CHAPTER 1

Introduction

This technical report was produced to make public the code produced as the main project of the PhD project by Kaare Græsbøll, with the title: "Modelling spread of Bluetongue and other vector borne diseases in Denmark and evaluation of intervention strategies".

1.1 The model

The main aim of the PhD thesis the code presented in this Technical report refer to, was to create a simulation model to predict the spread of Bluetongue and other vector borne diseases should they be introduced in Denmark. This model is presented in a publication with the title: "Simulating spread of Bluetongue Virus by flying vectors between hosts on pasture." [1] Which has been preliminary accepted for publication in Scientific Reports, and it is recommended to read this report in conjunction with the article. Mathematical expression and parameter values are not included in this report, but are to be found in the article.

The program code presented is for the case of Bluetongue Virus with cattle as hosts and biting midges as vectors. Bluetongue Virus (BTV) is a non-contagious infectious disease that infects ruminants. In Denmark the primary ruminant of concern is cattle in which the disease causes relative mild symptoms, but do

reduce milk yield and increase the risk of spontaneous abortions. In certain breeds of sheep BTV can have a very high mortality, and therefore the disease is considered notifiable by the OIE. Bluetongue does not transmit directly between ruminants but requires to pass through a blood-sucking vector. Inside the vector BTV needs to replicate to a certain level and make it from the gut to saliva glands. This process is very sensitive to temperature and cannot be completed if the vector is at temperatures below 13°C. Therefore we take in meteorological data to calculate the extrinsic incubation period (EIP) a.k.a. the incubation time in the vectors.

What especially differentiates the model presented in this report with previous models on vector borne spread is that hosts can be distributed onto pasture areas. We wanted to create a more process oriented approach so that the parameters describing spread of disease relates directly to parameters describing flight patterns of vectors. For a more detailed description of the reasons to choose this particular model type see the PhD thesis.

The model share in-herd dynamics described in Gubbins (2008) [2] and Szmaragd (2009) [3] (Figure 1.1), while the between herd model was presented in Græsbøll (2012) [1] (Figure 1.2). Vaccination was modeled on UK data in a collaboration with the Pirbright Institute presented in Græsbøll (2012b) [4] using vaccination as described in Szmaragd (2010) [5].

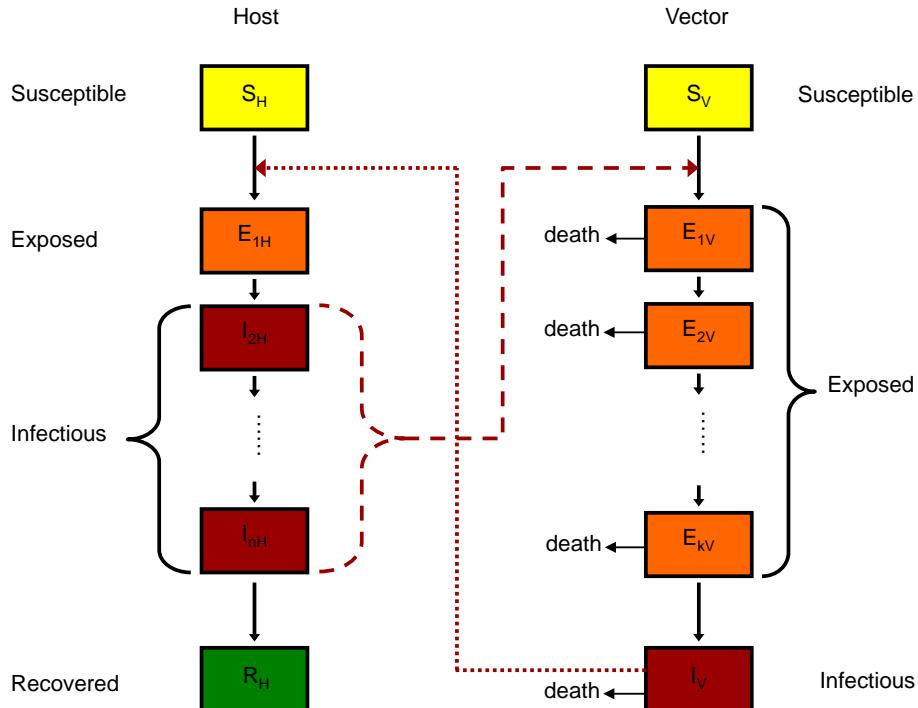

Figure 1.1: The viraemia of the hosts is described by an extended Susceptible Exposed Infectious Recovered (SEIR) model (left), and the vectors are described by an extended SEI model (right). All movements between the stages in the model are governed by the probabilities listed in Græsbøll (2012) [1], in the code most parameters are defined in `gdata` (section 2.2) or read in from the `input.txt` file (section 2.6.1).

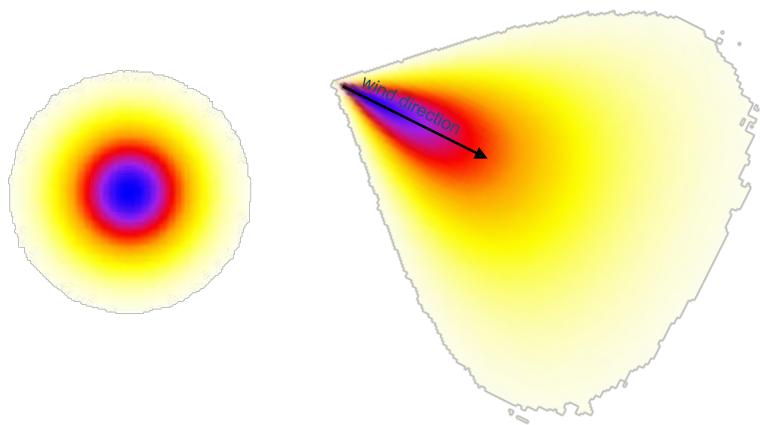

Figure 1.2: Movement of vectors between herds are described either as active flight or passively carried by wind. This can be interpreted by 2D density distributions. (Left) probability density when vectors are moving by active flight to neighboring areas (arbitrary length scale, darker colors are equivalent to higher probability). (Right) probability density when vectors are carried by wind (arbitrary length scale). Mathematical expression can be found in Græsbøll (2012) [1].

CHAPTER 2

Structure

The code was generated with an eye for speed, and alone for this reason the program was twice rebuild from scratch. The main issue with speed relates to the number of vectors: The number of vectors in high seasons is as many as 5,000 vectors per host. Given that there are approximately 1.7 million cattle in Denmark, this round up to almost 10 billion vectors, each need potentially be modeled for flight. This high number is never realistically reached, and optimizing for speed is therefore mainly a problem of best identifying relevant vectors to move. This is primarily achieved by keeping a list of all vectors and hosts with the disease, and only perform relevant operations: viraemia, movement, death, etc. on these animals. In the program this is handled by two lists that cross-reference to each other and to the map. Using a list proved much faster (at least a factor of ten) than just having vectors and host located in a grid matching the map and scanning across areas looking for animals with disease.

The code is structured with a control file `dk.f90` which then call 13 other modules to do as explained in the following sections as listed below (In parenthesis the section in appendix where to locate the code):

2.1 `dk.f90` ([A.1](#)) Determines the overall structure of the simulation.

2.2 `gdata.f90` ([A.2](#)) Defines the global data available to all modules.

2.3 `initialize.f90` ([A.3](#)) Initialises many of the variables and arrays.

2.4 `functions.f90` ([A.4](#)) Collates repeated functions.

2.5 `iohosts.f90` ([A.5](#)) Reads in pasture maps.

2.6 `iomodule.f90` ([A.6](#)) Initialization of pasture, farms, etc.

2.7 `host.f90` ([A.7](#)) Reads input from the `input.txt` file.

2.8 `temperatures.f90` ([A.8](#)) Handles temperature data.

2.9 `makemap.f90` ([A.9](#)) Distributes hosts onto pasture.

2.10 `viraemia.f90` ([A.10](#)) Emulates the viraemia of hosts and vectors.

2.11 `windy.f90` ([A.11](#)) Handles wind data.

2.12 `midge.f90` ([A.12](#)) Does the active and passive movements of vectors.

2.13 `bite.f90` ([A.13](#)) Transmission of disease between vectors and hosts.

2.14 `errorhandl.f90` ([A.14](#)) Various checks of the code.

Please note that section [A.15](#) contains a full list of all modules and subroutines. Some parts of the code have been omitted to increase the ease of the read, these parts are mainly lines of codes that determines events when running in certain test modes of the program. However there are also omitted reallocation statements that handles sizes of arrays, these were omitted mostly due to space considerations. For a fully functional copy of the code please contact the author. The version number of the code presented is 9.7.4.

2.1 `dk.f90` ([A.1](#))

The main control file calls the subroutines that handles everything. The program is structured in this way because it makes it easy to turn subroutines on and off, which is very convenient in the test phase, and when testing different scenarios with regards to e.g. vaccinations or different countries. The code here presented contains two loops in `dk.f90`, one 'repeat' which is simple replicates of the simulations, and one 'day' that goes from day one to the designated 'end-day'. When running sensitivity analysis extra loops can be added to control parameters outside these two loops. Furthermore the control file writes much of the output to file. Often it can be desirable to handle output in a separate module, I chose otherwise because the day-counter is in `dk.f90` it is very convenient to write output from this loop.

2.2 gdata.f90 (A.2)

As the program is build using the module functionality of Fortran 90 it is advantageous to define the global data arrays in a module which is then called by all other modules. Structuring data in this way ensures that this global data is permanently in the computer memory and only in one copy. Using a module to store global data also eliminates the need to move data between subroutines, or call it explicitly. This is very nice if much data is to be moved. However, this does come on the expense of the detailed knowledge of what goes in and out of the specific subroutines. Thus it sometimes becomes tricky to keep track of all variable names, I sincerely recommend using the `implicit none`, and also keep a separate file which contains names of the most important variables and arrays and their structure. Here I present parts of my own "variable list", both as an example, but also to ease the read of the code. The number of parenthesis after a variable indicates the dimensionality of the array, so that none = scalar, () = vector, ()() = matrix, and so on. Variable inside [] indicates optional variables. The [rand] indicates that variables are only used when generating fields at random.

==== List of variables =====

```
hosts(y)(x)(#C,C_id,[#S,S_id,]M_id) the spatial map linking to the list
csick_loc (C_id)(y,x,M_id,#H,SEIR) list of infected cattle
ssick_loc (S_id)(y,x,M_id,#H,SEIR) list of infected sheep
msick_loc(M_id)(y,x,C_id,#C,[S_id,#S,]#H,T_id,SEIR) list of infected midges
#C, #S, #M      number of cattle, sheep, midges at a given location
#H = #C + #S   total number of hosts at a given location
```

C_id, S_id, M_id the ID number to cross reference lists

==== gdata.f90 ===

-integer-

| | |
|---------|--|
| xsize | number of cells in x direction |
| ysize | number of cells in y direction |
| mstages | number of boxes used to emulate midge stages |
| ios | input/output error status |
| xstart | x value in cells of start of epidemic |

| | |
|-----------------|---|
| ystart | y value in cells of start of epidemic |
| msick | count of locations of sick midges |
| n_farms | number of cells with hosts [rand] |
| nmax | maximum number of cells in a cluster to represent fields [rand] |
| nmean | mean number of cells in a cluster to represent fields [rand] |
| input_type | is data generated or read from file |
| area_sel | area select between predefined or own definition |
| infherds | count of infected herds |
| fly_c | count of flying events per time unit |
| day | current day of simulation |
| m_var | number of additional variables in the msick_loc array |
| mboxes | number of stages in the midge EIP |
| mbij | integer value of number of boxes to jump when emulate mboxes |
| h_var | number of additional variables in the csick_loc2 array |
| a_fly | the allocated size of the fly array |
| a_msick | the allocated size of the msick array |
| host_types | number of hosts types (cattle, sheep, etc) |
| fly() | array of fly to locations |
| msick_loc() | array with all infected midges |
| hstages() | number of hosts stages (no need to emulate <- temp indep.) |
| mth() | midges per host |
| hsick() | count of locations of sick hosts |
| n_hosts() | number of hosts |
| hosts() | array with hosts location |
| csick_loc() | locations of sick cattle |
| csick_loc_com() | history of infected cattle |
| ssick_loc() | locations of sick sheep |
| ssick_loc_com() | history of infected sheep |
| hsick_com() | counter for csick_loc_com+ssick_loc_com |
| a_hsick() | allocated size of hsick |
| a_hsick_c() | allocated size of hsick_loc_com |
| mk | parameter determining the precision of variables |
| pi | pi = 3.1415.... |

-real-

| | |
|-------------|--|
| loclen | local length scale for the random walk of midges |
| mrec | 1 / EIP for midges |
| wile | width to length scale in wind spread cone |
| mmort | midge daily mortality |
| sizefac | cell side lenght in km |
| temperature | mean daily temperature |
| biterate | daily bite probability of midges |
| flytime | how long do midges stay in the wind [hours] |

| | |
|-----------------|---|
| midgefly | fraction of midges that fly away from hosts |
| midgestay | fraction of midges that stay where no hosts |
| ave_dist | average distance between cells with hosts |
| meaninf | mean number of infected hosts per affected cell |
| vac_cov | fraction of hosts immune from vaccination |
| wind_s | wind speed in current cell |
| wind_a | angle of the wind in current cell |
| mbjr | real value of number of boxes to jump when emulate mboxes |
| hrec() | 1/days for hosts to recover from infection |
| probtrans_mh() | probability of transmission midge to host |
| probtrans_hm() | probability of transmission host to midge |
| hosts_outside() | percentage hosts outside |

`gdata.f90` also contains statements to turn host movement, movement restriction and a debugging mode (debugging statements have though mostly been removed from the displayed code) on and off.

Additional subroutines included are also primarily connected to the start-up of the program.

2.2.1 init ([A.2.1](#))

Defines many of the parameters characterizing which disease and the effect on specific hosts. These statements are though somewhat obsolete as they are also read in from the `input.txt` file (section [A.6.2](#)). But some are needed to initialize the size of certain data arrays.

2.2.2 redistribute ([A.2.2](#))

This subroutine reset all hosts and vectors arrays to the starting setup. This section is used for test runs when it is not desirable to resample all hosts onto pasture at every repetition.

2.2.3 seeed ([A.2.3](#))

The `seeed` subroutine ensures that the random seed is indeed random. (Trivia: Seeed is also a name of one of the author's favorite German bands.)

2.2.4 alloc_cphid ([A.2.4](#))

This subroutine allocate cph numbers to all pasture, so that hosts can be tracked back to their owners.

2.3 initialize.f90 ([A.3](#))

The Initialize module in its full contains initialization of epidemic for both Denmark and the UK, and also the definition of the UK vaccination roll-out plan. Here I have only included the initialization of the Danish epidemic.

2.3.1 init_inf ([A.3.1](#))

It is possible to initiate using infected hosts or infected vectors. Here we also determine the area of first infection.

2.4 functions.f90 ([A.4](#))

The `functions` module contains functions used throughout the program, but also subroutines to collect data and distribute flying vectors. From the original code some subroutines have been removed. The removed pieces of code did reallocation of arrays and error checks.

2.4.1 BINV ([A.4.1](#))

This function approximates a draw from a binomial distribution. Fortran 90 has only a call to a uniform random distribution. The simple solution would be to do Bernoulli trials, however this method is significantly faster especially when the number of draws, n , is large and the probability, p , low. This combination of n and p is often fulfilled in the code given that there are often many vectors but transmission probability is very low. The algorithm was taken from Kachitvichyanukul and Schmeiser (1988) [6]. In this implementation the approximation crashes somewhere above $np = 500$ (probably due to rounding to zero), therefore for $np > 500$ the algorithm returns np . When running within

reasonable disease parameter and vector abundance this cutoff is almost never in use.

2.4.2 viraspread ([A.4.2](#))

`viraspread` simply calculates the maximum distance virus has traveled from the starting point.

2.4.3 herd_inf ([A.4.3](#))

This subroutine reports the number of currently infected herds and the prevalence in the herds.

2.4.4 flysort/flysortm ([A.4.4](#))

When implementing dispersal of vectors, dispersing vectors was assigned to a temporary array so that the same vector was not able to fly more than once (see section [2.12](#)). The two modes (active and passive) of vector dispersal can run with the temporary array being either a list or a matrix mode depending on the expected number of flying vectors. The subroutines `flysort` and `flysortm` distributes vectors from the temporary array (list and matrix respectively) and makes sure that all indexing arrays are updated.

2.5 iohosts.f90 ([A.5](#))

Until version 9.6 of the program pasture distribution was read in from pre-made files using the `read_mark_blocks` subroutine. These pre-maps were very large, and it was not feasible to store the number needed to ensure proper sampling. However they did load faster than generating new maps for every run, so when doing test runs it was often used. The o part of `iohosts.f90` is represented by subroutines `find_herds` and `find_farms` designed to make maps of the spread.

2.5.1 `read_mark_blocks` ([A.5.1](#))

Reads in pasture data from files and distribute hosts onto these pasture areas. Pasture data for Denmark comes with a percentage of grass, therefore the program tries to distribute hosts onto pasture with high grass percentage first. It is also defined how many cattle per hectare that is maximum allowed.

2.5.2 `find_herds/find_farms` ([A.5.2](#))

Outputs infected herd/farm locations to file.

2.6 `iomodule.f90` ([A.6](#))

This module was prematurely named as an `io` module, considering that it only does input.

2.6.1 `read_inputfile` ([A.6.1](#))

To avoid numerous recompiles and to ease use for other users an `input.txt` was constructed which contains most of the parameters the program needs to run. `read_inputfile` reads and checks that input file. It also generate some parameters if the input file specified some random distribution. An example of the input file is included in section [A.6.2](#).

2.7 `host.f90` ([A.7](#))

This module contains the subroutine to handle host movements.

2.7.1 `host_move` ([A.7.1](#))

Host movements in the model are modeled by use of a transmission kernel. The kernel is fitted to data from "The Knowledgecenter of Agriculture, Dairy &

Cattle farming” who tracks all movements of cattle in Denmark. Ideally a more process oriented network analysis should form the basis of movements in future models. However, using this simple kernel approach showed very little influence of cattle movement on the output of the model, so I do not believe that this approximation does much difference to the model.

2.8 temperatures.f90 ([A.8](#))

This module handles temperature related subroutines. Specifically the interpolation from daily to hourly temperature and mapping temperature stations so that herds share temperatures with the spatially nearest data point. From the original code was deleted subroutines which handles temperatures for UK, these were similar in function, and mostly differed because the structure of input data differs.

2.8.1 temp_var_h ([A.8.1](#))

Many of the parameters in this model are nonlinear with relation to temperature and most have cutoffs whereunder values go to zero. E.g. the Extrinsic Incubation Period (EIP) have a cutoff at 13.5°C so if the daily mean temperature is below this value virus cannot replicate inside vectors. However it is possible that a part of the day has temperatures above cutoff, and in these periods virus should be able to replicate. To emulate this we interpolate from daily minimum and maximum temperatures using a sinusoidal function to approximate hourly temperature data.

2.8.2 read_temp_id ([A.8.2](#))

The temperature data was provided by the Danish Meteorological Institute (www.dmi.dk) from 39 stations across Denmark. Data was processed for another project regarding Bluetongue (www.nordrisk.dk) where data was interpolated to a grid of 25 by 25 km. To increase the speed of the program a map of same resolution as the pasture map was made which indicate which temperature grid point the pasture should take temperature data from. This subroutine reads this pre-made map.

2.9 makemap.f90 ([A.9](#))

This module contains the subroutine to make the grid cells (mark blocks) that represent the range vectors can locate hosts within.

2.9.1 make_mark_blocks ([A.9.1](#))

While the size of the grid cells in the simulation represents the vectors ability to locate hosts, these are also pasture areas. This subroutine collate the input data with regards to which pasture areas are owned by which farmers, and how much cattle are owned by the individual farmer. Cattle are then randomly distributed onto pasture owned by the farmers according to criteria given in the `input.txt` file.

2.10 viraemia.f90 ([A.10](#))

The `viraemia.f90` module deals with the viraemia of hosts and vectors.

2.10.1 host_viraemia ([A.10.1](#))

This subsection moves the infected hosts through the stages in the SEIR model (figure [1.1](#)).

2.10.2 midge_viraemia ([A.10.2](#))

This subsection moves the exposed vectors through the exposed stages (figure [1.1](#)). The code starts by handling the cases where all exposed and infectious vectors have moved away. Then runs through the list of exposed/infected midges updating the parameters according to temperature, and moving them through the states or killing them. In the end the code handles the case where all exposed and infectious vectors have died. I have left in some out-commented code that claims to ensure constant amount of midges, this is a remnant from when the code ran with a fixed amount of midges, so all midges having died were replaced in the susceptible stage. However, when number of midges became variable on a daily and seasonal basis, the interpretation of number of midges became

equivalent to the number of susceptible midges. This was done because adjusting the total number of midges would be more computationally demanding than the out-commented line, and would also require further assumptions. An example: we sample daily between 1 and 5000 midges, day one there is 5000 midges, and we get 10 exposed midges, the next day we sample that there should be 1 midge. If this number is not assumed to be the susceptible number, we need to consider how to handle the 10 exposed midges from yesterday.

The observant reader might also have noted that the code seems to have 40 stages for the vectors, which is a lot different from the 11 as described in the theory section of Græsbøll (2012) [1]. From hereon the 40 partitions will be referred to as boxes to differentiate from the stages described in the theory. When this code was initially written the number of stages was only given as an interval, and while e.g. Gubbins (2008) [2] handled this by assigning the number of stages for the EIP to each farm, this could not be achieved in this model because vectors move around, and how to handle a vector in stage four out of seven when it arrives at an area with 11 stages? This was solved by emulating stages using the 40 boxes. To exemplify: if there are ten stages at a given location (and for a given temperature) the vectors will jump four boxes forward each time we evaluate the viraemia. In this implementation we can think of the boxes as each representing 2.5% of the completion of EIP. This implementation allows for vectors to move between areas with different number of stages, and number of stages can also vary with temperature if needed. If the number of boxes divided by the number of stages is not an integer, the vectors will be distributed to the nearest boxes in proportions according to the decimal.

2.11 `windy.f90` ([A.11](#))

The `windy` module handles wind in the code.

2.11.1 `wind_data` ([A.11.1](#))

Wind is drawn from a random distribution. In the code there are some out-commented examples of how to generate anisotropic winds.

2.12 midge.f90 ([A.12](#))

The module `midge` handles the movement of midges (vectors). Most importantly for the speed of the code, only vectors with the disease are allowed to move. Movement is designed to be handled in two different ways depending on the number of vectors to handle. When dealing with a small epidemic, every vector move is recorded into a list. When many vectors are flying all over the simulation box, the program can use a temporary matrix where all movements are subscribed to. The different modes are subsequently handled by the `flysort/flysortm` routines [A.4.4](#), which places the flying vector in their landing areas. Parts of the code is out-commented this mostly different ways of handling vectors that flies outside the simulation box. The opted mode is that flights ending outside the simulation box is canceled. Out-commented modes are flights terminates at the edge, or flights outside box means instant dead.

2.12.1 midge_local ([A.12.1](#))

Local flight is simulated by assuming a Gaussian random walk. To generate coordinates the Box-Muller algorithm is utilized [\[7\]](#).

2.12.2 midge_wind ([A.12.2](#))

Midges carried by wind also have coordinates generated using the Box-Muller algorithm [\[7\]](#).

2.13 bite.f90 ([A.13](#))

The `bite` module handles the transmission of virus between vectors and hosts. In the subroutines there are a lot of code which handles the different index arrays when bites leads to transmission. There is also different ways of handling vaccination included.

2.13.1 inf_hosts ([A.13.1](#))

In this subroutine hosts becomes exposed to the virus by bites from infectious midges.

2.13.2 inf_midges ([A.13.2](#))

In this subroutine susceptible vectors becomes exposed to the virus by biting infectious hosts. Notice that it is emulated that the titres of virus in blood is different in different stages of the disease, as has been seen in experimental data [8].

2.14 errorhandl.f90 ([A.14](#))

In the end I show parts of the testing algorithm. When using index lists it becomes very important to make sure that these list cross-reference exactly so that information is not lost or misinterpreted.

2.14.1 findmidges ([A.14.1](#))

Test if midge IDs are correctly handled in the host list.

2.14.2 findhosts ([A.14.2](#))

Test if host IDs are correctly handled in the host and vector lists.

APPENDIX A

Code

Following is the source code for version 9.7.4 of the program. This version is only a slight alteration from the version 9.7.2 which was used to produce data in paper [1]. It is also very little difference on this code and the code used to produce paper [4]. This print of the code have been edited from the original to make reading easier. Par example all statements relating to the parallelization of the code have been excluded. Various debugging statements have also been deleted. This code does only represent one simulation of Denmark. For real use additional loop were introduced to do sensitivity analysis.

The subroutines are tabled in section [A.15](#). Subroutines are therefore sectioned, which is not part of the original code.
