#### Abstract

A 2L-dimensional multiple phase-shift keyed MPSK ( $I \times$ MPSK) signal set is obtained by forming the Cartesian product of $L$ two-dimensional MPSK signal sets. A systematic approach to partitioning $L \times$ MPSK signal sets is used that is based on block coding. An encoder system approach is developed which incorporates the design of a differential precoder, a systematic convolutional encoder, and a signal set mapper. Trellis-coded $L \times 4$ PSK, $L \times 8$ PSK, and $L \times 16 \mathrm{PSK}$ modulation schemes are found for $1 \leq L \leq 4$ and a variety of code rates and decoder complexities, many of which are fully transparent to discrete phase rotations of the signal set. The new codes achieve asymptotic coding gains up to 5.85 dB .

## I. Introduction

SINCE the publication of the paper by Ungerboeck [1], trellis-coded modulation (TCM) has become a very active research area [2]-[13]. The basic idea of TCM is that by trellis coding onto an expanded signal set (relative to that needed for uncoded transmission), both power and bandwidth efficient communication can be achieved.
TCM can be classified into two basic types, the lattice type (e.g., $M$-pulse-amplitude modulation (PAM) and M-quadrature amplitude shift keying (QASK)) and the constant amplitude type (e.g., multiple phase-shift keying (MPSK)). Constant amplitude modulation schemes have a lower power efficiency compared with lattice type modulation schemes but are more suitable for certain channels, e.g., satellite channels containing nonlinear amplifiers such as traveling wave tubes (TWT). Taylor and Chan [5] and

Wilson et al. [6] have studied the performance of trelliscoded MPSK (TC-MPSK) modulation, in particular rate $2 / 3$ TC-8PSK and rate $3 / 4$ TC-16PSK, respectively, for various channel bandwidths and TWT operating points. Their results showed that TC-MPSK modulation schemes are quite robust under typical channel conditions.

In any TCM design, partitioning of the signal set into subsets with increasing minimum intrasubset distances plays a central role. It defines the signal mapping used by the modulator and provides a tight bound on the minimum free Euclidean distance ( $d_{\text {free }}$ ) between code sequences. For lattice-type TCM, Calderbank and Sloane [10] have made the important observation that partitioning the signal set into subsets corresponds to partitioning a lattice into a sublattice and its cosets. Forney [13] has developed a method, called the squaring construction, of constructing higher dimensional lattices from partitioned lower dimensional lattices.

We shall investigate a class of trellis-coded multidimensional (multi-D) MPSK modulation schemes. Signals from a $2 L$-dimensional ( $2 L$-D) MPSK signal set (which we shall denote as $L \times$ MPSK) are transmitted over a two-dimensional (2-D) modulation channel by sending $L$ consecutive signals of an MPSK signal set. Therefore, the $L \times$ MPSK signal set is the Cartesian product of $L$ 2-D MPSK signal sets. Trellis-coded mutli-D phase modulation (TC- $L \times$ MPSK) provides us with a number of advantages that usually cannot be found with TC-MPSK: 1) flexibility in achieving a variety of fractional information rates, 2) codes which are partially or totally transparent to discrete phase rotations of the signal set, 3) suitability for use as inner codes in a concatenated coding system [14], due to their byte oriented nature, and 4) higher decoder speeds resulting from the high rate codes used (rate $k /(k+1)$ with $k$ up to 15 for some codes).

In Section II, we introduce a block coding technique for partitioning $L \times$ MPSK signal sets. Section III contains a description of how the encoder system-comprising a differential precoder, a systematic convolutional encoder, and a multi-D signal set mapper-is obtained for the best codes found in a systematic code search. The signal sets are designed such that the codes can become transparent to integer multiples of $360^{\circ} / M$ rotations of the MPSK signal set. Also, due to the way in which they are mathe-
matically constructed, a signal set mapper can be easily implemented by using basic logic gates and $L$-bit binary adders. The systematic code search is based on maximizing $d_{\text {free }}$ (and thus the asymptotic coding gain) as well as minimizing the number of nearest neighbors ( $N_{\text {free }}$ ) for various degrees of phase transparency. TC- $L \times 4$ PSK, TC$L \times 8$ PSK, and TC- $L \times 16$ PSK codes for $L=1$ to 4 are found. For TC- $L \times 8$ PSK and TC- $L \times 16$ PSK, asymptotic coding gains up to 5.85 dB compared to an uncoded system are obtained. The TC- $L \times 4$ PSK codes exhibit asymptotic coding gains up to 7.8 dB . Among the $L=1$ codes listed are some new codes that have improvements in $N_{\text {free }}$ and phase transparency compared to codes found previously [1], [4], [6], [15]. Viterbi decoding of TC- $L \times$ MPSK is also discussed, concentrating on maximum-likelihood decoding of the parallel transitions within a code trellis.

## II. Multi-D Signal Set Partitioning

To describe set partitioning, we will start with the familiar partitioning of the 8PSK signal set. This is followed with an example of multi-D signal set partitioning using the $2 \times 8$ PSK signal set. Generalizations will be introduced gradually, so that by the end of this section the reader should become thoroughly familiar with the concepts involved.

## A. Partitioning the 8PSK Signal Set

In partitioning the 8 PSK signal set, or $1 \times 8 \mathrm{PSK}$, we form a minimum squared subset distance (MSSD) chain of $\delta_{0}^{2}=0.586, \delta_{1}^{2}=2, \delta_{2}^{2}=4$, and $\delta_{3}^{2}=\infty$ (assuming that the average signal energy is one). Fig. 1 illustrates this partitioning, in which each subset is equally divided into two smaller subsets such that the MSSD in each smaller subset
is maximized. Partitioning continues in this manner until we have eight subsets, each containing a single point, hence $\delta_{3}^{2}=\infty$.

## B. Partitioning $2 \times 8 P S K$

A $2 \times 8$ PSK signal set ( $L=2$ ) is illustrated in Fig. 2. We use integers $y_{1}$ to indicate the first 8 PSK point and $y_{2}$ for the second 8PSK point, where $y_{1}, y_{2} \in\{0,1, \cdots, 7\}$. Natural mapping is used to map the integer $y_{j}$ into each complex-valued 8PSK signal, i.e., $y_{j} \mapsto \exp \left[\sqrt{-1} y_{j} \pi / 4\right]$, for $j=1,2$. We can also represent $y_{1}$ and $y_{2}$ in binary form as the vector $y_{j}=\left[y_{j}^{2}, y_{j}^{1}, y_{j}^{0}\right]$, with $y_{j}^{i} \in\{0,1\}$, and where $y_{j}=4 y_{j}^{2}+2 y_{j}^{1}+y_{j}^{0}$, for $j=1,2$. That is, the least significant bit (LSB) of $\boldsymbol{y}_{j}$ corresponds to the rightmost bit and the most significant bit (MSB) to the leftmost bit. We will use this convention throughout the paper.

Fig. 2. $2 \times 8$ PSK signal set.
To represent a $2 \times 8$ PSK signal point, we form the $2 \times 3$ binary matrix

$$
\boldsymbol{y}=\left[\begin{array}{l}
\boldsymbol{y}_{1} \\
\boldsymbol{y}_{2}
\end{array}\right]=\left[\begin{array}{lll}
y_{1}^{2} & y_{1}^{1} & y_{1}^{0} \\
y_{2}^{2} & y_{2}^{1} & y_{2}^{0}
\end{array}\right] .
$$

Since a total of 6 bits is used to describe a signal point, the unpartitioned signal set (indicated by $\Omega^{0}$ ) has a total of $2^{6}=64$ points. We also say that $\Omega^{0}$ is at partition level $p=0$. It can easily be seen that the MSSD at partition

Fig. 1. Signal set partitioning of 8PSK with natural mapping.
level $p=0$ is $\Delta_{0}^{2}=\delta_{0}^{2}=0.586$ (we use capital $\Delta$ to indicate the MSSD's for $L>1$ and lower case $\delta$ for $L=1$ ). The next partition (at partition level $p=1$ ) divides $\Omega^{0}$ into two subsets of 32 points each. We call $\Omega^{1}$ the subset that contains the all-zero element (i.e., $y_{1}=y_{2}=0$ ). The other subset of 32 points is its coset, labeled $\Omega^{1}(1)$. In forming these two subsets, we would like their MSSD, $\Delta_{1}^{2}$, to be larger than $\Delta_{0}^{2}$. If this were not possible, then we should find a partitioning that leads to a maximum reduction in the number of nearest neighbors within the smaller subsets (i.e., the average number of signal points that are distance $\Delta_{1}^{2}$ away from any point). In principle, the partitioning could be carried out in this heuristic manner.

A more efficient way of partitioning $\Omega^{0}$ is to require the column vectors of $\boldsymbol{y}$, i.e., $\boldsymbol{y}^{i}=\left[y_{1}^{i}, y_{2}^{i}\right]^{T}$, for $0 \leq i \leq 2$, to be codewords in a block code. This representation using block codes is also known as multilevel coding (first described by Imai and Hirakawa [16] and later applied to quadrature amplitude modulation (QAM) by Cusack [17]). To express this mathematically, we need to introduce some further notation. We define $\boldsymbol{C}_{m}$, as that block code which contains the column vectors $\boldsymbol{y}^{i}$, for $0 \leq i \leq 2$. Thus $\boldsymbol{C}_{m_{0}}$ contains the least significant bits of $y_{1}$ and $y_{2}, \boldsymbol{C}_{m_{1}}$ contains the middle bits of $y_{1}$ and $y_{2}$, and so on. The actual value of $m_{i}$ indicates which block code is being used. For $L=2$ only three block codes are of interest to us: $\boldsymbol{C}_{0}$, which is the $(2,2)$ block code with Hamming distance $d_{0}=1$ (and codewords $\left[\begin{array}{ll}0 & 0\end{array}\right]^{T},\left[\begin{array}{ll}0 & 1\end{array}\right]^{T},\left[\begin{array}{ll}1 & 1\end{array}\right]^{T}$, and $\left[\begin{array}{ll}1 & 0\end{array}\right]^{T} ; \boldsymbol{C}_{1}$, which is the ( 2,1 ) block code with Hamming distance $d_{1}=2$ (and codewords $[00]^{T}$ and $[11]^{T}$; and $C_{2}$, which is the $(2,0)$ block code having only one codeword, $\left[\begin{array}{ll}0 & 0\end{array}\right]^{T}$ and Hamming distance $d_{2}=\infty$.

Also, since $C_{m_{i}}$ denotes a block code with $2^{L-m_{i}}$ codewords, we can write that the partition level $p$ is the sum of all the $m_{i}$ that produce the subset $\Omega^{p}$, i.e., $p=\sum_{i=0}^{2} m_{i}$. Since there are $I=\log _{2} M$ bits needed for each MPSK point, $p$ can range from 0 to $I L$ ( 0 to 6 in this case). A shorthand way of writing which column vectors $\boldsymbol{y}^{i}$ belong to which block codes is $\Omega\left(\boldsymbol{C}_{m_{2}}, \boldsymbol{C}_{m_{1}}, \boldsymbol{C}_{m_{0}}\right)$. Thus we can write $\Omega^{0}=\Omega\left(\boldsymbol{C}_{0}, \boldsymbol{C}_{0}, \boldsymbol{C}_{0}\right)$. Since $\boldsymbol{C}_{0}$ contains all possible length 2 binary vectors, then $\Omega^{0}$ is generated.

To obtain the next partition (at level $p=1$ ), we let $\Omega^{2}=\Omega\left(C_{0}, C_{0}, C_{1}\right)$. This partition satisfies our previous comments on partitioning. That is, $\boldsymbol{C}_{1}$ has only two codewords (reducing the number of points to 32 ), and $C_{1}$ contains the all-zero codeword. In partitioning, we also require the property that all the points in $\Omega^{1}$ belong to $\Omega^{0}$ (written as $\Omega^{1} \subset \Omega^{0}$ ). For this example, since $C_{1} \subset C_{0}$, this property is satisfied. This can be stated more generally as $\Omega^{p+1} \subset \Omega^{p}$, for $0 \leq p \leq I L-1$. Thus, if we have two partition levels $p$ and $p^{\prime}$, and $p^{\prime}=p+1$, then $\boldsymbol{C}_{m_{i}^{\prime}} \subseteq \boldsymbol{C}_{m_{i}}$ for $0 \leq i \leq I-1$.

The partition $\Omega^{1}$ is equivalent to forcing the LSB's of both $y_{1}$ and $y_{2}$ to be either zero or one. By inspection of Fig. 2 we can thus see that $\Delta_{1}^{2}=2 \delta_{0}^{2}=1.172$. In fact, we can use a more general expression that gives a lower bound on the MSSD. From [18], [19] we have

$$
\begin{equation*}
\Delta_{p}^{2} \geq \min \left(\delta_{I-1}^{2} d_{m_{t-1}} \cdots, \delta_{1}^{2} d_{m_{1}}, \delta_{0}^{2} d_{m_{0}}\right) \tag{1}
\end{equation*}
$$

where $d_{m_{i}}$ is the Hamming distance of the code $C_{m_{i}}$, for $0 \leq i \leq I-1$. From (1), we obtain for $2 \times 8 \mathrm{PSK}$,

$$
\begin{equation*}
\Delta_{p}^{2} \geq \min \left(4 d_{m_{2}}, 2 d_{m_{1}}, 0.586 d_{m_{0}}\right) \tag{2}
\end{equation*}
$$

For $p=0$ and 1 , we can see that (2) is satisfied with equality. In fact, due to the symmetry of the 8PSK signal set, (2) is an equality for all values of $p$. It can be seen that in partitioning $\Omega^{0}$ into $\Omega^{1}$ and its coset $\Omega^{1}(1)$, we could have formed $\Omega\left(\boldsymbol{C}_{0}, \boldsymbol{C}_{1}, \boldsymbol{C}_{0}\right)$ or $\Omega\left(\boldsymbol{C}_{1}, \boldsymbol{C}_{0}, \boldsymbol{C}_{0}\right)$ instead of $\Omega\left(\boldsymbol{C}_{0}, \boldsymbol{C}_{0}, \boldsymbol{C}_{1}\right)$. However, both these other partitions have $\Delta_{1}^{2}=0.586$ and are therefore not good partitions, since we want $\Delta_{1}^{2}$ to be as large as possible. This is because $d_{\text {free }}^{2}$ can be lower-bounded by $2 \Delta_{1}^{2}$ for many trellis codes [1].

Ignoring for the moment how the cosets are formed, we can partition $\Omega^{1}$ into $\Omega^{2}$ and its coset $\Omega^{2}(2)$, and so on. (The value within the brackets of the coset will be explained in Section II-C.) Every time we partition, we want to make $\Delta_{p}^{2}$ as large as possible. To do this we use the following rule. The $\boldsymbol{C}_{m_{i}}$ that we partition (into $\boldsymbol{C}_{m_{+}+1}$ ) from level $p$ to level $p+1$ should be the $i$ corresponding to the smallest $\delta_{i}^{2} d_{m_{i}}$ at partition level $p$. If there are two or more $\delta_{i}^{2} d_{m_{i}}$ that have the smallest value, we choose the one with the smallest $i$.

Note that once $\boldsymbol{C}_{m_{i}}$ has been partitioned to $\boldsymbol{C}_{2}$ (or $\boldsymbol{C}_{I-1}$ in general), then that particular block code cannot be further partitioned (since it contains only one codeword). Table I illustrates the partitioning of the $2 \times 8 \mathrm{PSK}$ signal set. The arrows show which $\boldsymbol{C}_{m_{,}}$are being partitioned as $p$ is increased. The values of $\Delta_{p}^{2}$ are also shown. Note that at $p=3$, we have $\delta_{i}^{2} d_{m_{i}}=4$ for both $i=1$ and 2 . As indicated by the above rule, $i=1$ is chosen to be partitioned to form $\Omega^{4}$. Even though $\Delta_{4}^{2}=\Delta_{3}^{2}=4$, partition level 4 is still useful for coding since the number of nearest neighbors for $\Omega^{4}$ is less than for $\Omega^{3}$. This will become more apparent when the actual codes are found.

TABLE I
$2 \times 8$ PSK Signal Set Partition

| Partition <br> Level ( $p$ ) | $\Omega^{\prime \prime}$ | Minimum Squared Subset Distance ( $\Delta_{p}^{2}$ ) | Generator $\left(t^{p}\right)^{T}$ |
| :---: | :---: | :---: | :---: |
| 0 | $\Omega\left(C_{0}, C_{0}, C_{0}\right)$ | $\min (4,2,0.586)=0.586$ | [01] |
| 1 | $\Omega\left(C_{0}, C_{0}, C_{1}\right)$ | $\min (4,2,1.172)=1.172$ | $\left[\begin{array}{ll}11\end{array}\right]$ |
| 2 | $\Omega\left(C_{0}, C_{0}, C_{2}\right)$ | $\min (4,2, \infty)=2.0$ | [02] |
| 3 | $\Omega\left(C_{0}, C_{1}, C_{2}\right)$ | $\min (4,4, \infty)=4.0$ | [22] |
| 4 | $\Omega\left(C_{0}, C_{2}, C_{2}\right)$ | $\min (4, \infty, \infty)=4.0$ | [04] |
| 5 | $\Omega\left(C_{1}, C_{2}, C_{2}\right)$ | $\min (8, \infty, \infty)=8.0$ | [4] |
| 6 | $\Omega\left(C_{2}, C_{2}, C_{2}\right)$ | $\min (\infty, \infty, \infty)=\infty$ | - |

The previous rule usually works quite well. For $L=3$, though, some of the best partitions do not follow this rule. Instead, we can allow a $\Delta_{p}^{2}$ to be smaller than the rule proposes, to obtain a larger $\Delta_{p^{\prime}}^{2}$ for some $p^{\prime}>p$ than is possible by following the rule.

## C. Formation of Cosets

Now consider partition level $p=1$. We have shown that there are two subsets, namely $\Omega^{1}$ and its coset $\Omega^{1}(1)$. To obtain $\Omega^{1}(1)$, we must look at how coset codes are derived
from block codes. Recall that $C_{1}$ is the $(2,1)$ block code with Hamming distance $d_{1}=2$. The coset $C_{1}(1)$ of this code is formed by adding modulo-2 a nonzero codeword that belongs to $C_{0}$ but does not belong to $C_{1}$ (called the generator $\tau^{0}$ ) to all the codewords in $C_{1}$. We illustrate this with an example. $C_{0}$ has codewords $\left[\begin{array}{ll}0 & 0\end{array}\right]^{T},\left[\begin{array}{ll}0 & 1\end{array}\right]^{T},\left[\begin{array}{ll}1 & 0\end{array}\right]^{T}$, and $\left[\begin{array}{ll}1 & 1\end{array}\right]^{T}$ (remember that these codewords correspond to column vectors of $\boldsymbol{y}$ ), and $C_{1}$ has codewords $[00]^{T}$ and [11 11 $]^{T}$. Therefore, the generator $\tau^{0}$ could equal $\left[\begin{array}{ll}0 & 1\end{array}\right]^{T}$ or $[10]^{T}$. We arbitrarily choose $\tau^{0}=\left[\begin{array}{ll}0 & 1\end{array}\right]^{T}$. Thus $\boldsymbol{C}_{1}(1)=\boldsymbol{C}_{1} \oplus$ $\tau^{0}=\left\{\left[\begin{array}{ll}0 & 1\end{array}\right]^{T},\left[\begin{array}{ll}1 & 0\end{array}\right]^{T}\right\}$. (In this paper the symbol $\oplus$ will be used to denote modulo-2 (EXCLUSIVE-OR) arithmetic and + to denote integer or modulo- $M$ arithmetic, $M>2$.) Note that if $\tau^{0}=[10]^{T}$, the same coset vectors would have been found, except that they would have been in a different order. Also note that the Hamming distance between codewords in $C_{1}(1)$ is equal to $d_{1}$.

We can also write a general expression for the cosets at partition level $p=1$ as

$$
\begin{equation*}
C_{1}\left(\zeta^{0}\right)=C_{1} \oplus \zeta^{0} \tau^{0} \tag{3}
\end{equation*}
$$

where $\zeta^{0} \in\{0,1\}$. Thus when $\zeta^{0}=0$, we obtain $C_{1}(0) \equiv C_{1}$, and when $\zeta^{0}=1$, we obtain the coset of $C_{1}, C_{1}(1)$. In a similar way we can divide $C_{1}$ into $C_{2}$ and its coset $C_{2}(2)$ and $C_{1}(1)$ into cosets $C_{2}(1)$ and $C_{2}(3)$. Fig. 3 gives an illustration of this partition. For the second generator, we have only one choice, i.e., $\tau^{1}=\left[\begin{array}{ll}1 & 1\end{array}\right]^{T}$. The general expres-

Fig. 3. Partitioning of $L=2$ binary vector space.
sion for the cosets at partition level $p=2$ becomes

$$
\begin{align*}
\boldsymbol{C}_{2}\left(2 \zeta^{1}+\zeta^{0}\right) & =\boldsymbol{C}_{2} \oplus \zeta^{1} \tau^{1} \oplus \zeta^{0} \tau^{0} \\
& =\zeta^{1}\left[\begin{array}{l}
1 \\
1
\end{array}\right] \oplus \zeta^{0}\left[\begin{array}{l}
0 \\
1
\end{array}\right] \tag{4}
\end{align*}
$$

where $\boldsymbol{C}_{2}$ is the all-zero vector and $\zeta^{m} \in\{0,1\}$ for $0 \leq m \leq$ 1. We also note that $C_{2} \subset C_{1} \subset C_{0}$ and that $\tau^{m} \in C_{m}$, but that $\tau^{m} \notin C_{m+1}$, for $0 \leq m \leq 1$.

Since we have shown how the cosets of $C_{m}$ are formed, we can now show how the cosets of $\Omega^{P}$ are formed. We start with the simplest case, the single coset of $\Omega^{1}$, namely, $\Omega^{1}(1)$. In the same way as the block codes are partitioned, we must find a $2 \times 3$ matrix that belongs to $\Omega^{0}$ but does not belong to $\Omega^{1}$. This is called the generator of $\Omega^{1}$ and is labeled $t^{0}$. Since $C_{m_{0}}$ is partitioned in going from $\Omega^{0}$ to $\Omega^{1}$, this implies that $\boldsymbol{t}^{0}=\left[0,0, \tau^{0}\right]$, where 0 is the all-zero
vector $[00]^{T}$, i.e.,

$$
\boldsymbol{t}^{0}=\left[\begin{array}{lll}
0 & 0 & 0 \\
0 & 0 & 1
\end{array}\right]
$$

An alternate notation for $\boldsymbol{t}^{0}$ (using the symbol $\boldsymbol{t}^{0}$ ), is to treat $\boldsymbol{t}^{0}$ as if it represented two integer values $y_{1}$ and $y_{2}$. Thus $t^{0}$ in integer form is $t^{0}=\left[\begin{array}{ll}0 & 1\end{array}\right]^{T}$.

To form the coset $\Omega^{1}(1)$, all that is required is to add $t^{0}$ modulo-2 to all the signal points in $\Omega^{1}$. We write this as

$$
\begin{equation*}
\Omega^{1}\left(z^{0}\right)=\Omega^{1} \oplus z^{0} \boldsymbol{t}^{0} \tag{5}
\end{equation*}
$$

where $z^{0} \in\{0,1\}$ indicates which of the two subsets is being selected. We can see that in coset $\Omega^{1}(1)$, the LSB's of $y_{1}$ and $y_{2}$ are either 0 and 1 or 1 and 0 , respectively. Thus this coset has the same MSSD as $\Omega^{1}$, i.e., $\Delta_{1}^{2}=1.172$. Alternately, $t^{0}$ can be added modulo- $M$ (modulo- 8 in this case) to the signal points in $\Omega^{1}$. With modulo- 8 arithmetic, the LSB's of $y_{1}$ and $y_{2}$ are still added modulo-2, but the LSB's now produce carries which affect the middle and most significant bits. This is denoted as

$$
\begin{equation*}
\Omega^{1}\left(z^{0}\right)=\Omega^{1}+z^{0} t^{0}(\bmod 8) \tag{6}
\end{equation*}
$$

For example, a signal $y=\left[\begin{array}{ll}1 & 3\end{array}\right]^{T}$ (where $y=\left[\begin{array}{ll}y_{1} & y_{2}\end{array}\right]^{T}$ ) in $\Omega^{1}$ becomes [12 1$]^{T}$ with modulo-2 addition of $\boldsymbol{t}^{0}$ to $\boldsymbol{y}$ or [14] ${ }^{T}$ with modulo- 8 addition of $t^{0}$ to $y$. Using either type of arithmetic, we still obtain the required partition, although the ordering of signal points within each coset is different. In constructing rotationally invariant trellis codes, we will find that there is a distinct advantage to using modulo- $M$ arithmetic over modulo-2 arithmetic.

Continuing with the set partitioning, it should be obvious that the next generator is $t^{1}=[11]^{T}$. From Table I, we see that $t^{1}$ corresponds to the generator of $C_{1}$. The expression for the cosets of $\Omega^{2}$ is

$$
\Omega^{2}\left(2 z^{1}+z^{0}\right)=\Omega^{2}+z^{1}\left[\begin{array}{l}
1  \tag{7}\\
1
\end{array}\right]+z^{0}\left[\begin{array}{l}
0 \\
1
\end{array}\right](\bmod 8)
$$

where $z^{i} \in\{0,1\}$, for $0 \leq i \leq 1$. For partition level $p=3$, we choose $t^{2}=\left[\begin{array}{ll}0 & 2\end{array}\right]^{T}$, with $z^{2} \in\{0,1\}$ used to select $t^{2}$. Continuing in the same way, we can partition the signal set until we obtain only a single (4-D) signal point. Thus we can form the equation (using the generators from Table I)

$$
\begin{align*}
y(z)= & {\left[\begin{array}{l}
y_{1} \\
y_{2}
\end{array}\right]=\Omega^{6}(z) } \\
= & z^{5}\left[\begin{array}{l}
4 \\
4
\end{array}\right]+z^{4}\left[\begin{array}{l}
0 \\
4
\end{array}\right]+z^{3}\left[\begin{array}{l}
2 \\
2
\end{array}\right]+z^{2}\left[\begin{array}{l}
0 \\
2
\end{array}\right] \\
& +z^{1}\left[\begin{array}{l}
1 \\
1
\end{array}\right]+z^{0}\left[\begin{array}{l}
0 \\
1
\end{array}\right](\bmod 8) \tag{8}
\end{align*}
$$

where $z=\sum_{i=0}^{5} 2^{i} z^{i}$, with $z^{i} \in\{0,1\}$, for $0 \leq i \leq 5$, and $y(z)$ gives the integer representations of the two 8PSK signal points. The signal set mapping given by $z$ can now be directly used by a convolutional encoder. Since $y_{1}$ and $y_{2}$ can be described in terms of $z$, the signal set mapper can be implemented using simple logic circuits (ExCLUSIVE-OR circuits for modulo-2 addition and binary adders for mod-ulo- $M$ addition). Alternatively, since $z$ can be represented with only six bits, one can use a small ROM. Fig. 4

(b)

Fig. 4. $2 \times 8$ PSK signal set mappers. (a) With modulo- 2 addition (b) with modulo-8 addition.
illustrates two possible signal set mappers for $2 \times 8 \mathrm{PSK}$. Fig. 4(a) shows a mapper using modulo- 2 arithmetic, and Fig. 4(b) shows a mapper using modulo-8 arithmetic.
In general, we can write (8) as

$$
y(z)=\left[\begin{array}{c}
y_{1}  \tag{9}\\
\vdots \\
y_{L}
\end{array}\right]=\Omega^{I L}(z)=\sum_{i=0}^{I L-1} z^{i} t^{i}
$$

where $z=\sum_{i=0}^{I L-1} 2^{i} z^{i}$, with $z^{i} \in\{0,1\}$, for $0 \leq i \leq I L-1$.

The addition in (9) is not specified but may be modulo-2 (using the binary matrix generators), modulo- $M$ (using the integer generators), or a combination of modulo-2 and modulo- $M$. Fig. 5 illustrates the partitioning of $\Omega^{0}$ into $\Omega^{3}$ and its cosets $\Omega^{3}\left(4 z^{2}+2 z^{1}+z^{0}\right)$ for the $2 \times 8 \mathrm{PSK}$ signal set using modulo- 8 addition.

## D. Partitioning $3 \times$ MPSK and $4 \times$ MPSK Signal Sets

In a similar fashion to $2 \times 8 \mathrm{PSK}$, to partition $L \times 8 \mathrm{PSK}$ (for $L>2$ ) requires the partitioning of length $L>2$ block codes. We again look for partitions that have an increasing Hamming distance. For $L=3$, there are two partitions that are interesting.

The first partition has Hamming distances $d_{0}=1, d_{1}^{1}=2$, $d_{2}^{1}=2$, and $d_{3}=\infty$. These Hamming distances correspond to the (3,3), (3,2), $(3,1)$, and (3,0) block codes $\boldsymbol{C}_{0}, \boldsymbol{C}_{1}^{1}, \boldsymbol{C}_{2}^{1}$, and $\boldsymbol{C}_{3}$, respectively, where $\boldsymbol{C}_{3} \subset \boldsymbol{C}_{2}^{1} \subset \boldsymbol{C}_{1}^{1} \subset \boldsymbol{C}_{0}$. Table II-a)

TABLE II

| Binary Generators for $L=3$ and 4 |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| a) $L=3$ (I) |  |  |  |  |
| $m$ | $d_{m}$ | $N_{m}$ | $\left(\tau_{1}^{m}\right)^{T}$ |  |
| 0 | 1 | 3 | $\left[\begin{array}{lll}1 & 1 & 1\end{array}\right]$ |  |
| 1 | 2 | 3 | $\left[\begin{array}{lll}1 & 1 & 0\end{array}\right]$ |  |
| 2 | 2 | 1 | $\left[\begin{array}{lll}0 & 1 & 1\end{array}\right]$ |  |

| b) $L=3$ (II) |  |  |  |
| :---: | :---: | :---: | :---: |
| $m$ | $d_{m}$ | $N_{m}$ | $\left(\tau_{2}^{m}\right)^{T}$ |
| 0 | 1 | 3 | $\left[\begin{array}{llll}0 & 0 & 1\end{array}\right]$ |
| 1 | 1 | 1 | $\left[\begin{array}{llll}0 & 1 & 1\end{array}\right]$ |
| 2 | 3 | 1 | $\left[\begin{array}{llll}1 & 1 & 1\end{array}\right]$ |
|  |  | c) $I=4$ |  |
| $m$ | $d_{m}$ | $N_{m}$ | $\left(\tau^{m}\right)^{T}$ |
| 0 | 1 | 4 | $\left[\begin{array}{lllll}0 & 0 & 0 & 1\end{array}\right]$ |
| 1 | 2 | 6 | $\left[\begin{array}{llll}0 & 1 & 1 & 1\end{array}\right]$ |
| 2 | 2 | 2 | $\left[\begin{array}{llll}0 & 1 & 0 & 1\end{array}\right]$ |
| 3 | 4 | 1 | $\left[\begin{array}{llll}1 & 1 & 1 & 1\end{array}\right]$ |

Fig. 5. Three-level $2 \times 8$ PSK signal set partition.
gives the three generators, $\tau_{1}^{0}, \tau_{1}^{1}$, and $\tau_{1}^{2}$, that were chosen, along with the Hamming distances $\left(d_{m}\right)$ and the number of nearest neighbors ( $N_{m}$ ) at each partition level $m$. The choice was not completely arbitrary, since one of the generators must be the all-ones vector (which in this case is $\tau_{1}^{0}$ ). The reason for this will be explained in Section III.

It is interesting to note that the generator matrix for these block codes can be formed from the generators. In general, a generator matrix $\boldsymbol{G}_{m}$ for an ( $L, L-m$ ) block code $C_{m}$, for $0 \leq m \leq L-1$, can be formed from the generators $\tau^{m}$ to $\tau^{L-1}$, i.e., $G_{m}=\left[\tau^{m}, \tau^{m+1}, \cdots, \tau^{L-1}\right]^{T}$. For example, for the $L=3$ block codes given in Table II-a),

$$
\begin{array}{ll}
\boldsymbol{G}_{0}^{1} & =\left[\begin{array}{lll}
1 & 1 & 1 \\
1 & 1 & 0 \\
0 & 1 & 1
\end{array}\right] \quad \boldsymbol{G}_{1}^{\mathbf{1}}=\left[\begin{array}{lll}
1 & 1 & 0 \\
0 & 1 & 1
\end{array}\right] \\
\boldsymbol{G}_{2}^{1}=\left[\begin{array}{lll}
0 & 1 & 1
\end{array}\right] .
\end{array}
$$

For the other $L=3$ partition, we have $d_{0}=1, d_{1}^{2}=1$, $d_{2}^{2}=3$, and $d_{3}=\infty$. These distances correspond to block codes $\boldsymbol{C}_{0}, \boldsymbol{C}_{1}^{2}, \boldsymbol{C}_{2}^{2}$, and $\boldsymbol{C}_{3}$, where $\boldsymbol{C}_{3} \subset \boldsymbol{C}_{2}^{2} \subset \boldsymbol{C}_{1}^{2} \subset \boldsymbol{C}_{0}$. Table II-b) shows the generators for these codes. Note that $\tau_{2}^{2}$ is the all-ones vector in this case. The advantage of this partition is that $d_{2}^{2}=3$ is larger than $d_{2}^{1}=2$. However, $d_{1}^{2}=1$ is less than $\dot{d}_{1}^{1}=2$.

The partitions of $3 \times 8$ PSK that will be useful for trellis coding are given in Tables III-V. Table III corresponds to

TABLE III

| 7 | $\Omega\left(C_{1}^{1}, C_{3}, C_{3}\right)$ | $\min (8, \infty, \infty)=8.0$ | [440] |
| 8 | $\Omega\left(C_{2}^{1}, C_{3}, C_{3}\right)$ | $\min (8, \infty, \infty)=8.0$ | [044] |
| 9 | $\Omega\left(C_{3}, C_{3}, C_{3}\right)$ | $\min (\infty, \infty, \infty)=\infty$ | - |

the first partition where we try to maximize $\Delta_{p}^{2}$ at each partition level. In Tables IV and V, the second set of block codes are used to increase $\Delta_{2}^{2}$ to 1.757 while $\Delta_{1}^{2}$ decreases to 0.586 . In Table $V, \Delta_{6}^{2}$ increases to 6.0 and $\Delta_{4}^{2}$ decreases to 2.0. Note how $\Delta_{6}^{2}=6.0$ is obtained in Table V. At $p=4$ we have $\Delta_{4}^{2}=\min (4.0,2.0, \infty)$ and at the next partition level, $\Delta_{5}^{2}=\min (4.0,6.0, \infty)=4.0$. Now $C_{m_{2}}$ is partitioned to give $\Delta_{6}^{2}=\min (8.0,6.0, \infty)=6.0$. In the next level we partition $\boldsymbol{C}_{m_{1}}$ to obtain $\Delta_{7}^{2}=8.0$. In Section III the reasons why these latter two partitions are used will be seen more clearly.

For $L=4$ there is only one good way to partition length 4 block codes. Table II-c) gives a summary of the basic parameters. Using Table II-c), we can partition the $4 \times$ 8PSK signal set as shown in Table VI.

For $L \times 4$ PSK and $L \times 16$ PSK we obtain from (1) that

$$
\begin{align*}
& \Delta_{p}^{2} \geq \min \left(4 d_{m_{1}}, 2 d_{m_{0}}\right)  \tag{10a}\\
& \Delta_{p}^{2} \geq \min \left(4 d_{m_{3}}, 2 d_{m_{2}}, 0.586 d_{m_{1}}, 0.152 d_{m_{0}}\right) \tag{10b}
\end{align*}
$$

respectively, where $p=\sum_{i=0}^{I-1} m_{i}$ ( $I=2$ for (10a) and $I=4$ for (10b)). In a similar fashion to $L \times 8$ PSK, the signal set

TABLE VI

partitions can be obtained for $L=2$ to 4 . Tables VII, VIII,
IX give a summary of the partitions for $L \times 4$ PSK, $L \times$ 8PSK, and $L \times 16$ PSK, respectively.

## E. Larger Dimensional MPSK Signal Sets and the Squaring Construction

One way to obtain larger dimensional MPSK signal sets is to take an $L \times$ MPSK signal set partition (with its corresponding MSSD's relabeled as $\delta_{i}^{2}$, for $0 \leq i \leq I L$ ) and
form a $2 L L^{\prime}$ dimensional MPSK signal set which we label as $L^{\prime} \times L \times$ MPSK. Thus, if we have a $2 \times 8$ PSK signal set, the MSSD's $\Delta_{p}^{2}, 0 \leq p \leq 6 L^{\prime}$, for $L^{\prime} \times 2 \times 8$ PSK are given by

$$
\begin{equation*}
\Delta p^{2} \geq \min \left(8 d_{m_{5}}, 4 d_{m_{4}}, 4 d_{m_{3}}, 2 d_{m_{2}}, 1.172 d_{m_{1}}, 0.586 d_{m_{0}}\right) \tag{11}
\end{equation*}
$$

where the $d_{m}$ are the Hamming distances of ( $L^{\prime}, L^{\prime}-m_{i}$ ) block codes. If $L^{\prime}=2$ we can form the $2 \times 2 \times 8$ PSK signal

TABLE X
$2 \times 2 \times 8$ PSK Signal Set Partition

| $p$ | $\Omega^{p}$ | Minimum Squared Subset Distance ( $\Delta_{p}^{2}$ ) | Gen. $\left(t^{P}\right)^{T}$ |
| :---: | :---: | :---: | :---: |

| 9 | $\Omega\left(C_{0}, C_{1}, C_{2}, C_{2}, C_{2}, C_{2}\right)$ | $\min (8,8, \infty, \infty, \infty, \infty)=8.0$ | [1616] |
| 10 | $\Omega\left(C_{0}, C_{2}, C_{2}, C_{2}, C_{2}, C_{2}\right)$ | $\min (8, \infty, \infty, \infty, \infty, \infty)=8.0$ | [032] |
| 11 | $\Omega\left(C_{1}, C_{2}, C_{2}, C_{2}, C_{2}, C_{2}\right)$ | $\min (16, \infty, \infty, \infty, \infty, \infty)=16.0$ | [32 32] |
| 12 | $\Omega\left(C_{2}, C_{2}, C_{2}, C_{2}, C_{2}, C_{2}\right)$ | $\min (\infty, \infty, \infty, \infty, \infty, \infty)=\infty$ | - |

set, which is equivalent to the $4 \times 8 \mathrm{PSK}$ signal set. Table X illustrates this partitioning. Note that the MSSD's obtained are exactly the same as those found with the $4 \times$ 8PSK partitioning given in Table VI. Fig. 6 shows a block diagram of a signal set mapper for the partition of $2 \times 2 \times$ 8PSK. The function $T_{1}$ corresponds to the mapping given by the generators in Table X and $T_{2}$ to the generators in Table I.

Fig. 6. Block diagram of $2 \times 2 \times 8 \mathrm{PSK}$ signal set mapper.

For $L^{\prime}=2$, the above method of obtaining larger dimensional MPSK is essentially equivalent to the squaring or two-construction described by Forney [13]. The cubing or three-construction corresponds to $L^{\prime}=3$. One can continue squaring or cubing various multi-D signal sets in an iterative fashion to obtain many larger dimensional signal sets. If we desire an $L \times$ MPSK signal set, all that is
required is to factor $L$ to determine which constructions are needed. For example, if $L=24$, we could factor this into a $2 \times 2 \times 2 \times 3 \times 8$ PSK signal set. If $L$ is a prime number, then the appropriate length $L$ block codes and their corresponding generators must be found.

Table XI gives the generators for $L=5$ and 7. Also given are the Hamming distances and the number of nearest neighbors for each length $L$ block code. Note that there are three different partitions for $L=5$ and four different partitions for $L=7$. This suggests that the number of useful partitions increases by one for each successive prime number. Thus $L=11$ is expected to have five useful partitions, and so on. These partitions were constructed by hand and probably represent the practical limit of hand constructions. For $L=11$ and above, an algorithmic or mathematical method is required. In forming each partition, we have tried to maximize the Hamming distance and minimize the number of nearest neighbors. For example, the type IV partition maximizes the Hamming distance and minimizes the number of nearest neighbors for the $(7,4)$ block code while the type III partition maximizes the Hamming distance and minimizes the number of nearest neighbors for the $(7,3)$ and $(7,2)$ block codes.

| 0 | 1 | 7 | [1111111] | 1 | 7 | [1111111] | 1 | 7 | [0000001] | 1 |  | [0000001] |
| 1 | 2 | 21 | [0000011] | 1 | 2 | [0000001] | 1 | 1 | [0001000] |  | 3 | [0001000] |
| 2 | 2 | 9 | [0001001] | 2 | 5 | [0000101] | 2 | 6 | [1111111] |  | 1 | [1000000] |
| 3 | 2 | 3 | [0010010] | 2 | 1 | [0100010] | 2 | 2 | [0000101] | 3 | 7 | [0110100] |
| 4 | 2 | 1 | [0001100] | 3 | 3 | [0011100] | 3 | 2 | [0101010] | 3 | 3 | [0011010] |
| 5 | 4 | 2 | [1111000] | 4 | 2 | [0001111] | 4 | 1 | [1100011] | 3 | 1 | [0001101] |
| 6 | 6 | 1 | [0111111] | 6 | 1 | [1110111] | 5 | 1 | [0011111] | 7 | 1 | [1111111] |

For larger dimensions, these methods may produce block codes which do not have the largest possible minimum distance. For example, the largest Hamming distance that can be obtained for the $(24,12)$ coset code is six. However, the $(24,12)$ Golay code has a Hamming distance of eight. For $L=2,3$, and 4 , the block codes are relatively simple. Thus we are fairly certain that the best partitions for these $L \times$ MPSK signal sets have been found.

## III. Trellis Coded Multi-D MPSK Design

This section describes how convolutional codes are constructed for the $L \times$ MPSK signal sets described previously. We first show how to construct signal sets that have good phase rotation properties. Following this, a method used to find good convolutional codes based on the parity check equations is presented.

## A. Construction of Signal Sets

Equation (9) can be used to describe a signal point in an $L \times$ MPSK signal set. The number of bits $z^{j}$ needed to describe each signal point is $I L$. If the LSB is used for coding, we can form a rate $(I L-1) / I L$ code. A more convenient measure of rate is to use the average number of information bits transmitted during each 2-D signal period $T$. This is called the effective rate of the code, $R_{\text {eff }}=$ $(I L-1) / L$ (bit/T). The unit bit/s $/ \mathrm{Hz}$ can also be used (for the actual bandwidth efficiency), but this assumes that perfect Nyquist filtering is used in the receive and transmit filters. Since this is not the case in many practical systems, we make a distinction between the units bit/T and bit/s/Hz.

Other rates can be achieved by setting the $q$ LSB's of the mapping to zero. We do this to ensure that the MSSD's are as large as possible, so that the best codes can be found. In this case (9) can be rewritten as

$$
y^{q}(z)=\left[\begin{array}{c}
y_{1}  \tag{12}\\
\vdots \\
y_{L}
\end{array}\right]=\sum_{j=q}^{I L-1} z^{j-q_{t} t^{j}}
$$

for $0 \leq z \leq 2^{\text {ll-q-1 }}-1,0 \leq q \leq L-1$, and where $y^{q}(z)$ represents a point $z$ in an $L \times$ MPSK signal set such that the first $q$ bits of (9) are zero. As before, we do not restrict the type of addition that is used. We now let $z=$ $\left[z^{I L-q-1}, \cdots, z^{1}, z^{0}\right]$, where $z$ is the binary representation of $z$, and the LSB of $z$ is always the coding bit. This notation ensures that the parity check equations of a convolutional code can always be expressed in terms of the LSB's of $z$ without depending on the type of signal set used or its partitioning. From (12), codes with effective rates $R_{\text {eff }}=(I L-q-1) / L$ can be formed. An upper limit of $q=L-1$ is set because for $q \geq L$ the signal set is partitioned such that $d_{m_{0}}=\infty$, i.e., an $M / 2^{j}$-PSK, for $j \geq 1$, signal set is being used (one exception is the $4 \times 8$ PSK signal set (Table VI) where $d_{m_{0}}=4$ for $q=L$ ). The MSSD's range from $\Delta_{q}^{2}$ to $\Delta_{I L}^{2}$ and the uncoded minimum squared Euclidean distance (MSED) is $\Delta_{q+1}^{2}$, since uncoded trans-
mission uses only half as many signals as coded transmission.

Example 3.1: We can form a rate $4 / 5$ code with an effective rate of $2.0 \mathrm{bit} / \mathrm{T}$ from a $2 \times 8 \mathrm{PSK}(L=2, I=3)$ signal set with $q=1$. Then
$y^{1}(z)=z^{4}\left[\begin{array}{l}4 \\ 4\end{array}\right]+z^{3}\left[\begin{array}{l}0 \\ 4\end{array}\right]+z^{2}\left[\begin{array}{l}2 \\ 2\end{array}\right]+z^{1}\left[\begin{array}{l}0 \\ 2\end{array}\right]+z^{0}\left[\begin{array}{l}1 \\ 1\end{array}\right](\bmod 8)$.
The uncoded MSED is $\Delta_{2}^{2}=2.0$, which is the same as uncoded 4PSK.

## B. Effect of a $360^{\circ} /$ M Phase Rotation on a Multi-D MPSK

 Signal SetUsing modulo- $M$ arithmetic in (12), multi-D signal sets can be constructed such that there are at most $I$ bits in $z$ affected by a signal set rotation of $\Psi \equiv 360^{\circ} / M$. For 4PSK, 8PSK, and 16PSK, this corresponds to rotations of $90^{\circ}, 45^{\circ}$, and $22.5^{\circ}$, respectively. Initially, we consider all possible mapped bits, i.e., $q=0$.

Consider that a $1 \times$ MPSK signal set has been rotated by $\Psi$. Since we are using natural mapping, the integer representation of the rotated signal point is $y_{r}=y+1(\mathrm{mod}$ $M$ ), where $y$ is the integer representation of the signal point before rotation. If $y$ is in binary notation, then

$$
\begin{align*}
& y_{r}^{0}=y^{0} \oplus 1=\overline{y^{0}}  \tag{13a}\\
& y_{r}^{1}=y^{1} \oplus y^{0}  \tag{13b}\\
& y_{r}^{2}=y^{2} \oplus y^{0} \cdot y^{1} \tag{13c}
\end{align*}
$$

If there are $I=\log _{2} M$ bits in a signal set, then we see from (13) that all $I$ bits are affected by a phase rotation of $\Psi$.

Consider the $2 \times 8$ PSK signal set, with the mapping given by (8). The phase rotation equations of this mapping can be determined as follows. From (8), the signal outputs can be written in terms of $z$ as

$$
\begin{align*}
& {\left[\begin{array}{l}
y_{1} \\
y_{2}
\end{array}\right]=\left(4 z^{5}+2 z^{3}+z^{1}\right)\left[\begin{array}{l}
1 \\
1
\end{array}\right] } \\
&+\left(4 z^{4}+2 z^{2}+z^{0}\right)\left[\begin{array}{l}
0 \\
1
\end{array}\right](\bmod 8) \tag{14}
\end{align*}
$$

After a $45^{\circ}$ phase rotation, we have $y_{j, r}=y_{j}+1(\bmod 8)$, for $j=1,2$. From (14), we can form the following phase rotation equations,
$\left[\begin{array}{l}y_{1, r} \\ y_{2, r}\end{array}\right]=\left(4 z^{5}+2 z^{3}+z^{1}+1\right)\left[\begin{array}{l}1 \\ 1\end{array}\right]$

$$
+\left(4 z^{4}+2 z^{2}+z^{0}\right)\left[\begin{array}{l}
1 \\
1
\end{array}\right](\bmod 8)
$$

Note that a 1 is added to the term whose coset is $\left[\begin{array}{ll}1 & 1\end{array}\right]^{T}$. Hence this term "absorbs" the effect of the phase rotation, leaving the remaining term unaffected. As can be seen, bits $z^{5}, z^{3}$, and $z^{1}$ are affected in a manner similar to $y^{2}, y^{1}$, and $y^{0}$ in (13), and bits $z^{4}, z^{2}$, and $z^{0}$ are unaffected by
the phase rotation. Thus we can form the phase rotation equations

$$
\begin{array}{lll}
z_{r}^{0}=z^{0} & z_{r}^{2}=z^{2} & z_{r}^{4}=z^{4}  \tag{15}\\
z_{r}^{1}=z^{1} \oplus 1 & z_{r}^{3}=z^{3} \oplus z^{1} & z_{r}^{5}=z^{5} \oplus z^{1} \cdot z^{3}
\end{array}
$$

If the signal set had been constructed using modulo-2 addition (instead of modulo-8), only $z^{0}$ would have remained unchanged by a $45^{\circ}$ phase rotation.

Using general notation, we can express (14) as

$$
\begin{align*}
& {\left[\begin{array}{c}
y_{1} \\
\vdots \\
y_{L}
\end{array}\right]=\left(2^{I-1} z^{p_{l-1}}+\cdots+2 z^{\left.p_{1}+z^{p_{0}}\right)}\left[\begin{array}{c}
1 \\
\vdots \\
1
\end{array}\right]\right.} \\
& \quad+2^{I-1}\left\{g_{I-1}\right\}+\cdots+2\left\{g_{1}\right\}+\left\{g_{0}\right\}(\bmod M) \tag{16}
\end{align*}
$$

where $p_{j}$, for $0 \leq j \leq I-1$, corresponds to those partition levels where $t^{p}$ equals the vector $\left[2^{j}, 2^{j}, \cdots, 2^{j}\right]^{T}$. The term $g_{j}$, for $0 \leq j \leq I-1$, corresponds to those remaining terms that have at least one (but not all) component in $t^{P}$ with value $2^{j}$. For (14) we would have $p_{0}=1, p_{1}=3$, and $p_{2}=5$. These values of $p_{j}$ are given for all the signal set partitions shown in Tables VII-IX. We can now write the phase rotation equations as

$$
\begin{equation*}
z_{r}^{p_{0}}=z^{p_{0} \oplus 1}, \quad z_{r}^{p_{1}}=z^{p_{1}} \oplus z^{p_{0}}, \quad z_{r}^{p_{2}}=z^{p_{2} \oplus} z^{p_{0}} \cdot z^{p_{1}}, \cdots \tag{17}
\end{equation*}
$$

and for all other partition levels $z_{r}^{p}=z^{p}$.
For $L=2$, there is only one term in each $g_{j}$. However, for $L \geq 3$, there are two or more terms in each $g_{j}$. Since the terms in $g_{j}$ do not contribute to the phase rotational properties of the signal mapping, these terms can be added modulo- 2 before being added modulo $-M$ to the other terms. This is best illustrated with an example. For the $3 \times 8$ PSK (I) signal set in Table III, we have the following mapping equation:

$$
\begin{aligned}
& {\left[\begin{array}{l}
y_{1} \\
y_{2} \\
y_{3}
\end{array}\right]=} z^{8}\left[\begin{array}{l}
0 \\
4 \\
4
\end{array}\right]+z^{7}\left[\begin{array}{l}
4 \\
4 \\
0
\end{array}\right]+z^{6}\left[\begin{array}{l}
4 \\
4 \\
4
\end{array}\right]+z^{5}\left[\begin{array}{l}
0 \\
2 \\
2
\end{array}\right]+z^{4}\left[\begin{array}{l}
2 \\
2 \\
0
\end{array}\right] \\
&+z^{3}\left[\begin{array}{l}
2 \\
2 \\
2
\end{array}\right]+z^{2}\left[\begin{array}{l}
0 \\
1 \\
1
\end{array}\right]+z^{1}\left[\begin{array}{l}
1 \\
1 \\
0
\end{array}\right]+z^{0}\left[\begin{array}{l}
1 \\
1 \\
1
\end{array}\right] \\
&=\left(4 z^{6}+2 z^{3}+z^{0}\right)\left[\begin{array}{l}
1 \\
1 \\
1
\end{array}\right]+4\left\{z^{8}\left[\begin{array}{l}
0 \\
1 \\
1
\end{array}\right] \oplus z^{7}\left[\begin{array}{l}
1 \\
1 \\
0
\end{array}\right]\right) \\
&+2\left\{z^{5}\left[\begin{array}{l}
0 \\
1 \\
1
\end{array}\right] \oplus z^{4}\left[\begin{array}{l}
1 \\
1 \\
0
\end{array}\right]\right\}+\left\{\begin{array}{c}
\left.z^{2}\left[\begin{array}{l}
0 \\
1 \\
1
\end{array}\right] \oplus z^{1}\left[\begin{array}{l}
1 \\
1 \\
0
\end{array}\right]\right\}(\bmod 8) \\
=
\end{array}\right. \\
&\left(4 z^{6}+2 z^{3}+z^{0}\right)\left[\begin{array}{l}
1 \\
1 \\
1
\end{array}\right]+4\left[\begin{array}{c}
z^{7} \\
z^{8} \oplus z^{7} \\
z^{8}
\end{array}\right]+2\left[\begin{array}{c}
z^{4} \\
z^{5} \oplus z^{4} \\
z^{5}
\end{array}\right] \\
&+\left[\begin{array}{c}
z^{1} \\
z^{2} \oplus z^{1} \\
z^{2}
\end{array}\right](\bmod 8) .
\end{aligned}
$$

The reason for this combination of modulo-2 and modulo$M$ arithmetic is that it reduces the number of logic circuits
required in a signal set mapper. For small $I L$, it may be simpler to use ROM's for signal set mapping, but for large IL this dual addition becomes preferable. Fig. 7 gives a block diagram of the three $3 \times 8$ PSK signal set mappers, and Fig. 8 illustrates the mapper for $4 \times 8$ PSK. This combination of modulo- 2 and modulo- $M$ addition has no effect on the MSSD's (at least for $L \leq 4$ ). In a similar manner, we can also obtain the signal set mappers for $L \times 4$ PSK and $L \times 16$ PSK.

(c)

Fig. 7. $3 \times 8$ PSK signal set mappers. (a) Mapper (I). (b) Mapper (II). (c) Mapper (III).

Due to the phase rotational properties and simplified hardware that the combined modulo-2 and modulo- $M$ mapping allows, these are the signal sets that are used to find all the trellis codes in this paper.

Fig. 8. $4 \times 8$ PSK signal set mapper.
We have shown that for $q=0$, the bits that are affected by a phase rotation of $\Psi$ are $z^{p_{j}}$, for $0 \leq j \leq I-1$. For $q>0$ the bits that are affected are $z^{p_{j}-q}$, for $0 \leq j \leq I-1$. However, depending on the signal set, $p_{j}-q$ for some $j$ may be less than zero. If this is true, the minimum phase transparency is $2^{d^{\prime}} \Psi$, where $d^{\prime}$ is the number of terms $p_{j}-q$ that are less than zero, and the number of bits that are affected by a $2^{d^{\prime}} \Psi$ phase rotation is $s^{\prime}=I-d^{\prime}$. For example, the $3 \times 8$ PSK signal set in Table III has $p_{0}=0$, $p_{1}=3$, and $p_{2}=6$. Thus if $q=1$, then $p_{0}-q=-1$, which is less than zero, implying that $d^{\prime}=1$, and thus only $s^{\prime}=I-d^{\prime}=2$ bits are affected by a $2 \Psi=90^{\circ}$ phase rotation. (A phase rotation of $\Psi=45^{\circ}$ of this signal set produces its coset.)

Fortunately, for the codes and signal sets considered in this paper, the above complication does not occur. This is partly due to the fact that for many signal sets with $q=0$, the first $L-1$ LSB's are not affected by a phase rotation of $\Psi$. Since we consider only signal sets with $0 \leq q \leq L-1$, $d^{\prime}=0$ in these cases. For those signal sets where this is not true (e.g., in some $3 \times$ MPSK signal sets), it has been found that the convolutional codes produced are inferior (in either $d_{\text {free }}$ or number of nearest neighbors) to an alternative signal set with $d^{\prime}=0$.

When a signal set is combined with a convolutional encoder we must consider the effect of rotating coded sequences. A similar result to the previously mentioned is obtained so that, depending on the code and the signal set, the signal set can be rotated in multiples of $2^{d} \Psi$ and still produce valid code sequences (where $d$ defines the degree of transparency). The actual determination of $d$ is de-
scribed in Section III-D. The number of bits that are affected by a $2^{d} \Psi$ phase rotation is $s=I-d$.
For $0 \leq q \leq L-1$, the actual bits that are affected by a phase rotation of $\Psi$ are $z^{b_{j}}$, where $b_{j}=p_{j}-q$, for $0 \leq j \leq$ $I-1$. More generally, the bits that are affected by a phase rotation of $2^{d} \Psi$ are $z^{c}$, where $c_{j}=p_{j+d}-q$ for $0 \leq j \leq$ $s-1$. These two separate notations ( $b_{j}$ and $c_{j}$ ) are used because the determination of $d$ depends on $b_{j}$, as will be shown in Section III-D.

## C. The General Encoder System

From the information given thus far, we can now construct a suitable encoder system, as illustrated in Fig. 9. The general encoder system consists of five sections. These sections are the differential precoder, the binary convolutional encoder, the multi-D signal set mapper, the parallel-to-serial converter, and the 2-D signal set mapper. The convolutional encoder is assumed to be in feedback systematic form, as in [1]. That is, $z^{j}(D)=x^{j}(D)$ for $1 \leq j \leq$ $k$, where $D$ is the delay operator and polynomial notation is used. The parity sequence, $z^{0}(D)$, will be some function of itself and the $x^{j}(D)$, for $1 \leq j \leq k$. The parity check equation of an encoder describes the relationship in time of the encoded bit streams. It is a useful and efficient means of describing high rate convolutional codes, since it represents the input/output encoder relationships in a single equation. For an $R=k /(k+1)$ code, the parity check equation is

$$
\begin{array}{r}
H^{\tilde{k}}(D) z^{\tilde{k}}(D) \oplus \cdots \oplus H^{1}(D) z^{1}(D) \oplus H^{0}(D) z^{0}(D) \\
=0(D) \tag{18}
\end{array}
$$

where $\tilde{k}, 1 \leq \tilde{k} \leq k$, is the number of input sequences checked by the encoder, $H^{j}(D)$ for $0 \leq j \leq \tilde{k}$ is the parity check polynomial of $z^{\prime}(D)$, and $O(D)$ is the all zero sequence.
Since the encoder is systematic, the differential precoder codes only those bits which are affected by a phase rotation. The input bits into the encoder which are precoded are denoted $w^{c_{0}}, w^{c_{1}}, \cdots, w^{c_{s-1}}$. If $c_{0}=0$, we replace $w^{0}$ (which does not exist) by $z^{0}$, as shown in Fig. 9 by the dashed line (a different precoder must then be used). For example, an encoder for a rate $8 / 9$ code which uses the $3 \times 8$ PSK (I) signal set given in Table III-a) may (depending on the phase transparency) need this modification. This is because this signal set has $b_{0}=0$, and thus if the code has $d=0$, then $z^{0}$ will need to be precoded. Fig. 10

Fig. 9. General encoder system.

Fig. 10. Differential encoders for general encoder. (a) $C_{0}>0$. (b) $C_{0}=0$.
illustrates the two types of precoders. Note that the storage elements have a delay of $L T$. Fig. 10(a) illustrates the precoder with $c_{0}>0$, where there are $s$ inputs that are precoded. The basic component of the precoder is the modulo- $2^{s}$ adder. For most codes this is the precoder to be used. For the bits that are not precoded, $x^{i}=w^{i}$, for $i \neq c_{j}$.

Fig. 10(b) shows the other case, where $c_{0}=0$ and $s-1$ input bits are precoded (the other precoded bit is $z^{0}$ ). The adder circuit for this case is different from Fig. 10(a), i.e., it is not a modulo- ${ }^{s}$ adder. The Appendix gives the equations for the differential encoder and decoder (for both cases) and an explanation of how these circuits work.

We now summarize the notation and indicate the limits on the parameters used in the search for good codes. For a rate $(I L-q-1) /(I L-q)$ code,
$I$ number of bits in each 2-D signal ( $2 \leq$ $I \leq 4$ ),
$M$ number of signal points in each 2-D signal set,
$L$ number of 2-D signal sets $(1 \leq L \leq 4)$,
$p$ partition level of signal set $(0 \leq p \leq I L)$,
$q$ partition level $p$ where mapping begins ( $0 \leq q \leq L-1$ ),
$z$ signal set mapping parameter ( $0 \leq z \leq$ $2^{p-q}-1$ ),
$k=I L-q-1 \quad$ number of input bits to encoder, number of bits checked by encoder ( $1 \leq$ $\tilde{k} \leq k$ ),
$\Psi=360^{\circ} / M$ minimum phase transparency with $q=0$,
$p_{j} \quad$ bits $z^{p_{j}}$ affected by a $\Psi$ phase rotation with $q=0$,
$d$ degree of phase transparency ( $2^{d} \Psi$, for $0 \leq d \leq I$ ),
$s=I-d$ number of bits in $z$ affected by a $2^{d} \Psi$ phase rotation,
$c_{j}=p_{j+d}-q$ the bits $z^{c_{j}}$ affected by a $2^{d} \Psi$ phase rotation.
There are two types of systematic convolutional encoders that can be constructed. Before proceeding with the description of these encoders, we return to the parity check equation given in (18). As in [1], we define the constraint
length $v$ to be the maximum degree of all the parity check polynomials $H^{j}(D)$, for $0 \leq j \leq \tilde{k}$. For $\tilde{k}<j \leq k$, $H^{j}(D)=0$, since the bits corresponding to these polynomials are not checked by the encoder. The parity check polynomials are of the form

$$
\begin{equation*}
H^{j}(D)=0 \oplus h_{v-1}^{j} D^{v-1} \oplus \cdots \oplus h_{1}^{j} D \oplus h_{0}^{j}, \quad 1 \leq j \leq \tilde{k} \tag{19a}
\end{equation*}
$$

$$
\begin{equation*}
H^{0}(D)=D^{c} \oplus h_{v-1}^{0} D^{v-1} \oplus \cdots \oplus h_{1}^{0} D \oplus 1 \tag{19b}
\end{equation*}
$$

If $\tilde{k}<v$, we let $h_{0}^{j}=0$, for $1 \leq j \leq \tilde{k}$. This insures that the squared Euclidean distance (SED) between paths in a trellis leaving or entering a state is at least $\Delta_{q+1}^{2}$. Thus all codes in this class have an MSED between all possible nonparallel coded sequences of at least $2 \Delta_{q+1}^{2}$. The parallel transitions provide an upper bound on the $d_{\text {free }}$ of a code. A theoretical justification for constructing codes in this manner can be found in [20] where it is shown, using random coding arguments, that these codes have a large free MSED on the average

A minimal systematic encoder can be implemented from (19), since $h_{0}^{0}=1$ [1]. The encoding equations are

$$
\begin{align*}
z^{j}(D)= & x^{j}(D), \quad 1 \leq j \leq k  \tag{20a}\\
z^{0}(D)= & H^{\tilde{k}}(D) x^{\tilde{k}}(D) \oplus \cdots \oplus H^{1}(D) x^{1}(D) \\
& \oplus\left(H^{0}(D) \oplus 1\right) z^{0}(D) \tag{20b}
\end{align*}
$$

An encoder implementation using (20) is shown in Fig. 11.
For all codes with $v=1$ and for some codes with $v>1$, $\tilde{k}=v$. For these codes we cannot restrict $h_{0}^{j}$, for $1 \leq j \leq \tilde{k}$. This is because $\tilde{k}$ checked bits require at least $\tilde{k}$ terms in $H^{j}(D)$, for $1 \leq j \leq \tilde{k}$, that are variable. If there are not enough variables, then there will be some nonzero $\boldsymbol{x}^{\tilde{k}}=$ $\left[x^{\tilde{k}}, \cdots, x^{2}, x^{1}\right]$ such that $\sum_{j=1}^{\tilde{k}} H^{j}(D) x^{j}=0(\bmod 2)$. That is, there will be more than $2^{k-\hat{k}}$ parallel transitions between states in the trellis. To avoid this problem, when $\tilde{k}=v$, we use (19) without any restrictions. In this case, the MSED between all possible nonparallel coded sequences is at least $\Delta_{q}^{2}+\Delta_{q+1}^{2}$, since the MSED between paths leaving a state is $\Delta_{q}^{2}\left(\right.$ since $h_{0}^{j} \in\{0,1\}$, for $\left.1 \leq j \leq \tilde{k}\right)$ and between paths entering a state is $\Delta_{q+1}^{2}\left(\right.$ since $h_{v}^{j}=0$, for $\left.1 \leq j \leq \tilde{k}\right)$.

Fig. 11. Systematic convolutional encoder with $\tilde{k}$ checked bits.

The multi-D signal set mapper can be implemented as described in Section II-D. We must insure that the correct labels are used to map the signal set if $q$ is greater than zero. All the labels in Figs. 4, 7, and 8 assume that $q=0$.

The second to last section of the encoder is the parallel to serial converter, which takes the $L$ groups of $I$ bits and forms a stream with $I$ bits in each group. That is, we assume that the channel is limited to transmitting one 2-D signal point at a time. Finally, the 2-D signal set mapper takes the $I$ bits for each 2-D signal point and produces the required real and imaginary (or amplitude and phase) components for a modulator.

Example 3.2: In this example, we describe how to implement a particular code. The code is used with a $3 \times 8$ PSK signal set. Thus $L=3$ and $I=3$. We also choose $q=1$, so that a 2.33 -bit/T (rate $7 / 8$ ) code is formed. The partition that is used is given in Table IV, from which we obtain $p_{0}=2, p_{1}=3$, and $p_{2}=6$. The code is $90^{\circ}$ transparent, so that $d=1$ and $s=2$. Therefore, $c_{0}=p_{1}-q=2$, and $c_{1}=$ $p_{2}-q=5$. Thus bits $w^{2}$ and $w^{5}$ are precoded using a modulo-4 adder. Since $c_{0}>0$, the precoder given in Fig. 10(a) is used. For this code, $\tilde{k}=2$ and the parity check polynomials are $H^{0}(D)=D^{4} \oplus D^{2} \oplus D \oplus 1, \quad H^{1}(D)=D$, and $H^{2}(D)=D^{3} \oplus D^{2}$. Excluding the parallel-to-serial converter and the 2D signal mapper, the encoder is shown in Fig. 12. This code has 16 states $(v=4)$. Note that the
multi-D signal set mapper does not correspond exactly to Fig. 7(b), since $q=1$.

## D. Convolutional Encoder Effects on Transparency

The convolutional encoder can affect the total transparency of the system. The method used to determine transparency is to examine the parity check equation and the bits affected by a phase rotation. A code is transparent if its parity check equation, after substituting $z^{j}(D)$ with $z_{r}^{j}(D)$ for $0 \leq j \leq \tilde{k}$ (the rotated sequences), remains the same. Normally, at most $I$ bits are affected by a phase rotation i.e., $z^{b_{0}}, \cdots, z^{b_{l-1}}, b_{j}=p_{j}-q$, for $0 \leq j \leq I-1$. We have

$$
\begin{align*}
& z_{r}^{b_{0}}=z^{b_{0}} \oplus 1  \tag{21a}\\
& z_{r}^{b_{1}}=z^{b_{1}} \oplus z^{b_{0}}  \tag{21b}\\
& z_{r}^{b_{2}}=z^{b_{2}} \oplus z^{b_{0}} \cdot z^{b_{1}} \tag{21c}
\end{align*}
$$

Assume that the largest value of $b_{j} \leq \tilde{k}$ is $b_{0}$. This implies that only one term in the parity check equation is affected by a phase rotation. The other bits have no effect since they are not checked by the encoder, i.e., $b_{j}>\tilde{k}$ for $1 \leq$ $j \leq I-1$. The parity check equation after a phase rotation

Fig. 12. Encoder system for rate $7 / 8(2.33 \mathrm{bit} / \mathrm{T}), 3 \times 8 \operatorname{PSK}$ (I) signal set and $90^{\circ}$ transparent code with 16 states and $\tilde{k}=2$.
of $\Psi$ then becomes

$$
\begin{gather*}
H^{\tilde{k}}(D) z^{\tilde{k}}(D) \oplus \cdots \oplus H^{b_{0}}(D)\left[z^{b_{0}}(D) \oplus 1(D)\right] \oplus \cdots \\
\quad \oplus H^{0}(D) z^{0}(D)=0(D) \\
H^{\tilde{k}}(D) z^{\tilde{k}}(D) \oplus \cdots \oplus H^{b_{0}}(D) z^{b_{0}}(D) \oplus \cdots \\
\oplus H^{0}(D) z^{0}(D)=E\left[H^{b_{0}}(D)\right](D) \tag{22}
\end{gather*}
$$

where $E\left[H^{b_{0}}(D)\right]$ is the modulo-2 number of nonzero terms in $H^{b_{0}}(D)$ and $1(D)=\sum_{j=-\infty}^{\infty} D^{j}$ is the all-ones sequence (i.e., $E\left[H^{b_{0}}(D)\right](D)=H^{b_{0}}(D) 1(D)$ ). Thus, if $H^{b_{0}}(D)$ has an even number of terms, (22) is the same as (18). That is, the code is transparent to integer, multiples of $\Psi$ phase rotations of the signal set. However, if $H^{b_{0}}(D)$ has an odd number of terms, then $E\left[H^{b_{0}}(D)\right]=1$ and the coset of the convolutional code is produced. Even though the two equations are closely related, the codes are quite different, and a decoder is not able to produce correctly decoded data from a $\Psi$ phase rotation of the signal set.

Now assume that the first two terms are affected by a phase rotation, i.e., the largest value of $b_{j} \leq \tilde{k}$ is $b_{1}$. The terms in the parity check polynomial $H^{b_{0}}(D) z^{b_{0}}(D) \oplus$ $H^{b_{1}}(D) z^{h_{1}}(D)$ now become

$$
\begin{aligned}
& {\left[H^{b_{0}}(D) \oplus H^{b_{1}}(D)\right] z^{b_{0}}(D) \oplus H^{b_{1}}(D) z^{b_{1}}(D) } \\
& \oplus E\left[H^{b_{0}}(D)\right](D)
\end{aligned}
$$

In this case the parity check equation is different after a phase rotation (even if $E\left[H^{b_{0}}(D)\right]=0$ ). This means that the code is not transparent to a $\Psi$ phase rotation, but it could be transparent to $2 \Psi$ or $4 \Psi$ phase rotations. This is because the phase rotation equations reduce to

$$
\begin{aligned}
& z_{r}^{b_{0}}=z^{b_{0}}, \cdots, z_{r}^{b_{d-1}}=z^{b_{d-1}} \\
& z_{r}^{b_{d}}=z^{b_{d} \oplus 1}, z_{r}^{b_{d+1}}=z^{b_{d+1}} \oplus z^{b_{d}}, \cdots
\end{aligned}
$$

for a $2^{d} \Psi$ phase rotation, where $d=1$ or 2 . If $H^{b_{1}}(D)$ has an even number of terms, then $d=1$. This is because an even number of terms in $H^{b_{1}}(D)$ cancels the effect on $z^{b_{1}}(D)$ when the signal set is rotated by $2 \Psi$. That is, the code is transparent to integer multiples of $2 \Psi$ phase rotations but not to multiples of $\Psi$. If $H^{b_{1}}(D)$ has an odd number of terms, this cancellation effect does not occur, implying that $d=2$ and the phase transparency is $4 \Psi$.
In general, if the largest value of $b_{j} \leq \tilde{k}$ is $b_{f}$, then $d=f+E\left[H^{b_{f}}(D)\right]$. We can then determine those bits $z^{c_{j}}$ which are affected by a $2^{d} \Psi$ phase rotation, i.e., $c_{j}=$ $b_{j+d}=p_{j+d}-q$, for $0 \leq j \leq s-1$, where $s=I-d$.

Example 3.3: For the code given in Example 3.2, $\tilde{k}=2$, $I=3$, and $q=1$. Thus $b_{0}=1, b_{1}=2$, and $b_{2}=5$. Since the largest value of $b_{j} \leq 2$ is $b_{1}$, then $f=1$. Therefore, $d=1+$ $E\left[H^{h_{1}}(D)\right]=1+E\left[D^{3} \oplus D^{2}\right]=1$. Thus the code is $90^{\circ}$ transparent, and $c_{0}=2$ and $c_{1}=5$.

## E. Systematic Search for Good Small Constraint Length Codes

An approximate lower bound for the symbol error probability [1] of a multi-D code is given by

$$
\begin{equation*}
P_{s}(e) \geqslant \frac{N_{\mathrm{free}}}{L} Q\left(\sqrt{\frac{d_{\mathrm{free}}^{2} R_{\mathrm{eff}} E_{b}}{2 N_{0}}}\right) \tag{23}
\end{equation*}
$$

where $E_{b} / N_{0}$ is the energy per information bit to singlesided noise density ratio and $Q(\cdot)$ is the complementary error function. In (23), the division by $L$ normalizes the average number of errors per multi-D signal to that of a 2D signal set.

For each multi-D signal set considered, a number of code rates can be achieved. As $v$ is increased, a comprehensive code search becomes time-consuming due to the greater complexity of each code. We have thus limited our search to $v+\tilde{k} \leq 10$. (The number of checked bits $\tilde{k}$ also affects the complexity of the code search.) As indicated by (23), the criteria used to find the best codes are the free MSED ( $d_{\text {free }}^{2}$ ) and the number of nearest neighbors ( $N_{\text {free }}$ ). We have also included the code transparency $d$ as a criteria in the code search. The code search algorithm that was implemented is similar to that in [1] but with a number of differences, including the extra criteria mentioned above.

The actual code search involves using a rate $\tilde{k} /(\tilde{k}+1)$ code. Thus two separate notations are used to distinguish the rate $k /(k+1)$ encoder and the simplified rate $\tilde{k} /(\tilde{k}+$ 1) encoder. For the rate $k /(k+1)$ encoder, we have $\boldsymbol{x}_{n}=\left[x_{n}^{k}, \cdots, x_{n}^{1}\right]$ (the input to the encoder) and $z_{n}=\left[z_{n}^{k}, \cdots, z_{n}^{1}, z_{n}^{0}\right]$ (the mapped bits or encoder output) at time $n$. Also, $e_{n}=\left[e_{n}^{k}, \cdots, e_{n}^{1}, e_{n}^{0}\right]$ is the modulo-2 difference between two encoder outputs $z_{n}$ and $z_{n}^{\prime}$ at time $n$, i.e., $e_{n}=z_{n} \oplus z_{n}^{\prime}$. Note that there are $2^{k+1}$ combinations of $z_{n}$ and $z_{n}^{\prime}$ that give the same $\boldsymbol{e}_{n}$. For the rate $\tilde{k} /(\tilde{k}+1)$ code, we denote reduced versions of $x_{n}, z_{n}$, and $e_{n}$ as $\tilde{\boldsymbol{x}}_{n}=\left[x_{n}^{\hat{k}}, \cdots, x_{n}^{1}\right], \quad \tilde{z}_{n}=\left[z_{n}^{k}, \cdots, z_{n}^{1}, z_{n}^{0}\right], \quad$ and $\quad \tilde{\boldsymbol{e}}_{n}=$ $\left[e_{n}^{\tilde{k}}, \cdots, e_{n}^{1}, e_{n}^{0}\right]$, respectively.

To find $d_{\text {free }}$ for a particular code, the squared Euclidean weights (SEW) $w^{2}\left(e_{n}\right)$ are used. As defined in [1], $w^{2}\left(e_{n}\right)$ is the MSED between all combinations of $a\left(z_{n}\right)$ and $a\left(z_{n}^{\prime}\right)$ such that $e_{n}=z_{n} \oplus z_{n}^{\prime}$ and $a\left(z_{n}\right)$ is the actual $L \times$ MPSK signal point. This can be defined as

$$
\begin{equation*}
w^{2}\left(e_{n}\right)=\min _{\text {all }:_{n}} d^{2}\left[a\left(z_{n}\right), a\left(z_{n} \oplus e_{n}\right)\right] \tag{24}
\end{equation*}
$$

where $d^{2}\left[a\left(z_{n}\right), a\left(z_{n}^{\prime}\right)\right]$ is the SED between $a\left(z_{n}\right)$ and $a\left(z_{n}^{\prime}\right)$. One can then use the all-zero path as a reference to find $d_{\text {free }}^{2}$ in a code search, i.e.,

$$
\begin{equation*}
d_{\mathrm{free}}^{2}=\min \sum_{n} w^{2}\left(e_{n}\right) \tag{25}
\end{equation*}
$$

where the minimization is over all allowable code sequences with the exception of the all-zero sequence. We can use (25) to find $d_{\text {free }}^{2}$ provided that the minimization of (24) does not depend on $z_{n}^{0}$, as shown by Ungerboeck [1].

Although the minimization of (24) does not depend on $z_{n}^{0}$ for $1 \times$ MPSK signal sets, it cannot be assumed that this also applies to $L \times$ MPSK for $L \geq 2$. By expressing $d^{2}\left[a\left(z_{n}\right), a\left(z_{n} \oplus e_{n}\right)\right]$ directly in terms of $z_{n}$ and $e_{n}$, it can be shown that $3 \times 4 \mathrm{PSK}$ (I), $3 \times 8 \mathrm{PSK}$ (I and II), and $3 \times 16$ PSK (I, II, and III) all depend on $z_{n}^{0}$. This implies that (25) becomes a lower bound in these cases. However, due to the large number of parallel transitions for these codes, we can still determine $d_{\text {free }}^{2}$ (and $N_{\text {free }}$ ) using a slightly modified version of (25).

Since there are $2^{k+1}$ values of $\boldsymbol{e}_{n}$, a total of $2^{2 k+2}$ computations are required to find all the values of $w^{2}\left(\boldsymbol{e}_{n}\right)$. For example, a rate $11 / 12$ code with $4 \times 8$ PSK modulation requires nearly 17 million computations. This can be reduced by letting $z_{n}^{0}=0$ (or 1 ) and minimizing (24) over all $z_{n}=\left[z_{n}^{k}, \cdots, z_{n}^{1}, 0\right]$. This reduces the number of computations to $2^{2 k+1}$. In fact, it is possible to decrease the number of computations even further. Using some difficult algebraic manipulations, it can be shown that the $L$ output bits $z_{n}^{p}$ corresponding to cosets $t^{p}$ with some components equal to $2^{I-1}$ can all be set to zero. For example, the $4 \times 8$ PSK signal set with $q=0$ can have bits $z_{n}^{7}, z_{n}^{9}, z_{n}^{10}$, and $z_{n}^{11}$ all set to zero when minimizing (24). This is due in part to the MPSK signals being antipodal for these values. Thus the total number of computations can be reduced to $2^{2 k-I+1}$.

To reduce the time needed to find $d_{\text {free }}^{2}$, we note that the trellis is equivalent to a rate $\tilde{k} /(\tilde{k}+1)$ code with $2^{k-\tilde{k}}$ parallel transitions. Also, there are $2^{\tilde{k}+1}$ different sets of parallel transitions. If the minimum SEW is found for each of these sets of parallel transitions, the code search is greatly simplified, since the search for a rate $\tilde{k} /(\tilde{k}+1)$ code is all that is needed and $\tilde{k}$ is usually small. Thus the SEW's required for a rate $\tilde{k} /(\tilde{k}+1)$ code search are

$$
\begin{equation*}
w^{2}\left(\tilde{e}_{n}\right)=\min w^{2}\left(e_{n}\right) \tag{26}
\end{equation*}
$$

where the minimization is over all $\left[e_{n}^{k}, \cdots, e_{n}^{\tilde{k}+1}\right]$. We define the free MSED of this rate $\tilde{k} /(\tilde{k}+1)$ code as

$$
\begin{equation*}
\tilde{d}_{\text {free }}^{2}=\min \sum_{n} w^{2}\left(\tilde{\boldsymbol{e}}_{n}\right) \tag{27}
\end{equation*}
$$

where the minimization is over all allowable code sequences ( $\tilde{\boldsymbol{e}}(D)$ ) defined by

$$
\tilde{\boldsymbol{e}}(D)=\tilde{\boldsymbol{e}}_{1} D \oplus \tilde{\boldsymbol{e}}_{2} D^{2} \oplus \cdots \oplus \tilde{\boldsymbol{e}}_{N} D^{N}
$$

for $\tilde{\boldsymbol{e}}_{1}, \tilde{\boldsymbol{e}}_{N} \neq \mathbf{0}$. and $N \geq 2$. The code sequences of length $N=1$ are the parallel transitions, where the MSED is the MSSD of the parallel transitions. A code might have $\tilde{d}_{\text {free }}^{2}$ larger than the MSSD of the parallel transitions, implying that $d_{\text {free }}^{2}$ occurs along the parallel transitions. With $\tilde{\tilde{k}}$ checked bits and a rate $\tilde{k} /(\tilde{k}+1)$ code, the MSSD of the parallel transitions is $\Delta_{q+\tilde{k}+1}^{2}$. Thus we can express $d_{\text {free }}^{2}$ as

$$
\begin{equation*}
d_{\text {frec }}^{2}=\min \left(\tilde{d}_{\text {free }}^{2}, \Delta_{q+\tilde{k}+1}^{2}\right) . \tag{28}
\end{equation*}
$$

The best value of $\tilde{k}$ can be determined from the free MSED of the best code for the previous value of $v$. The search starts with $v=1$ and $\tilde{k}=1$, and we find the code with the best $d_{\text {free }}^{2}$ and $N_{\text {free }}$. We then increase $v$ by one and determine $\tilde{k}$ as follows. If $d_{\text {free }}^{2}$ for the previous best code was $\tilde{d}_{\text {free }}^{2}$, then $\tilde{k}$ remains the same. This is because the limit of the parallel transitions $\Delta_{q+\tilde{k}+1}^{2}$ has not yet been reached and the trellis connectivity needs to be reduced to increase $d_{\text {frec }}^{2}$ or reduce $n_{\text {free }}$. If the previous best code had $d_{\text {free }}^{2}=\Delta_{q+\tilde{k}+1}^{2}$, then $\tilde{k}$ is increased by one from the previous value; otherwise, $d_{\text {free }}^{2}$ and $N_{\text {free }}$ would remain the same. If $\tilde{d}_{\text {free }}^{2}=\Delta_{q+\tilde{k}+1}^{2}$ for the previous best code, then $\tilde{k}$ can remain the same or increase by one. Both values of $\tilde{k}$ should be tried to find the best code. The best
code is then found for this value of $v$ and $\tilde{k}$, and the above process is repeated for each increasing value of $v$.

As can be seen from (24), there may be some values of $\boldsymbol{e}_{n}$ and $z_{n}$ for which $w^{2}\left(e_{n}\right)<d^{2}\left[a\left(z_{n}\right), a\left(z_{n} \oplus e_{n}\right)\right]$. The "number of nearest neighbors" for $\boldsymbol{e}_{n}$ (denoted $m\left(\boldsymbol{e}_{n}\right)$ ) is defined as the average number of times that $w^{2}\left(\boldsymbol{e}_{n}\right)$ equals $d^{2}\left[a\left(z_{n}\right), a\left(z_{n} \oplus \boldsymbol{e}_{n}\right)\right]$. If $w^{2}\left(\boldsymbol{e}_{n}\right)$ equals $d^{2}\left[a\left(z_{n}\right), a\left(z_{n} \oplus \boldsymbol{e}_{n}\right)\right]$ for all values of $z_{n}$, then $m\left(e_{n}\right)=1$. For example, in naturally mapped 8PSK, it is found that for $e_{n}=\left[\begin{array}{ll}0 & 1\end{array}\right]$ and [1111], $d^{2}\left[a\left(z_{n}\right), a\left(z_{n} \oplus e_{n}\right)\right]=0.586$ for four values of $z_{n}$ and 3.414 for the other four values of $z_{n}$. Thus $m\left(e_{n}\right)=$ 0.5 for $\boldsymbol{e}_{n}=\left[\begin{array}{lll}0 & 1 & 1\end{array}\right]$ and $\left[\begin{array}{lll}1 & 1 & 1\end{array}\right]$. For all other values of $\boldsymbol{e}_{n}$, it can be shown that $m\left(e_{n}\right)=1$. Zehavi and Wolf [21] give a general approach to determining the full code distance spectrum, whereas we are only interested in the number of nearest neighbors.

We can state this generally as follows. Let the number of bits in $z_{n}$ that are varied to find $w^{2}\left(e_{n}\right)$ be $b$. Then

$$
\begin{equation*}
m\left(\boldsymbol{e}_{n}\right)=\sum u\left(w^{2}\left(\boldsymbol{e}_{n}\right)-d^{2}\left[a\left(z_{n}\right), a\left(z_{n} \oplus \boldsymbol{e}_{n}\right)\right]\right) 2^{-b} \tag{29}
\end{equation*}
$$

where $u(\cdot)$ is the unit step function and the summation is over all the bits in $z_{n}$ that are varied to find $w^{2}\left(e_{n}\right)$. Normally, $b=k+1$, but this can be reduced to $b=k-L$ for the reasons mentioned previously.
For the simplified rate $\tilde{k} /(\tilde{k}+1)$ code, $m\left(\tilde{e}_{n}\right)$ is the sum of all the $m\left(e_{n}\right)$ for which $w^{2}\left(\tilde{e}_{n}\right)=w^{2}\left(e_{n}\right)$, i.e.,

$$
\begin{equation*}
m\left(\tilde{\boldsymbol{e}}_{n}\right)=\sum u\left(w^{2}\left(\tilde{\boldsymbol{e}}_{n}\right)-w^{2}\left(\boldsymbol{e}_{n}\right)\right) m\left(\boldsymbol{e}_{n}\right) \tag{30}
\end{equation*}
$$

where the summation is over all $\left[e_{n}^{k}, \cdots, e_{n}^{\tilde{k}+1}\right]$. We can think of $m\left(\tilde{\boldsymbol{e}}_{n}\right)$ as the total average number of nearest neighbors along each set of parallel transitions.

The number of nearest neighbors for the MSSD $\Delta_{q+\bar{k}+1}^{2}$ is

$$
\begin{equation*}
N_{\Delta}=\sum u\left(\Delta_{q+\tilde{k}+1}^{2}-w^{2}\left(\boldsymbol{e}_{n}\right)\right) m\left(\boldsymbol{e}_{n}\right) \tag{31}
\end{equation*}
$$

where the summation is over all $\boldsymbol{e}_{n}=\left[e_{n}^{k}, \cdots, e_{n}^{\dot{k}+1}, 0, \cdots, 0\right]$. The number of nearest neighbors for paths with SED $\tilde{d}_{\text {frec }}^{2}$ can be calculated using $m\left(\tilde{e}_{n}\right)$ as follows:

$$
\begin{equation*}
\tilde{N}_{\mathrm{free}}=\sum_{\alpha=1}^{A} \prod_{n=1}^{N_{\alpha}} m\left(\tilde{\boldsymbol{e}}_{n}\right) \tag{32}
\end{equation*}
$$

where $N_{\alpha}$ is the length of a path $\alpha$ that has a SED of $\tilde{d}_{\text {free }}^{2}$ and $A$ is the number of paths that have a SED of $\tilde{d}_{\text {free }}^{2}$. If $d_{\text {free }}^{2}$ occurs along the parallel transitions, $N_{\text {free }}=N_{\Delta}$, and we define the next nearest free SED and number of nearest neighbors as $d_{\text {nex }}^{2}=\tilde{d}_{\text {frec }}^{2}$ and $N_{\text {next }}=\tilde{N}_{\text {free }}$, respectively. (Note that $d_{\text {next }}^{2}$ and $N_{\text {next }}$ may not be the true next nearest paths, since there may be some closer paths occurring along the parallel transitions.) When there are several codes that have the same free MSED and number of nearest neighbors, the "next nearest" values are used in code selection. When $d_{\text {free }}^{2}$ occurs along paths with SED $\tilde{d}_{\text {free }}^{2}, N_{\text {free }}=\tilde{\tilde{N}}_{\text {frec }}$. The next nearest values in this case are not given in the code tables. If $\tilde{d}_{\text {free }}^{2}=\Delta_{q+\tilde{k}+1}^{2}$, then $N_{\text {free }}=$ $N_{\Delta}+\tilde{N}_{\text {free }}$.

Example 3.4: In Example 3.2 we have a $\tilde{k}=2, q=1$, rate $7 / 8(2.33 \mathrm{bit} / \mathrm{T})$ code with a $3 \times 8 \mathrm{PSK}$ (II) signal set. After determining the mapping of the signal set, (24) was
used to find the SEW's for each signal point. Equation (26) determines the $w^{2}\left(\tilde{\boldsymbol{e}}_{n}\right)$ used to find the best rate $2 / 3$ codes. For these codes $d_{\text {free }}^{2}=\Delta_{q+\tilde{k}+1}^{2}=\Delta_{4}^{2}=4.0$. Using (31) we determined that $N_{\text {free }}$ is 15 (after normalizing, there are only five paths per 2-D symbol). In the code search for the best rate $2 / 3$ codes, there were many codes that had $d_{\text {next }}^{2}=\tilde{d}_{\text {free }}^{2}=4.343$. Thus (32) was used to determine $N_{\text {next }}$ for each best code. Table XII gives the values of $w^{2}\left(\tilde{e}_{n}\right)$ and $m\left(\tilde{e}_{n}\right)$ for each $\tilde{e}_{n}$ used in the code search. The best code with a transparency of $90^{\circ}$ was found to have $N_{\text {next }}=$ 24.

| 110 | 1.757 | 4 |
| 111 | 0.586 | 1 |

To reduce the number of codes that must be tested in our code search algorithm, rejection rules were used. As in [ 1 , rule 1], time reversal of the parity check polynomials was used to reject codes. Even though $w^{2}\left(\tilde{e}_{n}\right)$ and $m\left(\tilde{e}_{n}\right)$ are used to find the best codes, [1, rule 2] can still be exploited, provided that $w^{2}\left(\tilde{e}_{n}\right)=\Delta_{r\left(\tilde{e}_{n}\right)+q}^{2}$, where $r\left(\tilde{e}_{n}\right)$ is the number of trailing zeros in $\tilde{\boldsymbol{e}}_{n}$. When this is not true, it may still be possible to find some combinations of the parity check polynomials that can be rejected (this was also implemented in our code search). Finally, [1, rule 3] was also used to eliminate codes.

In the code search a rate $\tilde{k} /(\tilde{\tilde{k}}+1)$ code is searched for a particular $v$. Before finding $\tilde{d}_{\text {free }}^{2}$, the code search program. checks to make sure that the code only produces sequences with length $N \geq 2$. If for some input $\tilde{\boldsymbol{x}}_{n} \neq \mathbf{0}$, the inputs to the systematic encoder are all zero, the state of the encoder goes from one state to the next as if a zero input had occurred. Thus parallel transitions will occur in the rate $\tilde{k} /(\tilde{k}+1)$ code, which should not have parallel transitions. Therefore, codes at level $i, 1 \leq i \leq \tilde{k}$, were rejected in the code search if for some $\left[x^{i}, \cdots, x^{1}\right] \neq \mathbf{0}$, $\sum_{j=1}^{i} x^{j} H^{j}(D)($ modulo 2$)=0(D)$.

Two programs were used in the code search, one for codes with $v>\tilde{k}$ and the other for codes with $v=\tilde{k}$. For specific values of $I, L$, and $q, y^{q}(z)$, for $0 \leq z \leq 2^{I L-q}-1$, was generated using the coset representative $t^{p}$, for $0 \leq$ $p \leq I L-1$, that are given in Tables VII-IX. The squared Euclidean weights $w^{2}\left(\boldsymbol{e}_{n}\right)$ were then calculated using (24) for all $e_{n}$. Since the value of $\tilde{k}$ can change with each $v$, $w^{2}\left(\tilde{\boldsymbol{e}}_{n}\right)$ and $m\left(\tilde{\boldsymbol{e}}_{n}\right)$ were computed, if necessary, as the program went from the smallest to the largest $v$.

The code search used the various rejection rules before the time consuming tasks of finding $\tilde{d}_{\text {free }}^{2}$ (using the bidi-
rectional search algorithm [22]) and $N_{\text {free }}$ (using a technique based on the Viterbi algorithm). The rejection rules were organized so that the best codes for each of the two possible phase transparencies were found. The code search found those codes that had the largest free distance (for a particular transparency). If a code was found to have its free MSED equal to or greater than the previous best code, $\tilde{N}_{\text {free }}$ was determined, and this code was listed if either its $\tilde{d}_{\text {free }}^{2}$ or $\tilde{N}_{\text {free }}$ had improved over the previous best code.

The octal code generators were then listed along with their $\tilde{d}_{\text {free }}^{2}, \tilde{N}_{\text {free }}$, and phase transparency $d$. A small list of codes was produced (for each code search) from which the best codes could be chosen. Every time that $\tilde{k}$ is increased by one in the code search (which is done automatically), the program determines and lists $\Delta_{q+\tilde{k}+1}^{2}$ and $N_{\Delta}$ for use in the code tables.

The asymptotic coding gain $\gamma$ of each code compared to the uncoded case, as shown in the code tables, is

$$
\begin{equation*}
\gamma=10 \log _{10}\left(d_{\text {free }}^{2} / d_{u}^{2}\right) \quad \mathrm{dB} \tag{33}
\end{equation*}
$$

where $d_{u}^{2}$ is the smallest MSSD of an equivalent uncoded 2-D or multi-D scheme. In nearly all cases, $d_{u}^{2}=\Delta_{q+1}^{2}$. For codes with a noninteger $R_{\text {eff }}$, no equivalent $1 \times$ MPSK scheme exists which has the same $R_{\text {eff }}$, and so the equivalent uncoded multi-D signal set is used instead. For the $4 \times 8$ PSK signal set with $q=3, R_{\text {eff }}=2 \mathrm{bit} / \mathrm{T}$. Thus a natural comparison would be against uncoded 4PSK, which has $d_{u}^{2}=2$. (In this case, $\Delta_{q+1}^{2}=2.343$, which is inconsistent with other codes that also have $R_{\text {eff }}=2$ bit/T.) The asymptotic coding gains compared to uncoded ( $M / 2$ )-PSK are found by adding to $\gamma$ the appropriate correction factor

$$
\begin{equation*}
\gamma_{M / 2}=10 \log _{10}\left(\frac{R_{\mathrm{eff}}}{(I-1)} \frac{d_{u}^{2}}{\delta_{1}^{2}}\right) \quad \mathrm{dB} \tag{34}
\end{equation*}
$$

as shown in the code tables. The transparency (in degrees) is also given for each code. The parity check polynomials are expressed in octal notation in the code tables, e.g., $H^{0}(D)=D^{6}+D^{4}+D^{2}+D+1 \equiv\left(\begin{array}{lll}001 & 010 & 111\end{array}\right)_{2} \equiv$ (127) ${ }_{8}$.

In Tables XIII, XXIII, and XXXIII codes for TC- $1 \times$ 4PSK (rate $1 / 24 \mathrm{PSK}$ ), TC- $1 \times 8$ PSK (rate $2 / 38$ PSK),

$$

and TC-1 $\times 16 \mathrm{PSK}$ (rate $3 / 416 \mathrm{PSK}$ ), respectively, are presented. These tables give the best code for each phase transparency, which (to the best of our knowledge) have not been previously published. The best codes, without regard for phase transparency, were original published by Odenwalder [15] for 4PSK (with the codes in non-systematic form), by Ungerboeck [1], [4] for 8PSK, and Wilson et al. [6] for 16PSK.

Tables XIV, XV, XXIV, XXV, XXXIV, and XXXV list the TC- $2 \times 4 \mathrm{PSK}$ codes (rates of 1.5 and $1.0 \mathrm{bit} / \mathrm{T}$ ), the TC- $2 \times 8$ PSK codes ( 2.5 and $2.0 \mathrm{bit} / \mathrm{T}$ ), and the TC- $2 \times$ 16PSK codes ( 3.5 and 3.0 bit/T). Tables XVI-XVIII,

${ }^{\mathrm{a}} \gamma_{2}=0.0 \mathrm{~dB} ; R_{\text {cff }}=1.00 \mathrm{bit} / \mathrm{T}, q=2, d_{u}^{2}=4.0, N_{u}=1(1 \times 2 \mathrm{PSK})$.

XXVI-XXVIII, and XXXVI-XXXVIII list the TC- $3 \times$ 4PSK codes ( $1.67,1.33$, and $1.0 \mathrm{bit} / \mathrm{T}$ ), the TC- $3 \times 8$ PSK codes ( $2.67,2.33$, and $2.0 \mathrm{bit} / \mathrm{T}$ ), and the TC- $3 \times 16 \mathrm{PSK}$ codes (3.67, 3.33, and 3.0 bit/T), respectively. Tables XIX-XXIII, XXIX-XXXIII, and XXXIX-XLII list the TC $-4 \times 4$ PSK codes ( $1.75,1.5,1.25$, and $1.0 \mathrm{bit} / \mathrm{T}$ ), the TC $-4 \times 8$ PSK codes ( $2.75,2.5,2.25$, and 2.0 bit $/ \mathrm{T}$ ), and the TC- $4 \times 16$ PSK codes $(3.75,3.5,3.25$, and $3.0 \mathrm{bit} / \mathrm{T}$ ), respectively.

Equivalent $R=5 / 6, \mathrm{TC}-2 \times 8 \mathrm{PSK}(2.5 \mathrm{bit} / \mathrm{T})$ codes with up to 16 states have been found independently by Lafanechére and Costello [8] and by Wilson [9], although with reduced phase transparency. The two-state TC- $L \times$ 8PSK and TC- $L \times 16$ PSK codes were also found by Divsalar and Simon [23].

parency is not required, one should choose the less phase transparent code to obtain the maximum performance for a given complexity.

## F. Decoder Implementation

When the Viterbi algorithm is used as the decoder, a measure of decoding complexity is given by $2^{v+k} / L$. This is the number of distinct transitions in the trellis diagram
for any TCM scheme normalized to a 2-D signal set. The maximum bit rate of the decoder is $k f_{d}$, where $f_{d}$ is the symbol speed of the decoder. Since $k$ is quite large for multi-D signal sets (at least ( $I-1$ ) $L$ ), high bit rates can be achieved. For example, a Viterbi decoder has been constructed for a rate $7 / 9$ periodically time-varying trellis code (PTVTC) with $v=4, \tilde{k}=2$, and 8PSK modulation [24]. This decoder has $f_{d}=60 \mathrm{MHz}$ and a bit rate of 140 $\mathrm{Mbit} / \mathrm{s}$. However, with the equivalent rate $7 / 8$ code with $3 \times 8$ PSK modulation, the bit rate will be $L=3$ times as fast, i.e., $420 \mathrm{Mbit} / \mathrm{s}$. The branch metric calculator, though, will be more complicated due to the larger number of parallel transitions between states. Alternatively, one could build a decoder operating at a 20 MHz speed and achieve the same bit rate of $140 \mathrm{Mbit} / \mathrm{s}$. In addition to providing decreased decoder complexity, this multi-D code has an asymptotic coding gain which is 0.56 dB greater and is $90^{\circ}$ transparent, compared with a $180^{\circ}$ transparency for the PTVTC [25].
Although the decoding complexity of the Viterbi algorithm is measured in terms of $2^{p+\tilde{k}} / L$, for multi-D schemes the complexity of subset (parallel transition) decoding must also be taken into account due to the large number of parallel transitions.
The Viterbi decoder must find which of the $2^{k-\tilde{k}}$ parallel transitions is closest, in a maximum likelihood sense, to the received signal. A brute-force method would be to determine the metric for each of the $2^{k-\tilde{k}}$ paths and then find the minimum. This would involve at least $2^{k-\grave{k}}-1$ comparisons. Since there are $2^{\tilde{k}+1}$ sets of parallel transitions, a total of $2^{k+1}-2^{k+1}$ comparisons would be required. For large $k$ and small $\tilde{k}$, this is an unacceptably large number of computations.
Fortunately, as shown in [13] for binary lattices, it is possible to reduce greatly the number of computations

required. In fact, the decoding scheme becomes very similar to Viterbi decoding except that finite length sequences are used.

To illustrate this we will present the decoding scheme for TC- $2 \times 8$ PSK parallel transitions with $\tilde{k}=2$ and an efficiency of $2.5 \mathrm{bit} / \mathrm{T}$ (a rate $5 / 6$ code). There are eight sets of parallel transitions, with eight paths in each set. Fig. 13 shows the parallel transition decoding trellis for $\tilde{z}=\left[\begin{array}{ll}0 & 0\end{array}\right]$ (i.e., the LSB's are set to zero). In Fig. 1 we use the notation A0 to indicate the whole 8PSK signal set, which divides into B0 and B1 (4PSK signal sets rotated $45^{\circ}$ from each other). B0 divides into C0 and C2 (2PSK signal sets rotated $90^{\circ}$ from each other), and B1 divides into C 1 and C 3 . This notation is also used in [1] for partitioning an 8PSK signal set. Each segment in Fig. 13 thus represents two parallel lines. The length of this trellis equals the dimensionality $L=2$ of the signal set.

Fig. 13. Parallel transition decoding trellis for $\tilde{z}=\left[\begin{array}{lll}0 & 0 & 0\end{array}\right]$ and $2 \times 8$ PSK signal set.

The path $\mathrm{C} 0 \times \mathrm{C} 0$ corresponds to those four paths that have $z^{3}=0$ and $\mathrm{C} 2 \times \mathrm{C} 2$ corresponds to those four paths that have $z^{3}=1$, giving a total of eight paths. To decode, hard decisions can be made for C 0 and C 2 for each time period, from which the values of $z^{4}$ and $z^{5}$ can be determined. For example, say that $\mathrm{C} 0 \times \mathrm{C} 0$ decodes into the points 04 , with a metric of $m_{0}$, and $\mathrm{C} 2 \times \mathrm{C} 2$ decodes into the points 66 , with a metric of $m_{1}$, where the metrics are the sum of the Euclidean distances (or log-likelihood met-
rics for a quantized channel) from the first and second received points. After comparing the two metrics, if $m_{0}<$ $m_{1}$, then $z^{3}=0$ and the point 04 would give $z^{4}=1$ and $z^{5}=0$ (see Table I). If $m_{0}>m_{1}$, then $z^{3}=1$, and the point 66 would give $z^{4}=0$ and $z^{5}=1$. This is equivalent to the add-compare-select (ACS) operation within a Viterbi decoder.

To decode the other sets of parallel transitions, the cosets formed by $z^{0}, z^{1}$, and $z^{2}$ can be added to the trellis paths $\mathrm{C} 0 \times \mathrm{C} 0$ and $\mathrm{C} 2 \times \mathrm{C} 2$ to form the required trellis. This is illustrated in Fig. 14, where the ending state in the trellis indicates which set of parallel transitions is being decoded. This example involves a total of eight hard comparisons and eight ACS-type comparisons. These 16 comparisons compare with the 56 comparisons required in a brute force approach, a 3.5 times reduction.

Fig. 14. Full parallel transition decoding trellis for $2 \times 8$ PSK signal set.
The above maximum likelihood method can be applied to other codes where a Viterbi-like decoder can be used to decode the parallel transitions. With this method the complexity of decoding the parallel transitions can approach
the complexity of the rate $\tilde{k} /(\tilde{k}+1)$ Viterbi decoder. A simpler approach may be with large lookup tables using ROM's. The ROM itself would output the $k-\tilde{k}$ bits of the chosen path, along with the branch metric for that path. For the TC- $2 \times$ PSK example given previously, we could use one ROM for each of parallel transitions. If the ROM's had 8 -bit words, then three bits could be used for the decision, and the remaining five bits for the branch metric. A total of eight ROM's would then be required, one for each set of the parallel transitions.

When using ROM's, it is desirable to reduce the number of bits $b$ required to represent each received 2-D signal point, since there are a total of $b L$ bits required to address the ROM. One way to reduce $b$ is to convert the "checkerboard" (rectangular) type decision boundaries that result from separate quantization of the in-phase $I$ and quadrature $Q$ components to "dartboard" (radial) type decision boundaries. For example, if four bits are used in $I$ and $Q$ for an 8PSK signal with checkerboard decision boundaries, a dartboard pattern as shown in Fig. 15 may be used instead with a total of five bits to represent each point (a reduction of three bits). A ROM may be used to do the conversion, or the dartboard pattern already may be available as polar coordinates from a digital demodulator.

Fig. 15. Dartboard decision boundaries for 8PSK ( 32 regions).
A problem with TC- $L \times$ MPSK is the need to synchronize the decoder with the $L$ 2-D symbols on each trellis branch. For $q=0$, most codes are fully transparent. The decoder performance can then be used to find the correct synchronization with the received sequence. For $q>0$, many codes are not fully transparent, and the decoder will need to synchronize to one of the $2^{d} L$ possibilities (which can be quite large for some codes). However, one can take advantage of the fact that not all signal points are used for $q>0$. For example, the $2 \times 8 \mathrm{PSK}$ signal set with $q=1$ consists of the signal sets $\mathrm{B} 0 \times \mathrm{B} 0$ or $\mathrm{B} 1 \times \mathrm{B} 1$. The synchronizer would find the smallest distance between a received pair of points and the expected signal set. These distances would then be accumulated over a sufficient length of time to make a reliable decision on the symbol timing.

If we let each signal point be represented by its phase (since the amplitude is constant for 8 PSK ), we can write $\mathrm{B} 0=\left\{0^{\circ}, 90^{\circ}, 180^{\circ}, 270^{\circ}\right\}$, and $\mathrm{B} 1=\left\{45^{\circ}, 135^{\circ}, 225^{\circ}\right.$, $\left.315^{\circ}\right\}$. Let $\phi_{n}^{1}$ and $\phi_{n}^{2}$ represent the phase of the first and second received symbols, respectively. The synchronizer distance metric is then given by

$$
\boldsymbol{\Phi}_{n}=\min _{i \in\{0,1\}}\left(\min _{\alpha \in B i}\left|\phi_{n}^{1}-\alpha\right|+\min _{\beta \in B i}\left|\phi_{n}^{2}-\beta\right|\right)
$$

In the synchronized noiseless case, $\boldsymbol{\Phi}_{n}$ will equal zero. In the nonsynchronized noiseless case, there are two possible outcomes for $\boldsymbol{\Phi}_{n}$, i.e., complete matchup ( $\boldsymbol{\Phi}_{n}=0^{\circ}$ ) and only one signal is matched $\left(\Phi_{n}=45^{\circ}\right)$. If each possibility is equally likely, then the average value of $\Phi_{n}$ is $22.5^{\circ}$. With noise, $\boldsymbol{\Phi}_{n}$ can be accumulated over a sufficient length of symbols to take advantage of this average phase distance between the nonsynchronized and synchronized cases to determine symbol synchronization reliably. This symbol synchronization is independent of the Viterbi decoder, so the decoder must only determine phase synchronization.

## G. Discussion

To make a comparison of all the codes listed, a plot of nominal coding gain $\gamma^{*}=10 \log _{10} d_{\text {free }}^{2}$ versus complexity $\left(\beta=\log _{2}\left(2^{v+\tilde{k}} / L\right)=v+\tilde{k}-\log _{2} L\right)$ for each code found is made. These plots are given in Fig. 16 for effective rates of 1.0 (with 4PSK modulation), 2.0 (8PSK), and 3.0 bit/T (16PSK), Fig. 17 for effective rates of 1.5 (4PSK), 2.5 (8PSK), and 3.5 bit/T (16PSK), and Fig. 18 (for the remaining rates). (Note that these graphs do not take into account the additional complexity due to parallel transitions.) Some one-state ("uncoded") codes are included as well. These one-state codes correspond to block-coded (or multilevel) schemes that have recently become an active research area [26]-[34]. Although the multi-D one-state codes have negative complexity (compared to trellis codes), they can achieve coding gains above 0 dB .

Fig. 16. Plot of $10 \log _{10} d_{\text {free }}^{2}$ versus complexity $\beta$ for $R_{\text {eff }}=1.0,2.0$, and $3.0 \mathrm{bit} / \mathrm{T}$.

Fig. 17. Plot of $10 \log _{10} d_{\text {free }}^{2}$ versus complexity $\beta$ for $R_{\text {eff }}=1.5,2.5$, and $3.5 \mathrm{bit} / \mathrm{T}$

Fig. 18. Plot of $10 \log _{10} d_{\text {free }}^{\prime}$ versus complexity $\beta$ for $R_{\text {eff }}=1.25,1.33$, $1.67,1.75,2.25 .2 .33,2.67,2.75,3.25,3.33,3.67$, and $3.75 \mathrm{bit} / \mathrm{T}$.

Note from Fig. 16 for TC- $L \times 8 \mathrm{PSK}, R_{\text {eff }}=2.0 \mathrm{bit} / \mathrm{T}$, and $v=1$, that as $L$ increases the complexity decreases and $\gamma^{*}$ increases, eventually reaching 6.0 dB for $L=4$. Thus, for the 8D signal set, the complexity factor can be reduced by a factor of four, while maintaining $\gamma^{*}$, compared to the TC- $1 \times 8$ PSK code with $v=2$. Beyond $\beta=4$ (and $\gamma^{*}=6.0 \mathrm{~dB}$ ), increases in asymptotic coding gain are achieved with the new codes that have been found. With $L=4$, a ceiling of $\gamma^{*}=9.0 \mathrm{~dB}$ will be reached due to the nature of the set partitioning. It would seem that very complex codes are required ( $\beta \geq 15$ ) if this 9.0 dB limit is to be exceeded.
Fig. 16 also shows the $L \times 16$ PSK codes with effective rates of $3.0 \mathrm{bit} / \mathrm{T}$. For small $\beta$, the same effect observed for TC- $L \times 8$ PSK and 2.0 bit $/ \mathrm{T}$ occurs. That is, $\beta$ decreases and $\gamma^{*}$ increases as $L$ increases. Between $\beta=3$ and $\beta=9$, the $L=1$ and $L=2$ codes are very close.

Fig. 18 illustrates the wide range of performance that can be achieved with the codes found. One can choose from a high-rate code with 3.75 bit/T (but requiring a large amount of power) to a low-rate code with $1.25 \mathrm{bit} / \mathrm{T}$. In choosing a code, a designer may start with a required $R_{\text {eff }}$ to obtain a certain bit rate through a bandwidth constrained channel. A trade-off can then be made between decoder complexity and the reduction in SNR that can be achieved with the codes found. Simulations or theoretical calculations of a few selected codes may also be made to obtain a more realistic assessment of the performance available.

Note that many codes have the same asymptotic coding gain for increasing complexity. In reality, these codes do increase in performance with increasing complexity due to a decrease in number of nearest neighbors. This is especially noticeable for low SNR where the effect of nearest neighbors becomes more important.

## IV. Conclusion

An efficient method of partitioning multidimensional MPSK signal sets has been presented that leads to easily implemented multi-D signal set mappers. When these signal sets are combined with trellis codes to form a rate $k /(k+1)$ code, significant asymptotic coding gains in comparison to an uncoded system are achieved. These codes provide a number of advantages compared to trellis codes with 2-D signal sets. Most importantly, $R_{\text {eff }}$ can vary from $I-1$ to $I-(1 / L)$ bit/T, allowing the coding system designer a greater choice of data rates without sacrificing data quality. As $R_{\text {eff }}$ approaches $I$, though, increased coding effort (in terms of decoder complexity) or higher SNR is required to achieve the same data performance.

The analytical description of multi-D signal sets in terms of block code cosets, and the use of systematic convolutional encoding, has resulted in an encoder design (from the differential encoder to the 2-D signal set mapper) that allows many good codes to be found. This approach has also led to the construction of signal sets
that allow codes to be transparent to multiples of $360^{\circ} / M$ phase rotations. In general, increasing phase transparency usually results in lower code performance, due to more nearest or next nearest neighbors or smaller free distance.

Another advantage is decoder complexity. As a Viterbi decoder decodes $k$ bits in each recursion of the algorithm, the large values of $k$ of codes using multi-D signal sets allows very high bit rates to be achieved (compared to convolutional codes that map only into a 2-D signal set). The large number of branch metric computations can be reduced either through the use of a modified Viterbi algorithm or large lookup tables. A method has been presented that uses the redundancy in some signal sets to achieve symbol synchronization at the decoder for codes that are not fully transparent.

Rate $k /(k+1)$ TC- $L \times$ MPSK codes also have the advantage of being useful as inner codes in a high rate concatenated coding system with Reed-Solomon (RS) outer codes over $\operatorname{GF}\left(2^{k}\right)$. If the inner decoder makes errors, one trellis branch error will exactly match one symbol in the outer RS codeword. It is shown in [14] that the symbol oriented nature of TC- $L \times$ MPSK inner codes can provide an improvement of up to 1 dB in the overall performance of a concatenated coding system when these codes replace bit oriented TC- $1 \times$ MPSK inner codes of the same rate.

Substituting (A.3) into (A.4), we obtain

$$
\begin{align*}
w_{r}(D)= & ((S-1) D+1)(x(D)+1(D)) & & (\bmod S) \\
= & ((S-1) D+1) x(D) & & \\
& +((S-1) D+1) 1(D) & & (\bmod S) \\
= & w(D)+(S-1) 1(D)+1(D) & & (\bmod S) \\
= & w(D)+(S) 1(D) & & (\bmod S) \\
= & w(D) & &
\end{align*}
$$

as required. Notice that since $1(D)$ is defined to be 1 for all time, then $D^{i} 1(D)=1(D)$ for all $i$. In practical situations, the sequence added to $x(D)$ to from $x_{r}(D)$ is not constant and will change with time (e.g., random phase slips within a demodulator). This will introduce short error bursts in $w_{r}(D)$ whenever a phase slip occurs due to the combined effect of decoding and postcoding. The precoder equation can be derived from (A.4) as

$$
\begin{equation*}
x(D)=D x(D)+w(D)(\bmod S) \tag{A.5}
\end{equation*}
$$

We shall now consider the case when $c_{0}=0$, i.e., $z^{0}(D)$ is affected by a $2^{d} \Psi$ phase rotation. In this case we redefine $w(D)$ to be

$$
\begin{equation*}
w(D)=\sum_{i=1}^{s-1} 2^{i-1} w^{c_{i}}(D) \tag{A.6}
\end{equation*}
$$

and $x(D)$ to be

$$
\begin{equation*}
x(D)=\sum_{i=1}^{s-1} 2^{i-1} x^{c_{i}}(D) \tag{A.7}
\end{equation*}
$$

For this case, we have $2 x_{r}(D)+z_{r}^{0}(D)=2 x(D)+z^{0}(D)+$ $1(D)$, where $x_{r}(D)$ and $z_{r}^{0}(D)$ are the inputs to the postcoder for a noiseless channel. Thus similar to (A.4), the postcoder equation is defined to be
$2 w_{r}(D)=((S-1) D+1)\left(2 x_{r}(D)+z_{r}^{0}(D)\right)(\bmod S) .(\mathrm{A} .8)$
Rearranging (A.8), we obtain the precoder equation

$$
\begin{equation*}
2 x(D)=2 D x(D)+2 w(D)+(D+S-1) z^{0}(D)(\bmod S) \tag{A.9}
\end{equation*}
$$
