# DCMA: A Label Switching MAC for Efficient Packet Forwarding in Multihop Wireless Networks

Arup Acharya, Senior Member, IEEE, Sachin Ganu, Student Member, IEEE, and Archan Misra, Member, IEEE

Abstract—This paper addresses the problem of efficient packet forwarding in a multihop, wireless "mesh" network. We present an efficient interface contained forwarding (ICF) architecture for a "wireless router," i.e., a forwarding node with a single wireless network interface card (NIC) in a multihop wireless network that allows a packet to be forwarded entirely within the NIC of the forwarding node without requiring per-packet intervention by the node's CPU. To effectively forward packets in a pipelined fashion without incurring the 802.11-related overheads of multiple independent channel accesses, we specify a slightly modified version of the 802.11 MAC, called data driven cut-through multiple access (DCMA) that uses multiprotocol label switching (MPLS)-like labels in the control packets, in conjunction with a combined ACK/RTS packet, to reduce 802.11 channel access latencies. Our proposed technique can be used in combination with "frame bursting" as specified by the IEEE 802.11e standard to provide an end-to-end cut-through channel access. Using extensive simulations, we compare the performance of DCMA with 802.11 DCF MAC with respect to throughput and latency and suggest a suitable operating region to get maximum benefits using our mechanism as compared to 802.11

*Index Terms*—Cut-through, mesh networks, pipelined, 802.11 MAC.

# I. INTRODUCTION

/ITH THE reduction in prices of commodity 802.11 products and their ready availability, there has been a substantial increase in the number of users that use wireless access for information. More recently, there has been a significant effort in using 802.11 in urban metropolitan areas to provide "hot-spot" high-speed coverage, as well as community wireless networks [1], [2]. The IEEE 802.11s Task Group [3] is also currently involved in efforts to standardize protocols for wireless mesh networks that will enable "instant wireless networks" such as in-building wireless networks in malls, hotels and apartment blocks, and community networks (where rooftop antennas are used to create an ad hoc wireless access infrastructure in specific residential areas). If the raw channel capacity of the basic 802.11 channel could be effectively utilized, multihop wireless networks can indeed become a compelling low-cost broadband access alternative, especially in relatively dense urban areas [4].

S. Ganu is with WINLAB, Rutgers University, New Brunswick, NJ 07902 USA (e-mail: sachin@winlab.rutgers.edu).

A. Misra is with the Next-Generation Web Infrastructure Department, IBM T. J. Watson Center, Hawthorne, NY 10598 USA (e-mail: archan@us.ibm.com).

However, the throughput achieved by current implementations of multihop 802.11 networks is still significantly lower than the underlying channel capacity. Some of the reasons for this overall lower throughput include the unfairness of the exponential backoff process on hidden nodes contending for the channel [5], the poor spatial reuse due to channel sensing-induced backoffs in the extended neighborhood of an ongoing transmission [6], the potential contention among packets of the same flow at different links [7], and the lack of an appropriate medium access control (MAC) layer to exploit the total number of 802.11 available channels [8]. A variety of proposals to remedy these problems have been suggested in literature, and these issues continue to be the subject of active investigation.

In this paper, however, we focus on an entirely different aspect of performance degradation in multihop wireless networks, namely, the packet forwarding inefficiency. Our work is motivated by the observation that, in a multihop wireless network, the action of packet forwarding undertaken by an intermediate node is significantly different from the corresponding operations performed in a wired network. In a wired network, a router typically has at least two physical network interfaces, with the forwarding functionality consisting of receiving a packet over one physical interface and subsequently sending it out over a second interface.1 In contrast, in a wireless network, a node N with a single wireless interface may act as an intermediary for two nodes that are each within the communication range of N but not directly within the range of each other. Thus, we see that packet forwarding in the wireless environment does not typically imply the transfer of a packet between distinct interfaces on a single host.

However, all implementations of 802.11-based packet forwarding operate at the network layer, treating the process of receiving a packet from the upstream node and of sending it to the downstream nodes as two independent channel access attempts. Fig. 1 shows a conventional implementation of software-based packet forwarding. This approach involves the reception of a packet on the wireless interface, transfer of the packet up the host's protocol stack to the Internet protocol (IP) layer where a routing lookup is used to determine the IP (and MAC) address of the next hop, and subsequent transmission of the packet using the same wireless interface to the MAC address of the next hop. This mechanism introduces two forms of latency in the multihop wireless forwarding process that are independent of all the other 802.11-related drawbacks enumerated earlier: 1) latency related

Manuscript received October 1, 2005; revised March 21, 2006. A preliminary version of this paper was presented in part at ACM International Workshop on Wireless and Mobile Multimedia (WoWMoM), 2002.

<sup>&</sup>lt;sup>1</sup>In high-end routers/switches, a packet is transferred from one interface to another via dedicated switching fabric, while in software-based routers, an incoming packet is processed by the CPU before subsequent transmission on the outgoing interface.

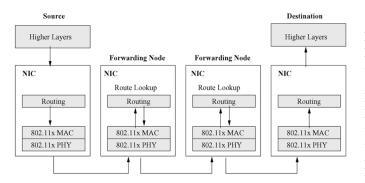

Fig. 1. Typical packet forwarding in a multihop wireless network.

to independent channel accesses required for each hop along the path and 2) latencies associated with interrupt-handling, packet copying, and route lookup at each forwarding node.

Our primary goal in this paper is to define a practical architecture and protocol for pipelined NIC contained forwarding and to evaluate its effectiveness compared with basic 802.11. To this end, we first propose an architecture for a forwarding node in a multihop wireless network that shifts the packet forwarding functionality away from the host processor to the wireless NIC. This is done by combining MAC for packet reception and subsequent transmission with address lookup in the interface card itself, using fixed-length addressing labels in the MAC control packets. This efficient "layer-2 forwarding," called interface-contained forwarding (ICF) can be enabled by using label-switching on the MAC-layer data path. The information needed by the NIC to perform NIC-resident lookups can be established offline using a separate label-distribution algorithm. The choice of the actual mechanism for label distribution does not affect the performance of the ICF architecture. A label itself can be similar to an multiprotocol label switching (MPLS) label [9]. For label distribution, existing routing protocols such as ad hoc on-demand distance vector (AODV) [10] may be adapted or distribution mechanisms such as LDP [11] may be used. This allows packet forwarding to be confined entirely to the NIC, which matches the label of an incoming packet with an entry in a data structure to determine the MAC address of the next-hop node and the label to be used for that hop.

To reap the full benefits of the optimized forwarding process, it is also necessary to define an efficient medium access protocol for packet forwarding, i.e., define an atomic channel access scheme that pipelines the reception of a packet from an upstream node and the subsequent transmission to the downstream node, to avoid the overhead of separate channel accesses on the upstream and downstream links. We present a simple modification of the 802.11 contention resolution scheme, called data-driven cut-through multiple access (DCMA) that provides preferential access to the pipelined forwarding, using a modified acknowledgment/ready-to-send (ACK/RTS) control packet. Both of these enhancements work in tandem: to exploit the "cutthrough" capability of DCMA, the NIC must be capable of determining the identity of the next-hop node from the signaling information in the contention resolution phase (without transferring the packet from the NIC to the host CPU and invoking a routing table lookup).

The rest of this paper is organized as follows. Section II presents a brief overview of the basic 802.11 forwarding process. Section III introduces the notion of label switching and its application to a multihop wireless network using the standard 802.11 MAC. Section IV then presents the basic DCMA protocol, based on a simple modification to the 802.11 MAC to enable atomic packet forwarding in wireless networks. Section V then describes our implementation of DCMA with the ns-2 simulator and presents simulation results comparing DCMA performance with basic 802.11-based packet forwarding. This section also explains how the forwarding behavior can be modified to ensure that DCMA causes no additional unfairness in channel access over 802.11, and suggests a suitable operating region to get maximum benefits using the above mechanism as compared with 802.11. Finally, Section VI concludes with a discussion and summary of future work and open research issues.

### A. Related Work

The use of MPLS (or labels) for providing fast and efficient packet forwarding on the wireless channel has not been extensively reported in literature. In [12], the authors have suggested using MPLS to support packet routing and handoff in wireless cellular networks along with the use of label merging to accommodate multiple links between a mobile node and the cellular infrastructure. To the best of our knowledge, there appears to be no prior public work in the area of devising MAC algorithms for providing label-based forwarding in multihop wireless networks. DCMA's pipelined mode of channel access, described in Section IV, is similar to the contention-free "burst" mode of 802.11e[13]. While the contention-free burst is on a per-hop basis, DCMA extends this burst by providing an end-to-end cut-through access across multiple hops along the path. Several approaches for pipelining data transmissions have been proposed in [14] and [15]. More recently, in [16], the authors propose a control channel-based MAC (C<sup>2</sup>M) which uses a combination of advanced channel reservation and packet aggregation on the low data rate control channel to improve the efficiency of the data channel. However, these approaches are based on using out-of-band signaling for coordinating data transmissions on the main channel, whereas our approach uses does not need a separate control channel. Also, based on our earlier work [17], alternative mechanisms for distributing labels amongst nodes have been considered such as [18] and [19]. Additionally, in [20], the authors propose a queue driven cut-through model that performs cut-through access at an intermediate node only for packets buffered in its queue irrespective of the flow to which they belong. Thus, cut-through is enabled only when the buffer at the intermediate relays builds up.

# II. CONVENTIONAL PACKET FORWARDING IN 802.11 NETWORKS

In this section, we briefly explain the 802.11 distributed coordination function (DCF) contention resolution mechanisms commonly employed in multihop ad hoc networks. Each node essentially acts a peer to all nodes within its transmission range. To avoid the hidden node problem, unicast communication in the DCF mode involves a four-way handshake mechanism

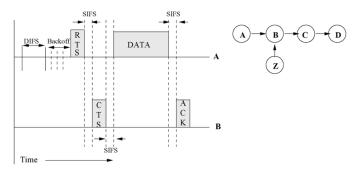

Fig. 2. 802.11 DCF channel access mechanism.

(shown in Fig. 2) between sender A and recipient B using ready-to-send/clear-to-send (RTS/CTS) exchange prior to data transmission. The same topology represented in the Fig. 2 is used for later discussions in this section.

The interaction consists of an RTS-CTS exchange that silences the neighbors in the vicinity of the sender (A) and receiver (B), respectively, followed by the data transfer and an ACK. For contention resolution, 802.11 uses a timer-based exponential backoff scheme where the node selects a random backoff time in the range [0, contention window] (specified in terms of slots) if the channel is busy. Each time the medium becomes idle, the station waits for a DIFS, and then decrements the backoff timer in units of aSlotTime. The node makes a fresh attempt at sending an RTS packet upon the expiration of the timer. Upon failure of the RTS packet, the contention window is doubled and a random timer is chosen from the new window. Each 802.11 node also maintains a network allocation vector (NAV) that monitors the state of the channel. Whenever the node overhears a control packet (RTS or CTS) transmitted by a neighboring node (to some other node), it updates its NAV appropriately to reflect the duration of the corresponding four-way data exchange. Even in the case of the 802.11a and 802.11g, the basic carrier sensing and channel access mechanism remains the same.

### A. Forwarding Operation in 802.11 Ad Hoc Networks

We now discuss the overheads associated with a forwarding operation when using the 802.11 MAC in a multihop wireless environment. The upstream node (node A) sends a data packet to the forwarding node (node B); which then forwards the packet to the downstream node (node C), as shown in Fig. 3.

After the IP lookup function, host A determines that B is the next hop of the DATA packet, and the packet is transferred to A's NIC. The MAC implementation on A's NIC then performs a four-way handshake (including any backoff timer-based countdown that may be needed to gain access to the channel) to forward the packet to B's NIC. At B, the packet is transferred from the device to the main memory either using DMA or Programmed I/O (PIO) techniques, and the host CPU is notified (e.g., via interrupts or soft IRQs) [21]) for further processing of the packet. The host software (IP protocol stack) would typically queue up the packet in a transmission queue and select packets for transmission based on a scheduling algorithm [typically, first-in–first-out (FIFO)]. When this packet reaches the head of the queue, the same steps as those executed at A,

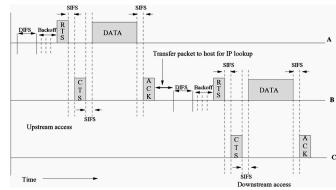

Fig. 3. Multihop forwarding in 802.11-based network.

would be taken, e.g., perform lookups to determine the IP address and then the MAC address of the next hop (C), insert the MAC-layer header (corresponding to next hop C), and transfer the packet to the NIC.<sup>2</sup> This packet is now treated as an independent data transfer between the nodes B and C; accordingly, B performs the usual backoff timer countdown before initiating an RTS-CTS-DATA-ACK exchange with C. Once this handshake is successfully completed, the packet is received by C's NIC, at which point the whole forwarding process is repeated. As with the initial data transfer (from A to B), the NAV of node A is blocked (by the RTS sent by B) for the entire duration of the four-way exchange between B and C.

# III. THE LABEL-BASED ICF ARCHITECTURE

In this section, we describe the label-based interface contained forwarding (ICF) architecture that reduces the latency associated with the NIC-host-NIC interaction at the forwarding node. More importantly, eliminating the NIC-host-NIC interaction enables us to subsequently perform atomic packet-forwarding at the MAC layer, eliminating the more significant latency component associated with independent channel accesses in 802.11. To support label-based forwarding, the NIC is enhanced to store a label-switching table, consisting of an incoming MAC address, an incoming label, an outgoing MAC address, and an outgoing label. Fig. 4 shows a schematic diagram of the interaction between the host software and the enhanced NIC that contains the label-switching table.

As in basic MPLS, labels are associated with routes or destinations, i.e., at any node, all entries in the label switching table that refer to the same route (the same path to the same destination) will share the same outgoing MAC address (of the next hop) and outgoing label. For example, let an entry in the switching table of B be  $(A, L_{AB}, C, L_{BC})$ . This means that any packet received at B from A with a label  $L_{AB}$  will use C as the next downstream hop with a label  $L_{BC}$ .<sup>3</sup>

<sup>&</sup>lt;sup>2</sup>Zhu *et al.* [22] have benchmarked the sources of latency in typical packet handling operations on an MPI architecture using 20 byte packets to about 100  $\mu$ s for NIC-host-NIC (excluding route-lookups and related overheads). Even though these values may be OS and driver specific, we use similar values to the ones described.

<sup>&</sup>lt;sup>3</sup>The MAC address itself cannot be used as a label, since packets that are received at B need to be further distinguished based on their individual destination. Thus, two identifiers are needed, one for the next-hop node and the other for the eventual destination.

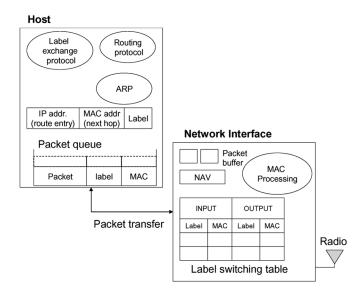

Fig. 4. Host and NIC components for packet forwarding using labels.

The combination of the outgoing label  $L_{BC}$  and the MAC address of the next-hop node C, essentially defines a specific route to a destination, say D. If B has another neighbor, say Z, which uses B to reach D as well, then there will a corresponding entry in the label-switching table  $(Z, L_{ZB}, C, L_{BC})$ . The number of distinct outgoing labels is equal to the number of destinations in the network. It should be noted that each label is unique only to a single hop, and the same label may be reused by different nodes of the network. We shall see that the label information is not needed in the DATA packets, but is carried only in control packets such as the RTS and CTS frames. This is possible because the MAC protocol reserves a time duration (via control packets) during which a forwarding node can expect to receive a DATA packet.

# *A. Alternative Choices for "Labels" and Their Distribution Mechanisms*

It is important to note that the gain associated with labelbased switching arises from eliminating the route lookup overhead and replacing it with ICF. The label used for enabling interface based switching can thus be just a simple flow identifier or a combination of MAC address and flow identifier. ICF gains will not be affected by the choice of any particular labeling mechanism. Also, there may be different mechanisms for distributing these labels amongst nodes. In [18], the authors propose a wireless ad hoc label switching (WALS) architecture that extends the 802.11 data frame header to carry label and flow information for multipath setup and forwarding, thereby eliminating separate signaling. In [19], a label routing protocol (LRP) that is used to setup, configure, and maintain paths between communicating endpoints. Also, 802.11 Wireless Distribution System (WDS) uses nested MAC headers for switching a packet between the source and destination APs in a network consisting of multiple APs connected by a wired/wireless backbone. Space for these addresses in the MAC header could potentially be used to carry labels for our proposed scheme. A separate scheme for assigning labels to routes would still be needed since address

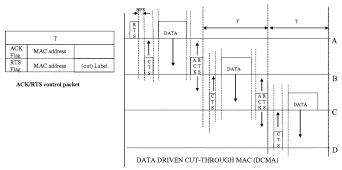

Fig. 5. DCMA timing diagram.

discovery techniques used in WDS (e.g., broadcasting ARP requests, observing MAC headers of in-flight packets) would not scale to large multihop networks.

The overhead for storing the label lookup table at a node also is relatively small. The number of entries in the table is proportional to the number of destinations (or nodes) in the topology. Each entry consists of (incoming MAC, incoming label, outgoing MAC, outgoing label). With a 48 bit MAC address and 32 bit label, every entry requires  $48 \times 2 + 32 \times 2 = 160$  bits for storage. Thus, even for 1000 destinations (an extremely large wireless mesh!), the table size would be  $\approx 160$  Kb, which is relatively small.

# IV. DCMA: THE CUT-THROUGH MAC PROTOCOL

In this section, we describe the MAC-layer enhancements to gain full advantage of the label-switching described in the previous section. Without these enhancements, a packet would need to be buffered at the NIC between the two separate channel accesses thereby nullifying the performance benefits (in terms of latency or throughput) achieved by the elimination of the routing lookups.

Our proposed MAC scheme is based on enhancements to the IEEE 802.11 DCF mode of channel access and follows the associated four-way handshake involving the exchange of RTS/CTS/DATA/ACK packets. We term this scheme as DCMA. DCMA attempts to replace the two distinct channel accesses, upstream and downstream, with a combined access. The reservation for the downstream hop (B to C) is attempted only after successfully receiving the DATA packet from the upstream node (A). The advantage is that a downstream reservation is made only after the upstream channel access has been granted and the packet reception from the upstream node is successful. Accordingly, as shown in Fig. 5, DCMA combines the ACK (to the upstream node) with the RTS (to the downstream node) in a single ACK/RTS packet that is sent to the MAC broadcast address.

The payload of the ACK/RTS packet now contains the MAC address of the upstream node, A, and the MAC address of the downstream node, C. It also includes a label intended for use by the downstream node to figure its next hop. Since the downstream node (and all other neighboring nodes of the forwarding node) is assured to be silent until the completion of the ACK, piggybacking the RTS packet provides the forwarding node with preferential channel access for the downstream transmission. Before sending the ACK/RTS, the forwarding node (B) performs channel sensing to check whether the medium in its vicinity is idle. This reduces the likelihood of backoffs that might be generated at node B when its cut-through request (RTS/ACK sent to C) fails due to hidden node effects (e.g., when a currently transmitting downstream node D prevents node C from responding with a CTS) associated with the discrepancy between channel sensing and transmission ranges. If cut-through does fail; the forwarding node simply queues the packet in the NIC queue and resumes normal 802.11 channel access. DCMA requires no modification of the 802.11 NAV-a node simply stays quiet as long as it is aware of activity involving one or more of its neighbors. Any node that overhears an ACK/RTS not addressed to it merely increments the NAV by the specified time interval; this NAV increment is also performed by the target of the ACK (the upstream node).

In DCMA, the label is carried in the RTS/ACK (or RTS). In principle, the DATA field could also have carried this label, since the label lookup (to find the downstream node) is not strictly necessary until after the DATA is received. However, by carrying the label information in the RTS, we provide the forwarding node additional time to complete the lookup (in parallel with the DATA transfer from the upstream node). Thus, DCMA provides an end-to-end "reservation" for the flow, assuming that all cut-through attempts are successful. IEEE 802.11e [13] standard specifies a frame bursting mode in which, after gaining access to the channel, the sender does not wait for the required DIFS interval between two frames. Instead, it waits only for SIFS and then transmits the second data frame. DCMA can be thought of as an "end-to-end" extension to this bursting mode.

## A. Impact on the Latency Using Cut-Through

As stated earlier, the conventional packet forwarding process results in two types of latencies, one associated with the multiple NIC-to-host packet transfers, and the other with the separate independent channel access attempts. While the overhead associated with the NIC-to-host packet transfers and route lookups will be hardware and operating system dependent, as explained in Section II-A, we use an upper bound of 1 ms at each hop to quantify the total latency in all the required operations. Consider a single data path consisting of N links, defined over the hosts  $H_1$  to  $H_{N+1}$ . Let us consider the 802.11b standard and assume that each of the N links can sustain a raw "data" transfer rate of X Mb/s (where X is one of 2, 11, and 54 Mb/s). To ensure that all stations are able to correctly update their NAV by listening to the signaling packets, the RTS/CTS packets are always sent out at the base rate of 2 Mb/s for 802.11b and 6 Mb/s for 802.11g, while the ACKs are sent out at the data rate. By considering the additional overhead imposed by the PHY layer), we can see that for a MAC-layer DATA payload of Lbytes, each individual packet transfer consumes a total delay (we ignore propagation delays in our analysis), as shown in Table I. For 802.11, we assume that each of the transfers over an N-hop path is independent.

 TABLE I

 SUMMARY OF 802.11B/G AND DCMA PARAMETERS

Event	Time(in $\mu$ s)
	(with b/ with g
SIFS	10 (10)
aSlotTime	20 (9)
T <sub>rtlookup</sub> (Route lookup delay	
at each forwarder)	1000 ( <b>1000</b> )
DIFS	50 ( <b>28</b> )
$T_{PHY} = (PLCP \text{ header } + \text{ long preamble})$	192 ( <b>20</b> )
$T_{RTS} = (T_{PHY} + 20 \text{ bytes at 2Mbps}) (802.11b)$	272 (46.6)
or 6 Mbps (802.11g)	
$T_{CTS} = (T_{PHY} + 14 \text{ bytes at 2Mbps}) (802.11b)$	248 ( <b>38.6</b> )
or 6 Mbps (802.11g)	
$T_{ACK} = (T_{PHY} + 14 \text{ bytes at X Mbps})$	192 + 192/X
	(20 + 192/X)
$T_{DATA} = T_{PHY} +$	192+8*(L+36)/X
8*(L+36 byte MAC hdr)/X	(20+8*(L+36)/X)
$T_{backoff} = 0.5 * CW_{min} * aSlotTime$	310 ( <b>67.5</b> )
$T_{RTS\_DCMA} = (T_{PHY} + 20 \text{ bytes RTS} +$	
4 byte label) at 2Mbps)	288 ( <b>52</b> )
$T_{ACK\_RTS} = (T_{PHY} + 14 \text{ byte ACK} +$	
1 byte flag + 4 byte label +	
6 byte MAC addr at 2Mbps)	292 ( <b>53.33</b> )

Hence, the total latency to send L bytes of DATA payload at X Mb/s over N hops, is given as follows:

$$T_{80211}(N, L, X)$$

$$= N * (T_{\text{backoff}} + \text{DIFS} + T_{\text{RTS}}$$

$$+ T_{\text{CTS}} + T_{\text{DATA}} + T_{\text{ACK}} + 3 * \text{SIFS})$$

$$+ (N - 1) * T_{\text{rtlookup}}$$

$$= N * \left[ 1294 + \frac{480 + 8 * L}{X} \right] + (N - 1) * T_{\text{rtlookup}}$$

For DCMA, RTS packets have an additional label field (4 bytes) intended for the downstream neighbor. The ACK/RTS packet is the same as 802.11 ACK with the following additional fields: upstream node MAC address (6 bytes), label for the downstream neighbor (4 bytes), and a flag to indicate ACK/RTS (1 byte).

Now, consider the case of pipelined transfers from  $H_1$  to  $H_{N+1}$  using the DCMA protocol. In this case, the channel access delay is incurred only in the first host (original sender). Moreover, now since ACK and RTS share the same frame (on all intermediate hops), the total latency to send *L* bytes of DATA payload at *X* Mb/s over *N* hops is given as follows:

$$T_{\text{DCMA}}(N, L, X)$$

$$= T_{\text{backoff}} + \text{DIFS} + T_{\text{RTS}-\text{DCMA}}$$

$$+ N * (3 * \text{SIFS} + T_{\text{CTS}} + T_{\text{DATA}} + T_{\text{ACK}-\text{RTS}})$$

$$= 658 + N * \left[762 + \frac{8 * (L+36)}{X}\right].$$

We plot the latency for a seven-hop chain for DCMA and 802.11 with different data rates (2 and 11 Mb/s) and different packet sizes (80 bytes and 1536 bytes) in Fig. 6. Additionally, latencies using 54 Mb/s data rate provided by 802.11g/a cards and the appropriate interframe spaces are calculated using similar analysis as shown above

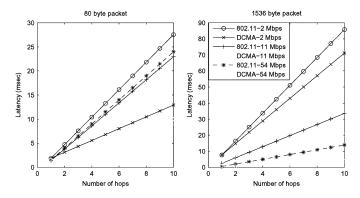

Fig. 6. Latency for different rates and packet sizes (802.11 versus DCMA).

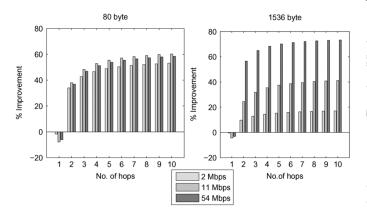

Fig. 7. Percent improvement in latency at different PHY rates (802.11 versus DCMA).

and are also shown in the figure. We also plot the percentage improvement in latency of DCMA versus 802.11 in Fig. 7. The percentage improvement is calculated as 100 \* (802.11 latency - DCMA latency)/802.11 latency. At higher data rates and packet sizes, the contribution of packet transmission time to the total latency is much smaller compared with the channel access latency. Hence, by reducing the channel access latencies, DCMA will provide a significant improvement in end-to-end latency, especially as *wireless technology evolves* to support higher and higher data rates. As seen in the Fig. 7, the improvement in latency for 1536 byte payload transmitted at 54 Mb/s is  $\approx$ 73% as compared with  $\approx$ 17% at 2 Mb/s.

# V. PERFORMANCE RESULTS

To study the performance of our pipelined forwarding mechanism, we implemented the DCMA protocol as part of the ns-2 simulator [23] with the CMU wireless extensions [24]. We focus on three metrics: a) the throughput improvement achieved by the cut-through protocols; b) the potential reduction in end-to-end latency due to the expedited MAC forwarding; and c) percentage of cut-through out of the total packets received. To study the throughput and latency behavior of flows, we ran user datagram protocol (UDP) flows with varying packet arrival rates. The buffer size at each node was 50 packets. The routing tables were preconfigured with the shortest path routes to their respective destinations. Each node keeps track of the number of packets sent out and the number of cut-through ACKs received.

 TABLE II

 COMMON PARAMETERS FOR ALL SIMULATION RESULTS

Topology	7 node chain and 100 node grid
1 67	0
Traffic model	CBR (UDP)
Data Rate	11 Mbps
Transmission/Interference Range	250m/550m
RTS Threshold	0 (always on)
Min. distance between adjacent nodes	248m
Host processing delays at each relay	1 millisecond
(for 802.11)	

Fig. 8. Simple chain topology with six hops and seven nodes.

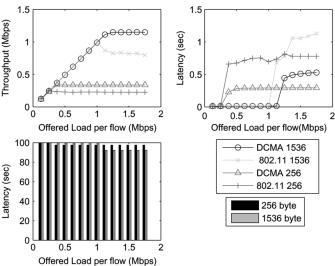

Fig. 9. (a) Throughput, (b) latency, and (c) percent cut-throughs for a simple chain topology (CBR traffic).

The cut-through percentage is calculated as the ratio of sum total of the cut through ACKs (ACKs for RTS/ACK-driven transmissions) received to the total number of packet transmissions (each packet transmission on a link is considered separately). The parameters of the ns-2 simulator are summarized in the Table II.

#### A. Investigations on the Chain Topology

We first present results of performance studies on a seven-hop chain shown. We vary the offered load and configuration of the flows to understand the various interactions between the cutthrough and conventional packets.

1) Single Flow Topology: In this scenario, the traffic consists of a single UDP flow between the two end nodes of the chain. Even though this scenario has only a single flow as shown in Fig. 8, it helps to understand the benefits of DCMA over 802.11 under different offered loads and acts as a baseline for further experiments. The offered load was increased from 125 kb/s to 1.75 Mb/s in steps of 125 kb/s using two different packet sizes: 256 bytes and 1536 bytes. Fig. 9 shows the throughput and delay results for DCMA and 802.11 for two different packet sizes. We see that for both packet size, the DCMA throughput is higher than 802.11. As expected, DCMA offers almost a 50% reduction in end-to-end delay, especially at higher offered loads.

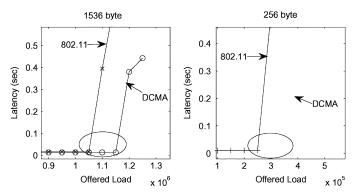

Fig. 10. Zoomed view of flow latencies for (a) 256 byte and (b) 1536 byte payload.

Moreover, the lower throughput for 256 byte packets is due to the proportionally larger overhead of the MAC/PHY-layer headers. One of the most important advantages with DCMA is that the pipelined access mechanism essentially reduces the channel contention effects among consecutive intraflow packets-by allowing most packets to cut-through faster to downstream nodes, it lowers the incidence of contention-induced backoffs at upstream (hidden) nodes for subsequent packets. This intraflow contention becomes especially more pronounced for larger packet sizes with 802.11, where the throughput actually declines from  $\approx 1$  Mb/s to  $\approx 750$  kb/s -since each packet transmission now takes longer, each transmitting node now "holds" the channel for a longer duration, and may thus cause repeated multiplicative backoff for upstream hidden nodes (an observation also reported in [6]). At relatively low traffic rates, the packets arrive sufficiently spaced apart to avoid this problem of intraflow contention. We expect the latency difference between 802.11b and DCMA to be much higher for higher data rates (54 Mb/s), as shown in Fig. 7. Fig. 9(c) shows the percentage of cut-through packets to the total number of packets delivered from the source to the destination. For lower offered loads, there are 100% successful cut-throughs at all intermediate nodes. However, as the offered load increases beyond 1 Mb/s, the packet injection rate is much higher than the cut-through delivery time, resulting in queue build up at the intermediate nodes and reduced cut-throughs.

Fig. 10 provides a zoomed view of the average delays for each packet size. Note that many representative interactive or multimedia applications require the end-to-end latency not to exceed 100–200 ms. Accordingly, we define the *operating range* of a protocol to be that where the end-to-end latency does not exceed 200 ms. As seen in the figure, DCMA extends the operating range from 1.05 to 1.15 Mb/s for 1536 byte packets and from 250 to 350 kb/s for 256 byte packets, while maintaining reasonably low latency.

We also tested the same scenario with Poisson traffic where the traffic was varied from an average offered load of 125 kb/s to 1.75 Mb/s in steps of 125 kb/s. The results for throughput and delay (as shown in Fig. 11) for two different packet sizes show similar performance as with the constant bit rate traffic.

2) Simple Chain With Two Flows in Reverse Direction: We next considered two flows in reverse direction (from node 1 to 7 and from node 7 to 1, respectively, as shown in Fig. 12). This

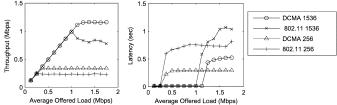

Fig. 11. (a) Throughput, (b) latency of each flow, and (c) percentage cutthroughs for a simple chain topology (Poisson traffic).

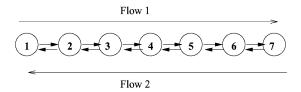

Fig. 12. Chain topology with two reverse flows.

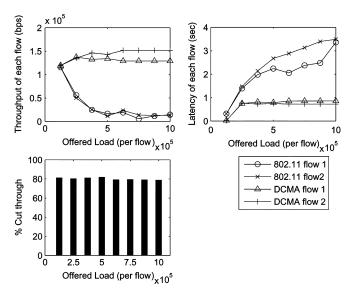

Fig. 13. (a) Throughput, (b) flow latencies, and (c) percentage cut-throughs for two flows in reverse direction.

scenario also provides insights into the behavior of TCP traffic, which has the data flowing from the source to the destination and ACKs flowing in the reverse direction. In this case, the offered load was increased from 125 kb/s to 1 Mb/s per flow. Only the results for the 256 byte packets are presented for reasons of space).

Fig. 13 plots the throughput, end-to-end latency and percentage cut-through rates for DCMA and 802.11 for this scenario. Once again, we see that DCMA is able to obtain significantly higher (almost double the throughput of 802.11) in this case. Note that the two flows have similar throughput and delay values indicating that each flow gets a fair allocation of the channel for both 802.11 and DCMA. It is also important to note that the sources of traffic (nodes 1 and 7) do not participate in the relaying process.

3) Simple Chain With Two Flows in the Same Direction: Next, we look at a case where the two flows are in the same direction (1 to 7 and 4 to 7, as shown in Fig. 14). This scenario deals with the case when the intermediate relay nodes may also

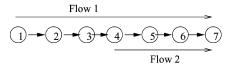

Fig. 14. Simple chain (flows in same direction).

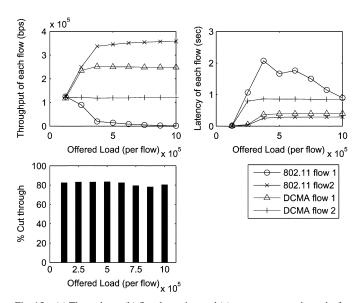

Fig. 15. (a) Throughput, (b) flow latencies, and (c) percentage cut-throughs for two flows in same direction.

TABLE III PARAMETERS FOR THE GRID TOPOLOGY

Number of flows	5, 10, 15, 20, 25 30
Packet sizes (bytes)	256
Dimensions	2500m×2500m
Distance between adjacent nodes	248 m

have traffic of their own to send. We study the per flow behavior with 802.11 and DCMA using the same traffic profile, as described in Section V-A2.

The results in Fig. 15 show that for both 802.11 and DCMA, one of the flows is starved, resulting in disproportionate throughput and average delays. Note that even in this case, DCMA still performs slightly better since by using efficient cut-throughs, the packet is delivered faster, resulting in an earlier channel access for the starved flow when the medium is idle. In Section V-C, we propose a simple heuristic algorithm to address this starvation problem.

#### B. Investigations With the Grid Topology

After studying the chain topologies described earlier, we tested DCMA on a general  $10 \times 10$  grid topology with randomly selected sources and destinations. The parameters used in the simulations are summarized in Table III.

Thus, the grid topology was a combination of the scenarios described earlier (multiple flows—in the same direction, reverse directions, as well as interfering flows). We showed earlier in the simple chain single flow topology (Fig. 9) that for 256 byte packets, the performance of DCMA and 802.11 diverges at an offered load of around 200–400 kb/s per flow. This can be attributed to the fact that for low offered loads, queues are usually

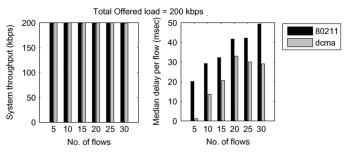

Fig. 16. Lightly loaded case: System throughput and median delay per flow.

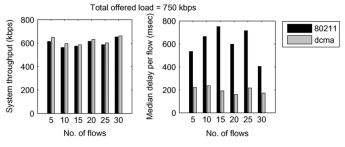

Fig. 17. Medium loaded case: System throughput and median delay per flow.

small or empty and the major component of the end-to-end delay is thus the packet exchange times between nodes (which is almost the same for both 802.11 and DCMA). At offered loads of about 200-400 kb/s, there are enough packets in the pipe to keep the channel busy. Here, the performance of 802.11 and DCMA diverges as the channel access delays become comparable to the packet transmission times. DCMA outperforms 802.11 as it saves one channel access at every intermediate node as compared with 802.11 that needs two distinct channel accesses. Note that the operating load per flow in the grid scenario might be lower than in the single flow chain, due to contention among packets belonging to different flows that have intersecting paths. In our simulations, we only look at the useful operating range where the end-to-end latencies are within 1 s. We consider two different cases, as described below, both for lightly loaded and medium loaded traffic. For all the cases, we ran the simulation for 20 topologies and present the system throughput and the median delays per flow.

1) Constant Total Offered Load, Increasing Number of Flows: In this case, the total offered load to the grid was kept constant at 200 kb/s and 750 kb/s representing the lightly loaded and medium loaded conditions. Across the simulation runs, we varied the number of flows (from 5 CBR flows to 30 flows). As shown in Fig. 16, for the lightly loaded case, both DCMA and 802.11 have similar performance. As the number of flows increases, there is a higher probability that flows interfere with one another due to common relays along their paths. At lower loads, DCMA still outperforms 802.11 since cut-throughs allow a packet to be delivered faster, resulting in an earlier medium access for competing flows. Also, it can be seen that for the medium loaded case, as shown in Fig. 17, 802.11 latencies are almost three times the corresponding DCMA latencies. Thus, DCMA outperforms 802.11 for both the light and medium loaded cases.

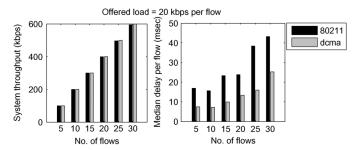

Fig. 18. Lightly loaded case: System throughput and median delay per flow.

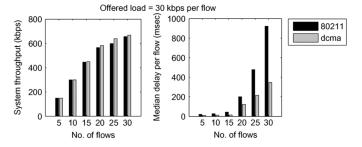

Fig. 19. Medium loaded case: System throughput and median delay per flow.

2) Constant Offered Load Per Flow, Increasing Number of Flows: In this case, the individual offered load per flow was kept constant (20 kb/s and 30 kb/s) and the number of flows was increased from 5 to 30. Thus, the total offered load was increased from 100 to 600 kb/s and 150 to 900 kb/s for the two cases, respectively. As seen in Fig. 18, both DCMA and 802.11 have low latencies at lighter loads. As the offered load per flow increases, the number of successful cut-throughs reduces and the delays increases. However, as seen in Fig. 19, DCMA maintains the latencies to within 250 ms as compared with the high latencies of 450–850 ms for the case of 802.11 due to repeated collisions and backoff.

# C. Heuristic Approach to Address Flow Starvation and Related Unfairness

In all our simulations, we have given preferential access to a cut-through when forwarding a packet to the next hop. One potential problem of the preferential access provided to a cutthrough flow is that it may cause starvation for other flows, since the NIC may respond to ACK/RTS requests, while it has packets of its own to send in its buffer. As a simple fix to this problem, we modified the interface behavior to monitor if the node had any packets pending in its MAC buffer that belonged to the flow originating at this node itself. If so, the NIC would decline the cut-through attempt by any other flow by not sending a CTS in response to an RTS/ACK request from a neighbor. Although our simulations are based on UDP sessions, this fairness policy is especially useful for TCP flows, since it protects against out-of-order delivery of packets. Without the fairness measure, a packet from a flow could get queued at an intermediate node, while a subsequent packet could cut-through to the destination node. Fig. 20 shows the per-flow throughput and delay before and after applying the fairness policy for two flows on a simple chain topology, as described in Section V-A3. We can see that with fair-DCMA, individual flow throughputs and

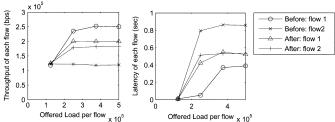

Fig. 20. Per flow throughputs and delays (before and after fairness policy).

delays are much closer than with DCMA without fairness. Note that other fairness policies may also be applied; however, we defer the detailed investigation of various fairness schemes and their impact on system performance to a future paper.

# VI. CONCLUSION

In this paper, we presented an efficient ICF architecture for a "wireless router," i.e., a forwarding node with a single wireless NIC in a multihop wireless network that allows the process of packet forwarding to be confined entirely within the NIC. The ICF architecture uses an enhancement to the base 802.11 DCF behavior, using a combined RTS/ACK transmission to reduce the number of channel accesses at the forwarding nodes. Simulation results and analyses demonstrate the significance of DCMA's atomic MAC-layer forwarding scheme—even if future hardware improvements almost eliminated the NIC-host-NIC transfer latency, the absence of a pipelined forwarding mechanism in base 802.11 would still result in substantially high end-to-end latency in multihop wireless paths, even with everincreasing channel data rates.

Extensive simulation studies show that DCMA performs better than 802.11 DCF in almost all scenarios. In particular, on simulations over a grid-like wireless mesh, DCMA was able to extend the useful operating range (traffic loads such that end-to-end delays for flows stay bounded below  $\approx 200 \text{ ms}$ ) by more than 30%, compared with 802.11. In general, packet cut-through is especially useful at relatively low to moderate network loads (which is typically the case in well-provisioned wireless networks). Thus, a combination of DCMA and call admission control (so that the network load stays within specified bounds) could prove to be especially useful for relatively low-bandwidth, delay sensitive applications such as VoIP-over-wireless. We also identified an important unfairness issue that might arise in DCMA, where cut-through transmissions of one flow might preemptively starve the transmission of packets belonging to other flows. As a simple solution to this issue, we have proposed a fairness scheme that uses queue occupancy information at the MAC layer to allow competing flows to get equitable channel access. Simulation results show that this simple modification of base DCMA significantly improves the fairness across flows.

There are many interesting ideas for future research on the idea of the wireless router. Our studies indicate that *intraflow* packet contention can undermine the benefit of packet pipelining; this suggests that multipath interleaved routing (where successive packets are sent on link-disjoint paths) could be especially useful with DCMA. Additionally, the pipelining scheme can be even more effective if multiple packets could be pipelined in bursts; this suggests research into techniques for "cumulative" packet cut-through schemes.

Arup Acharya (M'04–SM'06) received the B.Tech. degree in computer science from the Indian Institute of Technology (IIT), Kharagpur, and the Ph.D. degree in computer science from Rutgers University, New Brunswick, NJ, in 1995.

He is a Research Staff Member in the Internet Infrastructure and Computing Utilities Group at IBM T. J. Watson Research Center, Hawthorne, NY, and leads the Advanced Networking Micropractice in On-Demand Innovation Services. Presently, he is leading a IBM Research Project on scalability and

performance of SIP servers for large workloads. In addition, he also works on different topics in mobile/wireless networking such as mesh networks. He has published extensively in conferences/journals and has been awarded seven patents. Before joining IBM T. J. Watson Research Center in 2000, he was with NEC C&C Research Laboratories, Princeton, NJ. His current work includes SIP-based services such as VoIP, Instant Messaging and Presence, and includes customer consulting engagements and providing subject matter expertise in corporate strategy teams.

Sachin Ganu (S'04) received the B.E. degree in electronics from Mumbai University, Mumbai, India, in 1998 and the M.S. degree in electrical engineering from the Virginia Polytechnic Institute and State University, Blacksburg, VA, in 1999. He is currently working towards the Ph.D. degree at WINLAB, Rutgers University, New Brunswick, NJ, working under the guidance of Dr. D. Raychaudhuri.

Prior to joining WINLAB, he worked as a Systems Engineer with Lockheed Martin Global Telecommunications, Clarksburg, MD, from February 2000 until

December 2001 on radio resource management tools for ATM-based geosynchronous satellite systems. He worked as a Research Scientist at Avaya Research Laboratories, Basking Ridge, NJ, during the summer of 2002 and as a Network Software Engineer with the Communications Technology Group, Intel Corporation, Hillsboro, OR, during the summer of 2005. His research interests include cross-layer architectures for wireless mesh networks focusing on MAC-routing interactions and location estimation in wireless networks. Currently, he is also involved in the design and development of a large-scale indoor wireless testbed, ORBIT, to facilitate wireless experimentation.

Archan Misra (M'04) received the B.Tech. degree in electronics and communication engineering from the Indian institute of Technology (IIT), Kharagpur, in July 1993 and the Ph.D. in electrical and computer engineering from the University of Maryland, College Park, in May 2000.

He is a Research Staff Member at the IBM T. J. Watson Research Center, Hawthorne, NY, where he works on infrastructural components for pervasive networking and middleware for presencebased, context-aware computing. His current re-

search projects include middleware for SIP-based "rich presence" in converged networks, high-performance wireless mesh networks and sensor data management techniques for healthcare and remote monitoring scenarios. Prior to joining IBM T. J. Watson Research Center in 2001, he worked at Telcordia Technologies on architectures for QoS in the Internet and adaptive IP-based mobility management algorithms. He has published extensively in the areas of wireless networking and pervasive computing.

Dr. Misra is a coauthor on papers that received the Best Paper Awards in ACM WOWMOM 2002 and IEEE MILCOM 2001. He is presently on the Editorial Board of the *IEEE Wireless Communications Magazine*, and currently chairs the IEEE Computer Society's Technical Committee on Computer Communications (TCCC).
