ABSTRACT

25

Purpose: To describe the radiological findings of radiation-induced lung damage (RILD) present on CT imaging of lung cancer patients 12 months after radical chemoradiation.

Material and Methods: Baseline and 12-month CT scans of 33 patients were reviewed from a phase
30 I/II clinical trial of isotoxic chemoradiation (IDEAL CRT). CT findings were scored in three categories derived from eleven sub-categories: (1) parenchymal change, defined as the presence of consolidation, ground-glass opacities (GGOs), traction bronchiectasis and/or reticulation; (2) lung volume reduction, identified through reduction in lung height and/or distortions in fissures, diaphragm, anterior junction line and major airways anatomy, and (3) pleural changes, either
35 thickening and/or effusion.

Results: Six patients were excluded from the analysis due to anatomical changes caused by partial lung collapse and abscess. All remaining 27 patients had radiological evidence of lung damage. The three categories, parenchymal change, shrinkage and pleural change were present in 100%, 96% and
40 82% respectively. All patients had at least two categories of change present and 72% all three. GGOs, reticulation and traction bronchiectasis were present in 37%, 52% and 44% of patients.

Conclusions: Parenchymal change, lung shrinkage and pleural change are present in a high proportion of patients and are frequently identified in RILD. GGOs, reticulation and traction
45 bronchiectasis are common at 12 months but not diagnostic.

50

Introduction

55 Radiation-induced lung damage (RILD) is a side effect of radical radiotherapy (RT) and a significant cause of reduced quality of life in cancer survivors[1]. While the early, acute phase has been extensively investigated, the late, chronic phase of RILD is less well studied and described [2–6]. The historically poor prognosis of lung cancer patients has led to a lack of objective and standardised criteria to describe and quantify the process [4,7,8], leading to variable reporting across centres and trials. As lung cancer survivorship improves, the importance of long term treatment side effects grows
60 [9–14].

Repetitive or severe lung injuries result in permanent radiological scarring, often referred to as fibrosis, that impairs lung function [15]. CT imaging is a sensitive indicator of RILD [16–22]. In addition to parenchymal density changes many other related abnormalities exist that are under-
65 reported in the literature and poorly understood [5,17,20,21,23–29]. These include more obvious changes such as segmental collapse and pleural effusions, and more subtle changes such as traction bronchiectasis, elevation or tenting of the hemidiaphragm, mediastinal shift and rotation, distortion of major airways and pleural thickening.

70 Using patient data from the completed IDEAL CRT trial we studied the incidence of anatomical abnormalities found on CT imaging of lung cancer patients 12 months after RT, compared to their pre-treatment CT. This study is the first step toward developing a CT-based scoring system for RILD. The aim was to describe key radiological findings to inform the diagnosis of RILD.

75 Methods and Materials

Study design

80 Patient data were derived from the IDEAL CRT trial cohort [11]. This was a stage I/II clinical trial of isotoxic chemoradiation for patients with stage II-III non-small cell lung cancer (NSCLC). Patients received 63-73Gy RT in 30 fractions over 6 weeks or 63-71Gy in 30 fractions over 5 weeks (with one day of twice daily RT weekly) with two concurrent cycles of cisplatin and vinorelbine. The lung EQD2mean dose was planned to be 18.2Gy in all patients, so that although the tumour dose varied between patients, the lung dose was homogeneous across the entire cohort. The protocol called for CT
85 scans to be performed at 12 months post-RT in all patients. Median overall survival (OS) for the 6-

week protocol was 36.9 months. The 5-week outcomes are pending full follow-up. Baseline and 12 month CT scans were collected centrally. Information on tumour stage, recurrence status and patient characteristics are presented in Table 1.

90 *CT scans*

Each patient underwent a baseline PET/CT or diagnostic CT before treatment and a diagnostic CT 12 months after treatment. Pairs of baseline and follow-up CT images were rigidly co-registered using the open-source NiftyReg software [30]. The transformation was optimised to match the anatomy of
95 the thoracic vertebrae.

Scoring of radiological findings of RILD

Analysis of CT abnormalities was achieved by consensus in a multidisciplinary team: AD, thoracic
100 radiologist, DL, clinical oncologist and CV, medical physicist. Scans were inspected in pairs (baseline vs follow-up) to assess new findings indicative of lung damage. There was no knowledge of the patient's identity or RT treatment details. Window and level settings were the same for all images (W=1300, L=-350). The abnormalities identified were categorised as follows: (1) parenchymal, (2) lung volume reduction, and (3) pleural.

105

Classification of radiological changes

Parenchymal findings of four types were noted as defined in Gotway *et al* (2005) (Figure 1): ground-
glass opacities (GGO), consolidation, reticulation and traction bronchiectasis [31]. Since rounded
110 consolidation and residual masses may have a similar radiological appearance [32,33], residual masses were defined as opacities with rounded shape in the same anatomical location of the initial tumour. Follow-up clinical and imaging data from the trial were used to identify residual masses with local recurrence.

115 Lung volume reduction measurement was recorded in five ways (Figure 2): reduction in lung height, distortion of ipsilateral pleural fissure anatomy, changes in the position and shape of the ipsilateral hemidiaphragm [23], displacement and/or thickening of the anterior pleural junction line[34], and gross distortions of the anatomy of the main bronchi. Reduction in lung height was assessed on coronal reconstructed images. Fissure distortion was identified through changes in the relationship
120 between the oblique fissure and diaphragm on axial images. Distortions of the bronchial tree were identified on coronal views.

125 Pleural changes included thickening and effusion (Figure 3). Effusion is a region of homogeneous liquid at the boundary between the lung and thoracic cage. Thickening is an increase in the size of the pleural reflection, with the intensity of soft tissue and occurring at any interface between lung and thoracic cage.

130 In total three categories and eleven sub-categories of lung damage were analysed. For each patient, the presence or absence of each category and sub-category was annotated. Qualitative details on sub-types of patterns of damage were also recorded for future analysis. For the purposes of this analysis changes were not empirically measured but were recorded as present or absent based on routine inspection.

135 **Results**

140 Out of 120 patients in IDEAL CRT, baseline and 12-month scans were available for central review in 33 patients at the time of this analysis. All available pairs of baseline and 12-month scans were reviewed by the multidisciplinary team. For a total of six patients there was radiological evidence of major radiation damage that did not correspond to typical RILD. In five patients there was partial lung collapse due to airways damage. One patient had a lung abscess with extensive inflammatory change. These anatomical changes obscure the described findings of RILD. 27 patients are included in this analysis. The median time from end of treatment to time of second scan was 353 days, range: 265-367 days.

145 The number of patients with each category and sub-category of change is shown in Figure 4. Parenchymal changes were detected in all patients and volume reduction in all patients but one. Pleural changes were found in 82% of patients. All patients had at least two categories of lung damage and all three categories were present in 78% of patients.

150 Within the parenchymal category, the sub-category of consolidation was most commonly present, affecting 93% of patients. GGOs, reticulation and traction bronchiectasis were present in 37%, 52% and 44% of patients respectively.

155 In the volume reduction category, fissure and diaphragm distortion were present in 78% and 67% of patients respectively. Lung height was reduced in 59%. Major airways distortion and anterior junctional change were present in 63% and 78% respectively, representing mediastinal change. Pleural thickening was present in 70% and pleural effusion in 19%.

160 Table 2 shows more information regarding the patterns of damage and incidence for each sub-
category.

Discussion

165 We performed a systematic assessment of RILD changes on CT scans acquired 12 months following
radical CRT for NSCLC. The analysis was performed on scans from a prospective cohort of
homogeneously treated patients within the IDEAL CRT study. IDEAL CRT made use of modern RT
technologies, namely planning on 3D or 4D-CT imaging based planning, 3D-CRT or IMRT treatment
delivery, and limited mean lung dose. Based purely on radiological findings, all patients had evidence
of lung damage at 12 month of follow-up, with variable levels of severity. RILD is a common but
170 often asymptomatic consequence of lung RT. Our findings demonstrate the extent to which it is
under-reported across centers and trials. While different sub-categories of damage can also be
encountered in other diseases, the patterns of change are quite different from other forms of lung
damage [31,35]. These findings will be useful in differentiating RILD from other lung diseases.

175 The presence of radiation damage in all patients is a key finding of this study. In IDEAL CRT, the
target dose was escalated from 63 to 73 Gy, which might explain the high incidence of radiological
findings of RILD. However, for the reported cohort, patients with higher prescribed doses did not
have higher numbers of sub-categories of RILD. Further investigation, comparing the incidence and
severity of RILD in larger cohorts with varying treatment prescriptions is required.

180 Three key categories of change were identified on CT: lung parenchymal changes, lung volume
reduction and pleural effusion or thickening. These were present in 100%, 96% and 82% of patients
respectively and 78% of patients had all three categories of change. These changes are therefore
frequently identified in RILD. Specific forms of parenchymal CT change, such as GGOs, reticulation
and traction bronchiectasis, occur with sufficient frequency to be consistent with RILD.
185

Mah et al (1986) reported 6-month changes after non-conformal radical RT. They found that
parenchymal changes (air bronchograms, present in 25%), loss of lung volume (15%) and pleural
thickening (15%) were common findings. CT scan slices were at 1cm thickness and the quality of the
scans was likely not up to modern standards. Less than half of the patients were treated for NSCLC
190 and there was no record of how reduction in lung volume was defined. Kroenig et al (2001) studied 19
NSCLC patients after radical conformal RT of 69.6Gy to 90Gy. They too found evidence of RT
damage in all patients, concentrating on parenchymal lung changes.

195 Parenchymal damage is of core interest in RILD as the lung is the key organ at risk. We have
described various parenchymal changes which likely manifest according to the predominant process
of damage in individual patients. GGOs have been interpreted as inflammatory but might also be
fibrotic [17,36,37]. Reticulation and traction bronchiectasis are interpreted as fibrotic and are core
diagnostic findings in idiopathic pulmonary fibrosis [35]. Consolidation could represent either an
200 inflammatory or fibrotic processes and might be a common radiological endpoint for both. It is likely
that RILD is a process with both chronic inflammatory and fibrotic mechanisms reflected in the
radiological findings. This has been described in diffuse pulmonary fibrotic diseases [15].

The distinction between radiotherapy induced inflammatory and fibrotic changes on CT has
205 sometimes been defined by time. That is, changes before 6 months are described as most likely
representing inflammation and those beyond 12 months most likely fibrotic [21,29]. The period of 6
to 24 months is often accepted as the period of stabilisation of fibrosis [17,38]. This paper describes
CT changes 12 months following RT, a time point by which one might predict there to be little or no
residual inflammatory changes. We have described significant consolidation and GGOs at 12 months.
210 Whether these findings represent significant ongoing inflammation or areas of fibrosis is uncertain. A
review of CT scans at 24 months is required to verify whether these changes persist or resolve.
Identifying the presence of a chronic inflammatory process is important because it offers the
possibility of successful intervention to reduce the extent of RILD even at a relative late stage.

215 Lung volume reduction as demonstrated by visible lung volume and mediastinal changes was evident
in almost all patients (96%). Volume loss reflects fibrotic change including extensive microscopic
fibrosis not apparent with standard CT imaging. It remains to be seen whether more quantitative
measures of volume loss on CT necessarily correlate with clinical markers of lung damage.

220 The commonly observed finding of pleural changes has not been previously recognised as a classic
RILD finding [5,6]. Clinical pleural syndromes are not commonly reported after RT. It is unknown
whether these changes are caused by direct RT damage or through a reaction to parenchymal lung
changes.

225 RILD scoring systems are based on clinical, radiological and functional criteria, such as the Radiation
Therapy Oncology Group and European Organization for Research and Treatment of Cancer
(RTOG/EORTC) late radiation morbidity scoring system, and the Common Terminology Criteria for
Adverse Events (CTCAE) [39,40]. Based on our findings the radiological components of these
systems may be inadequate. RTOG/EORTC criteria score non-specified 'radiological changes' as
230 either slight, patchy or dense. CTCAE scores pulmonary fibrosis radiologically on the extent of
'radiological pulmonary fibrosis' from <25% to <75% and adds 'honeycombing' in grade 4. These

criteria may well be appropriate for other causes of pulmonary fibrosis but seem inappropriate for use in RILD. Radiology-only scoring systems have been proposed based on qualitative assessments of CT intensity and texture changes. These have mostly been applied in the context of conventionally fractionated RT for early follow-up scans (≤ 6 months) [5,41] or multiple time-points over 36 months [6,18]. There are also studies following stereotactic RT that score RILD in terms of consolidation subtypes [20,22,42,43]. In these studies only parenchymal changes are considered. In stereotactic delivery the lung volumes irradiated are considerably smaller, and hence a radiological-system looking only at parenchymal consolidation is likely adequate. We have demonstrated that indirect signs of lung volume loss characterized by a variety of anatomical deformities, as well as the identification of pleural abnormalities, may be critical in diagnosing RILD following conventionally fractionated RT.

The spatial relationship between RILD and radiation dose is crucial and requires further detailed research investigating both local dose and global lung doses. We are exploring co-registration of images to propagate planning isodose surfaces [44,45]. Parenchymal changes seem to occur in areas of higher dose (approximately 40Gy and greater). Anatomical distortion and pleural reactions reflect dose delivered in distant anatomical locations. The lung doses in IDEAL CRT were relatively homogeneous, and dose relationship studies require advanced statistical methods such as principal component analysis of DVHs and permutation testing [46,47].

Our study has limitations. We have used an exhaustive examination of a relatively small cohort to define the key parameters with which to interrogate future large numbers. Another limitation is that the initial clinical trial was not designed to identify symptoms specific to the findings that we have now described. Lung function, MRC breathing score and performance status are available and will be investigated. More specific questions would be required to fully examine the clinical impact of RILD CT changes.

We have demonstrated that RILD changes occur in all patients following radical RT for NSCLC. We have purposely limited our study to clinically identifiable radiological changes aiming to describe them in a manner potentially transferrable to the clinic. We believe this is the first step towards generating a validated radiological scoring system that is objective, clinically sound, easily interpretable, repeatable and user independent that provides relevant information on RILD. To date there is still no objective scoring systems of long term RILD which leads to variability in reporting of toxicity amongst trials [48]. In the case of pneumonitis studies, other groups have worked on developing deformable image registration based methods to measure local changes in the parenchymal texture, which correlate well with radiologist scores of pneumonitis [49,50]. However, as found in this study, long term RILD causes both complex changes in the lung parenchyma and

distortions on thoracic anatomy. These changes pose a difficult challenge for image registration,
270 described by our group elsewhere [45]. Next steps include developing objective quantification
methods using image analysis techniques independent of image registration [51,52] and correlating
radiological findings with clinical measures of respiratory function and with radiation dose
distribution.
