These results are presented graphically in **Figure 2**.

Maternal prenatal cortisol and infant NR3C1 1F and BDNF IV DNA methylation

Two measures of maternal cortisol were available: mean change in response to a stressor and the log AUC for diurnal cortisol. Regression models were constructed as previously described, but each measure of maternal cortisol was used in the place of prenatal depression, and days-of-gestation was entered as a covariate. Neither measure of cortisol significantly predicted mean infant *NR3C1* 1F DNA methylation (mean change: β =0.219, P =0.828; log AUC cortisol: β =0.296, P =0.769), and neither

did a cortisol*gender interaction (mean change: $\beta=1.227$, $P=0.226$; log AUC cortisol: $\beta=0.436$, $P=0.665$).

Similarly, neither cortisol measure significantly predicted mean *BDNF* promoter IV DNA methylation (mean change: $\beta=-0.639$, $P=0.532$; log AUC cortisol: $\beta=-0.069$, $P=0.945$), and neither did a cortisol*gender interaction (mean change: $\beta=1.345$, $P=0.185$; log AUC cortisol $\beta=-1.633$, $P=0.109$).

Discussion

Maternal depression is predictive of adverse psychiatric and physical outcomes in offspring⁷⁻¹⁰ and it has been speculated that elevated maternal glucocorticoids may induce these effects^{1, 4, 14}. Moreover, there is increasing evidence for the role of epigenetic variation in the lasting consequences of early life adversity^{19, 22, 23, 26}. In the current study, we find a sex-specific effect of maternal prenatal depressive symptoms on DNA methylation within the *NR3C1* 1F gene, with elevated *NR3C1* 1F DNA methylation in male, but not female, infants exposed to maternal prenatal depression. Analysis of the *BDNF* promoter IV region revealed that both male and female infants exposed to prenatal depression had decreased DNA *BDNF* IV methylation. However, for both *NR3C1* and *BDNF*, maternal cortisol did not predict infant DNA methylation changes.

Variation in DNA methylation within the *NR3C1* 1F region has been reported in both animal^{15, 18, 19} and human²³⁻²⁷ studies, suggesting that this epigenetic marker is developmentally sensitive to the quality of the environment. These studies have consistently reported increased DNA methylation of *NR3C1* 1F and our findings

complement previous reports examining the epigenetic impact of maternal depressed mood during pregnancy²⁶. While previous studies have indicated increased *NR3C1* 1F DNA methylation in cord blood samples at birth, here we illustrate that increased *NR3C1* 1F DNA methylation associated with prenatal depression persists into the postnatal period in infant buccal cells, independent of postnatal depressed maternal mood, and is particularly evident in male infants. Previous studies in humans have not examined the question of sex differences in environmentally-induced *NR3C1* 1F DNA methylation²³⁻²⁷, and although animal studies have primarily examined these effects exclusively in males, there is emerging evidence suggestive of a particular epigenetic vulnerability in males in response to prenatal³³ and postnatal³⁵ experiences. These findings complement a body of literature, which suggests that males may more be at risk of adverse outcomes compared to females as a result of exposure to maternal distress during pregnancy³⁶⁻⁴⁰. Therefore, sex differences in *NR3C1* DNA methylation could, in part, explain stronger associations between prenatal mood disturbance and more adverse outcomes in males. Importantly, the differentially methylated region of *NR3C1* contains the binding site for the transcription factor NGFI-A (**Figure 1**; CpG sites 8 and 9) and is directly involved in the DNA methylation-mediated regulation of *NR3C1* expression²³. Although it is unlikely that DNA methylation differences occurring at a single gene could account for the increased risk for complex outcomes in later life, our findings suggest that epigenetic disruption at this locus may be functionally relevant to the impact of maternal depression on offspring development.

Previous studies in animals have suggested that increased *bdnf* IV DNA methylation emerges as a consequence of elevated prenatal stress²⁹ and Bisphenol A (BPA)

exposure¹⁶. In contrast, we report that in human infants, exposure to prenatal depression results in decreased infant *BDNF* IV methylation at CpG3. This CpG site is adjacent to the binding site of the transcription factor CREB (Figure 1), which controls *BDNF* transcription via DNA methylation-dependent mechanism⁴¹. Although species differences in the regulation of this gene may account for our findings, recent analyses indicate increased DNA methylation in human cord blood samples within the CREB binding site associated with elevated *in utero* BPA exposure, which is consistent with the direction of reported effects in rodents⁴². An alternative explanation for these findings may involve the biphasic epigenetic changes that have been observed to occur across development⁴³.

The decreased *BDNF* methylation we observe in infants exposed to prenatal depression could reflect a molecular basis for the rapid maturation that may be induced by adverse prenatal events. *BDNF* is a critical growth factor involved in neurogenesis, and so the timing of regulation and expression of *BDNF* serves as a marker of developmental time. Stress during pregnancy induces an increased risk of preterm delivery⁴⁴ and may lead to an advanced pace of neurodevelopment⁴⁵⁻⁴⁷. Consistent with this, children who have experienced maternal deprivation in early life have been shown to have mature connectivity between the amygdala and medial prefrontal cortex that is comparable to an adolescent phenotype⁴⁸, suggestive of more rapid brain development. Further exploration of this hypothesis from both a molecular and neurodevelopmental level may provide insights into the mechanisms that underlie adversity-induced changes in brain maturation.

A prevailing theory in the field of perinatal psychiatry is that prenatal depression impacts on fetal development via increased circulating maternal glucocorticoids^{1, 4, 34, 49}. However, it is important to note that investigations of maternal depression and cortisol in pregnancy have reported mixed results^{12, 13, 50-55}. Nonetheless, it has been suggested that biological markers of prenatal stress may be better indicators of offspring outcomes than self-report measures³⁴. Thus, we expected that maternal cortisol would significantly predict infant *NR3C1* IF and *BDNF* IV methylation. However, we found no evidence to support this hypothesis. Moreover, in our cohort, maternal depressive symptoms were not correlated with elevated diurnal or stress-induced glucocorticoid levels. The lack of group differences in glucocorticoid levels and the relatively low variability of cortisol levels between individuals may account for this finding. However, this initial investigation suggests that perhaps maternal cortisol does not account for the association between prenatal depression and changes in infant DNA methylation, and future studies should consider other potential mediating pathways, such as changes in maternal immune activation.

The prospective longitudinal design and the inclusion of both biological and psychological measures of maternal prenatal distress as predictors of infant methylation are significant strengths of this study. This is also the first study to replicate the previous finding of increased *NR3C1* DNA methylation in response to maternal depression²⁶ using buccal tissue, which has significant implications for assessing epigenetic effects in larger cohorts. However, a number of limitations should be considered. It is unclear how epigenetic variation in the periphery (i.e., blood, buccal cells) relates to epigenetic variation within the brain. Studies of consistency of methylation profiles across peripheral tissues have produced

conflicting results, but are generally limited by small sample sizes and a candidate gene approach^{56, 57}. Recently, Davis and colleagues (2012) have analyzed DNA methylation patterns in human blood and post-mortem brain tissue and found that between-tissue variation in DNA methylation greatly exceeded between-individual differences⁵⁸. The current study is also limited by the modest sample size and reliance on self-reported mood rather than on a clinical diagnosis. Previous studies of prenatal depression have suggested that clinical diagnoses correlate more reliably with biological markers of depression, such as awakening cortisol, than do self-report measures¹². Therefore, using clinical diagnoses to define the depressive symptom group may have revealed a potential relationship between depressed mood, maternal glucocorticoids, and epigenetic outcomes.

Furthermore, it is likely that a number of postnatal environmental influences, such as parental care, abuse or sleep disturbance, may have implications for infant DNA methylation. Unfortunately, these measures were not available in the current dataset. However, future studies should comprehensively document postnatal environmental variables, to both control for postnatal effects but also in order to fully understand potential mechanisms by which early environmental factors impact on infant DNA methylation. Further, assessments of infant and childhood behavior are required fully disseminate the role of epigenetic mechanisms in mediating associations between prenatal depressed mood and offspring outcomes.

In conclusion, this study found that antenatal symptoms of depression have implications for changes in infant *NR3C1* and *BDNF* DNA methylation. Conversely, measures of maternal cortisol were not related to infant DNA methylation. Thus,

these initial findings suggest that maternal glucocorticoids may not mediate the association between antenatal depression and infant epigenetic regulation. Future studies should consider other potential mediating pathways that likewise contribute to coordinated physiological and behavioral responses to the environment, such as the maternal immune system and sympathetic nervous system activity.

Methods and Materials

Participants

The participants (N=57) were derived from a larger cohort of pregnant women participating in a longitudinal study based in Oxford, UK. This study was designed to investigate the effects of antenatal mood disturbance on maternal and infant stress responses. This study was reviewed and approved by the South Central Oxford B Research Ethics Committee (REF: 12/SC/0473), and all participants provided informed consent.

Procedures

Participants were assessed during either the second or third trimester of pregnancy. Self-reported symptoms of depression were obtained using a paper-based questionnaire (Edinburgh Postnatal Depression Scale) and maternal salivary cortisol samples were collected in two contexts: in response to a stressor (infant distress video) and diurnally. Participants were visited at home approximately 2 months after birth. Self-report measures of postnatal depression from the mother and two buccal swabs from each infant were collected.

Measures

Maternal mood

Edinburgh Postnatal Depression Scale (EPDS). The EPDS is the most widely used self-report questionnaire to identify symptoms of depression during the peripartum period. The scale consists of 10 items that describe common symptom of depression; however, it does not include somatic symptoms of depression, such as change in appetite, which are commonly experienced in pregnancy. Each item is scored from 0 to 3, with a maximum score of 30. A cut-off score of 10 is frequently used to identify a group "at risk" of depression⁵⁹⁻⁶³. A recent study has shown that using a cut-off of 10 in the second and third trimester of pregnancy provides a good balance between sensitivity (70-79%) and specificity (96-97%)⁶³.

Maternal prenatal cortisol

Response to infant distress stimulus. During either the second or third trimester, participants were invited to an afternoon test session between the hours of 2 P.M. and 7 P.M., and asked to watch a short film depicting distressed young infants, all under the age of 6 months. The film was 6 minutes in length and included 8 short clips of crying infants. The clips were taken from online sources with permission from the owners. This video has been used in a previous study¹³ and found to induce significant salivary cortisol responses in a group of late first/early second trimester pregnant women with symptoms of depression. Saliva samples were collected at five time points during the test session using saliva collection aids and plastic cryovials (Salimetrics, UK). Two samples were taken before the film, approximately 20 minutes apart. The third sample was taken immediately post-film, and the fourth and fifth samples were taken 10 and 20 minutes post-film, respectively. Saliva samples were stored at -20°C until analysis. Cortisol mean-change in response to the stressor

was used as a main predictor in these analyses. This variable was calculated by subtracting the mean baseline cortisol measure from the 20-minute post-stimulus measure. Notably, there were no differences between the control and depressive-symptom group in baseline cortisol.

Diurnal cortisol. Participants were asked to collect six saliva samples at home over two working days (three per day) within two weeks of the test session. On each day samples were collected immediately after awakening, 30 minutes and 12 hours post-awakening. Participants were provided with a stamped addressed envelope to return the samples, which were stored at -20°C until analysis. The area under the curve of the diurnal cortisol data was skewed to the left, and was therefore log transformed (log AUC), and log AUC was used as a main predictor in this study.

Cortisol assay

Salivary cortisol analysis was carried out by a direct double-antibody radioimmunoassay (RIA) with utilization of ¹²⁵I-cortisol as the ligand, in accordance with the manufacturer's instructions (Salimetrics Inc., UK).

Infant NR3C1 1F and BDNF IV methylation

Buccal swab collection

Infants were on average 53.6 days old (SD=9.99, range=26-98 days) when the buccal swabs were collected. The buccal swabs were obtained using Catch-All soft sample swabs (Epicentre Ltd), which were firmly brushed across the inside of the infant's cheek, and stored in sterilized 2 ml tubes. Samples were stored at -20°C at the Department of Psychiatry, Oxford, before being shipped to the Department of

Psychology at Columbia University on dry ice (World Courier Ltd), where they were stored at -80°C until analysis.

DNA isolation

Buccal cell DNA isolation was performed using a QIAamp DNA mini kit (Qiagen Ltd, USA) in accordance with the manufacturer's protocol, and the buccal DNA was quantified using a Nanodrop 1000 spectrophotometer (Thermo Scientific Ltd, USA). The extracted DNA was in a range of 6-31 ng/µl.

Bisulfite pyrosequencing

DNA methylation at specific CpG sites was analyzed using the quantitative bisulfite-pyrosequencing method. The extracted buccal DNA (125ng) was bisulfite converted using an EpiTect Bisulphite kit (Qiagen Ltd, USA) according to the manufacturer's instructions, and stored at -20°C until further analysis. A PyroMark PCR kit (Qiagen Ltd, USA) and PCR primers specific for *NR3C1* and *BDNF* were used to obtain biotinylated PCR products and a specific sequencing primer was then used to determine CpG methylation in the regions of interest. Two separate assays were used to assess 10 CpG sites within *NR3C1* exon 1F, and one assay was used to assess 5 CpG sites within *BDNF* promoter IV (**Figure 3**). Details of the primers used are available in **Table 3**. The PCR and pyrosequencing primers were designed using PyroMark Assay Design Software 2.0. The regions of interest within *NR3C1* and *BDNF* were chosen based on previous research that has identified these areas as susceptible to epigenetic regulation following early exposure to adverse environmental influences^{23, 26, 28, 33}. Pyrosequencing was performed using a PyroMark Q24 pyrosequencer (Qiagen Ltd, USA) with specific pyrosequencing primers. Before

sample analysis, each pyrosequencing assay was validated using standard curves by analysing 0, 20, 40, 60, 80, and 100% methylated human genomic DNA standards (**Supplementary Figure 1**). Those standards were generated by mixing commercially available unmethylated and hypermethylated DNA standards (EpiTect PCR Control DNA Set, Qiagen) in the following ratios: 0:5; 1:4; 2:3; 3:2; 4:1; and 5:0 (10 ng of total bisulfite-converted DNA). Following assay validation, 10 ng of each bisulfite-converted sample DNA was run in a 25- μ L PCR reaction; 3 μ L of a PCR product was run on a gel to confirm the band size and 20 μ L was run on a pyrosequencer. The average DNA methylation levels of specific CpG sites were quantified using PyroMark Q24 2.0.4 software (Qiagen Ltd, USA).

Statistical analysis

For analysis, participants were split into two groups based on maternal EPDS score: those scoring 9 or below were the control group, whereas those scoring 10 or above were the "depressive symptom" group. Independent samples t-tests and Pearson chi-squared tests were used to determine group differences in demographic characteristics and maternal prenatal mood. Pearson's correlations were used to assess the relationship between variables and DNA methylation at independent CpG sites, and multiple regression models were constructed to examine predictive models. Data were entered into each model in a stepwise fashion: batch number for DNA methylation analysis was entered at step 1 as a covariate, as was postnatal depression. The postnatal depression group (control vs. depressive-symptoms) was defined using the same criteria as the prenatal depression group. Main predictor variables were entered at step 2. Either prenatal depression or maternal cortisol was used as a main predictor, as was infant gender. Where prenatal cortisol was a main predictor, days of gestation

at the point of cortisol collection was entered as a covariate. Interaction variables between infant gender and prenatal depression or cortisol were created using standardized or centered variables, and entered into step 3 of the model.

Financial Disclosures

Dr. Susannah E. Murphy has received consultancy payments from p1Vital and has participated in paid speaking engagements for Lilly UK. Dr. Braithwaite, Dr. Kundakovic, Dr. Ramchandani and Professor Champagne report no financial disclosures or conflicts of interest.

Acknowledgements

We would like to thank all of the mothers and their infants who volunteered their time to take part in this study. We would also like to acknowledge Li Chen at the Department of Psychiatry, University of Oxford, for assaying the maternal saliva samples for cortisol. This research was funded by a UK Medical Research Council Studentship awarded to Dr. Elizabeth Braithwaite (grant number MR/J500501/1). Dr. Susannah E. Murphy is supported by the National Institute for Health Research (NIHR) Oxford Biomedical Research Centre Programme. Dr. Frances Champagne is supported by the National Institute of Mental Health (grant number 1R01MH092580-01A1).

Table 1 Maternal demographic and salivary cortisol variables

Demographic Variables	Control Group (N=37)	Depressive symptom group (N=20)
Age (mean, SD)	32.14 (4.33)	31.85 (4.50)
Education (n, %)		
A-level	1 (2.7)	0
Undergraduate degree	16 (43.2)	9 (45)
NVQ	2 (5.4)	1 (5)
Postgraduate degree	18 (48.6)	10 (50)
Ethnicity (n, %)		
Caucasian	35 (84.6)	16 (80)
Black	0	1 (5)
Asian	1 (2.7)	3 (15)
Mixed Race	1 (2.7)	0
Alcohol units/week (n, %)		
None	28 (75.7)	17 (85)
1-5	9 (24.3)	3 (15)
Cigarettes/week (n, %)		
None	33 (89.2)	18 (90)
Did not respond	4 (10.8)	2 (10)
Weeks of gestation (mean, SD)	28.4 (12.4)	29.9 (6.67)
Planned Pregnancy (n, %)	33 (89.2)	18 (90)
Previous history of mental health problems (n, %)	10 (27)	7 (35)
Prenatal EPDS (depression)	4.68 (2.82)	12.2 (2.12)
Postnatal EPDS (depression)	6.22 (3.30)	8.95 (4.96)
Salivary Cortisol Variables (nmol/l)		
Mean change in response to stressor (mean, range)	-0.54 (-8.63 - 5.66)	-1.13 (-4.13 - 3.07)
Log AUC diurnal cortisol (mean, range)	15.81 (6.70 - 25.66)	17.79 (6.61 - 31.32)

EPDS: Edinburgh Postnatal Depression Scale,
 NVQ: National Vocational Qualification

Table 2 Regression model using prenatal depression and infant gender to predict infant *NR3C1* IF and *BDNF* IV methylation

Model		Unstandardized coefficients		Standardised coefficients	t	Sig.
		B	Std. error	Beta		
Outcome: Mean <i>NR3C1</i> IF methylation						
1	Batch number	0.238	0.234	0.167	1.208	0.233
	Postnatal depression	0.338	0.40	0.117	0.845	0.402
2	Batch number	0.263	0.241	0.155	1.089	0.282
	Postnatal depression	0.352	0.432	0.122	0.815	0.419
	Prenatal depression	0.066	0.184	0.053	0.36	0.720
	Infant gender	0.069	0.185	0.054	0.372	0.711
3	Batch number	0.157	0.233	0.093	0.676	0.502
	Postnatal depression	0.427	0.412	0.148	1.037	0.305
	Prenatal depression	-0.024	0.179	-0.019	-0.132	0.896
	Infant gender	0.114	0.177	0.089	0.642	0.524
	Prenatal depression*gender	-0.435	0.176	-0.350	-2.475	0.017
Outcome: Mean <i>BDNF</i> IV methylation						
1	Batch number	0.114	0.217	0.072	0.524	0.602
	Postnatal depression	-0.405	0.382	-0.145	-1.061	0.294
2	Batch number	0.253	0.205	0.16	1.232	0.224
	Postnatal depression	-0.402	0.376	-0.144	-1.069	0.290
	Prenatal depression	-0.419	0.164	-0.336	-2.565	0.013
	Infant gender	-0.322	0.158	-0.271	-2.034	0.047
3	Batch number	0.274	0.209	0.173	1.31	0.196
	Postnatal depression	-0.421	0.38	-0.151	-1.107	0.274
	Prenatal depression	-0.427	0.165	-0.343	-2.59	0.013
	Infant gender	-0.296	0.165	-0.249	-1.796	0.079
	Prenatal depression*gender	0.100	0.162	0.084	0.620	0.538

Table 3 PCR and pyrosequencing primers

<i>NR3C1 1F Assay 2 – CpG sites 5-1 - chr5:143,404,013-143,404,147*</i>	
PCR primer forward- Biotinylated	/5Biosg/ GTTGTTATTAGTAGGGGTATTGG
PCR primer reverse	AACCACCCAATTTCTCCAATTTCTTTTC
Pyrosequencing primer (reverse)	CAACTCCCCCACTCCAAACCC
<i>NR3C1 1F Assay 1 – CpG sites 6-10 - chr5:143,404,011-143,404,097*</i>	
PCR primer forward	AGTTTTAGAGTGGGTTTGGAG
PCR primer reverse- Biotinylated	/5Biosg/ AAAACCACCCAATTTCTCCAATTTCTT
Pyrosequencing primer (forward)	GAGTGGGTTTGGAGT
<i>BDNF IV – CpG sites 1-5 - chr11:27,701,519-27,701,826 *</i>	
PCR primer forward	GGGTTGGAAGTGAAAATATTTGTAAA
PCR primer reverse- Biotinylated	/5Biosg/CCCCATCAACCAAAAACCTCCATTTAATCTC
Pyrosequencing primer (forward)	GGTAGAGGAGGTATTATATGATAG

*Genomic coordinates show genomic regions amplified by PCR and are based on the UCSC Genome Browser Human Dec. 2013 (GRCh38/hg38) Assembly.

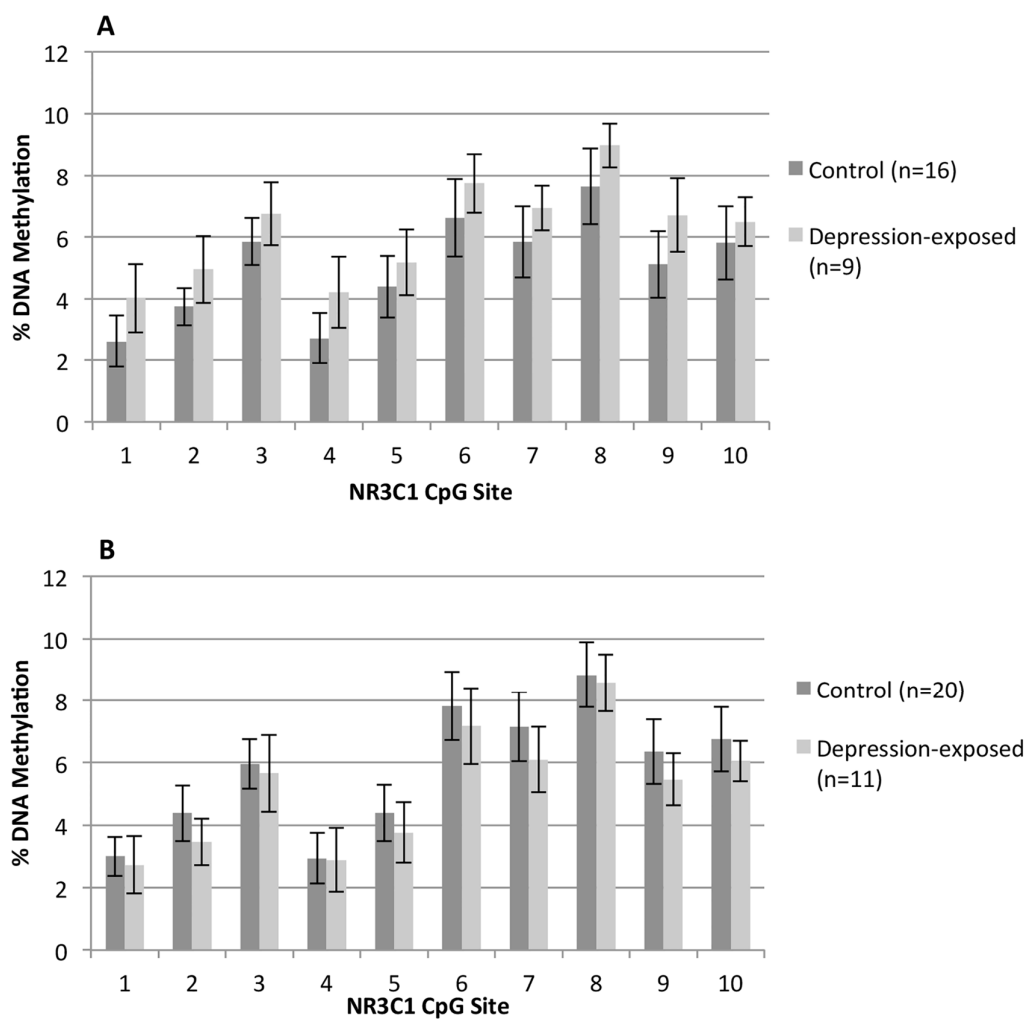

Figure 1 Percent methylation at each CpG site (1-10) within the examined *NR3C1* 1F region for the depression-exposed and control infants. A shows the values for the male infants and B the female infants.

Figure 2 Percent methylation at each CpG site within the examined *BDNF* IV region for the depression-exposed and control infants.

Figure 3 Schematic and the analyzed sequence of the *NR3C1* (A) and *BDNF* (B) gene. Shown are specific CpG sites analyzed using bisulfite-pyrosequencing assays as well as NGFI-A (blue box) and CREB (purple box) binding sites within *NR3C1* exon 1F and *BDNF* promoter IV, respectively.
