Introduction

Photonic crystal fibers (PCFs) have attracted significant attention during the last years and much research has been devoted to develop fiber designs for various applications, hereunder tunable fiber devices. This type of devices were first demonstrated by Eggleton et al. [1], where a high-index liquid plug was dynamically positioned in a tapered 'grapefruit' fiber, thereby creating a fiber device with tunable transmission properties. Later, Bise et al. [2] demonstrated a tunable photonic bandgap fiber, where the air holes of a solid-core PCF was filled with a high-index oil. Recently, thermally tunable fiber devices based on Liquid Crystals (LCs) was demonstrated [3], where tunable and switchable bandgaps was demonstrated. Here we present an all-optical tunable Liquid Crystal Photonic BandGap (LCPBG) fiber device, which utilizes a pulsed 532nm laser to modulate the spectral position of the bandgaps in a PCF infiltrated with a dye-doped nematic liquid crystal. A modulation frequency of 2kHz is demonstrated for a pump power of only 2-3mW.

Optically tuned LCPBG fibers.

In this experiment we have used a so-called 'large-mode area' PCF, which is an all-silica PCF, which has a silica core surrounded by 7 periods of air holes arranged in a triangular lattice. The hole diameter, inter hole distances and core size is 3 μ m, 7 μ m and 10 μ m, respectively. The fiber is endlessly single mode and guides light by the principle of Total-Internal-Reflection (TIR). When infiltrating the air holes of the PCF with a LC, which has a higher refractive index than that of silica, the infiltrated section cannot guide by TIR, but can support a finite number of guided wavelength bands due to anti-resonant reflection from the LC-filled holes [3]. The spectral position of these bandgaps is determined by the alignment of the LC, the structural parameters of the PCF and refractive indices of the LC. Since the refractive indices of the LC is considerably higher than that of silica, the LC infiltrated holes can be approximated as isolated waveguides and the spectral position of the bandgaps becomes insensitive to the inter hole distance and is dominated by the features of the inner ring of holes surrounding the core [4,5]. The transmission losses within the bandgaps are reduced when increasing the number of periods surrounding the core, and necessary for achieving good transmission. Having fixed the PCF parameters in the manufacturing process, the bandgaps can be tuned by changing the orientation or/and modifying the refractive indices of the LC. The refractive indices of a LC can be easily tuned using the high thermo-optic effect of most nematic LCs. The temperature dependent refractive indices of the nematic LC used in this experiments (E7, Merck, Darmstadt, Germany) is shown in figure 1. The refractive indices are shown for $\lambda=450$ nm and for $\lambda=656$ nm and the experimental data is fitted using a four parameter model developed by Jun Li et al. [6] (Jun Li is acknowledged for providing experimental data on E7).

The alignment of the LC mesogens in the PCF was determined by polarized microscopy of a single fused-silica capillary tube infiltrated with the LC. The LC was homogeneously aligned with the LC director pointing in the direction of the fiber axis. Due to this alignment, the spectral position of the bandgaps is dominated by the ordinary refractive index of E7 (n_o), which is the refractive index seen in the transverse plane of the PCF, but a contribution from the extraordinary index (n_e) should also be expected due to a non-zero z-component of the cladding mode field.

Figure 1 Left: Temperature dependence of the refractive indices of LC E7. Experimental data points is provided by Jun Li and the temperature dependence is fitted using a four-parameter model by Jun Li [4]. Right: The air holes of a PCF is infiltrated with a dye doped LC (E7, Merck), and by using polarized microscopy on a single capillary tube, a homogeneously alignment of the LC were observed.

The tuning sensitivity is therefore linked to the temperature gradient of n_o , and from figure 1 (left) it is seen that the temperature gradient of n_o is close to zero around room temperature but becomes positive, when the temperature is increased to above approx. 35°C. The air holes of a 40m long PCF were infiltrated with E7 for 10mm of the fiber length and the photonic bandgaps were measured using an unpolarized halogen-tungsten source. The bandgaps from 450nm to 1750nm at 40°C is shown on the top left figure of figure 2, and the temperature dependence of the spectral position of the two bandgaps around 540nm and 1400nm is shown on figure 2 (right).

In order to decrease the thermal response time, compared to heating/cooling the entire fiber, a 532nm pulsed laser is used to locally heat the LC positioned in the inner ring of holes surrounding the core. The heating efficiency is increased when there is a high overlap between the core mode and the inner ring of cladding holes. This is achieved by heating the entire fiber using a hotplate, such that the 532nm source is positioned on the edge or just outside a bandgap. On the bandgap edges, the effective area of the core mode increases substantially [7], thereby leading to a higher overlap between the core mode and the LC in the inner ring of holes. As seen from figure 2 (right) the 532nm laser will be positioned on the bandgap edge or outside a bandgap when the LC temperature is between 44°C and 52°C. Further, increasing the absorption of the LC around 532nm can increase the temperature sensitivity. This is achieved by doping the LC with a dye. We therefore doped E7 with an azobenzene dye called Disperse Red 1 (0.4wt%). The dye DR1 has an absorptions peak around 502nm and the dye doping does not affect the alignment of the LC. Figure 2 (left) shows the bandgaps of the LCPBG fiber before and after dye doping. The figure clearly shows that the presence of the dye, decreases the transmission in the bandgaps located around the dye absorption peak, but does not alter the position or the transmission level of the remaining bandgaps.

Figure 2 Left: Transmission spectrum of a nematic LCPBG fiber infiltrated for 10mm with E7. Spectrum is without and with dye doping with DR1. Right: Temperature dependence of the bandgaps around 540nm and 1400nm in a LCPBG fiber without dye doping.

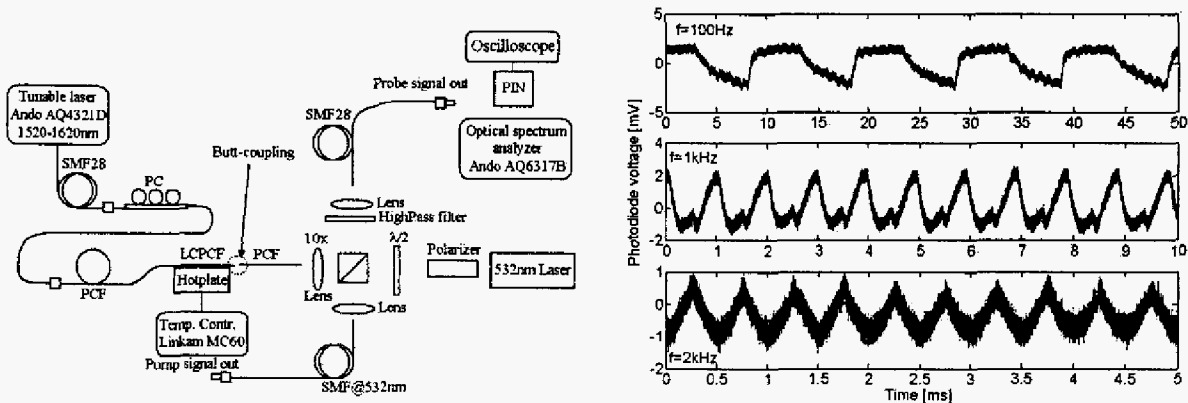

Figure 3 Left: Experimental setup for measuring the time response of the probe laser. Right: Oscilloscope traces of the 1620nm probe laser when the 532nm pump laser is modulated with 100Hz, 1kHz and 2kHz.

In order to investigate the time response of the LCPBG fiber device, a low-power CW probe laser was coupled into the fiber together with the pulsed pump laser. Both the polarization of the pump and the probe could be individually adjusted using the setup shown on figure 3 (left). The probe laser was chosen to be located on the long-wavelength side of the bandgap centered around 1400nm (as shown on figure 2, right). In the center of the bandgap, no polarization sensitivity was observed on the transmission level, while this was not the case on the edge of the bandgap. Using a polarized tunable laser, we measured the polarization sensitive bandgap edge from 1520-1620nm and observed a small shift (approx. 10nm) of the bandgap edge depending on the polarization of the laser. This shift is attributed to very small variations (few tens of nanometers) in the hole diameter and shape of the inner ring of holes, thereby leading to small birefringence. When operating the probe laser on this edge, we therefore observed sensitivity to both the polarization of the pump and the probe laser, but we will not discuss this further in this paper. The temperature of the LCPBG fiber was raised to 45°C and the probe laser was monitored using a PIN photo detector and a storage oscilloscope. The pulsed pump laser (square-wave modulated, 50% duty cycle) was turned on and the polarization of both the pump and probe laser was adjusted until a modulation of the probe laser was observed on the oscilloscope. Figure 3 (right) shows the observed waveforms of the 1620nm probe laser when the 532nm pump laser were modulated with 100Hz, 1kHz and 2kHz square wave signal. The power of the pump laser was monitored and we estimate that the power of the pump coupled into the LCPBG device, in the junction of the butt-coupling, was around 2-3mW peak power. Increasing the input power did not yield any improvement, which is attributed to a too large increase in temperature, whereby a bandgap shift up in wavelength and assist in confining the pump to the core region, and hence decrease the overlap with the LC (see inset on figure 2, right). We believe that these optically tuned LCPBG fiber devices can find use as distributed devices i.e. with signal processing elements, such as tunable bragg gratings, distributed in a transmission fiber and with the data signal (the probe) and the control signal (the pump) carried in the same fiber.

Conclusion

In this paper we have, to our knowledge, presented the first optical tunable PBG fiber device. We have demonstrated how a 532nm pulsed laser can modulate a 1620nm CW laser by locally modifying the optical properties of LC inclusions in a LC infiltrated PCF. This is achieved using a low pump power of only 2-3mW, and we have demonstrated a modulation frequency of up to 2kHz.
