Farming different species in RAS in Nordic countries: Current status and future perspectives

Research highlights

- Compilation and assessment of data from hard-to-assess literature as well as hand-on experiences with operating RAS in practice
- Description / information on system setup for different species including not formerly published data
- List of water quality parameters for different species observed under general conditions in operating, commercial RAS
- High capital costs are one of the biggest challenges to sustainable RAS calling for large scale intensive productions to reduce investment and operation costs

Abstract

1
2 Recirculating aquaculture systems (RAS) have gained increasing interest in recent years as a means
3
4 to intensify fish production while at the same time minimize the environmental impact. Considerable
5
6 hands-on experience has accumulated within the Nordic countries over the last 20-30 years in
7
8 designing, building, and operating intensive land-based RAS for different species. This study compiles
9
10 and assesses published literature along with un-published hands-on experiences with rearing
11
12 different species in RAS in the Nordic countries, including Atlantic salmon (*Salmo salar*), rainbow
13
14 trout (*Oncorhynchus mykiss*), European eel (*Anguilla anguilla*), pike perch (*Stizostedion lucioperca*),
15
16 Arctic char (*Salvelinus alpinus*), sturgeon (order Acipenseriformes), Nile tilapia (*Oreochromis*
17
18 *niloticus*), and European lobster (*Homarus gammarus*). High capital costs are one of the biggest
19
20 challenges to sustainable RAS calling for large scale intensive productions to reduce investment -and
21
22 operation costs. Consistent with this, production of Atlantic salmon smolts in indoor RAS and
23
24 rainbow trout in outdoor Model-Trout-Farms (MTFs) have been the commercially most successful
25
26 productions so far. Aside from end-of-pipe treatment including sludge handling and efficient
27
28 nitrogen removal, much of the RAS technology applied is well known and is, as such, more or less
29
30 ready to apply for culturing a variety of species. Successful production of “new” species in RAS
31
32 therefore largely comes down to identifying the biological requirements of that specific species, and
33
34 designing the RAS to fulfill and support the specific requirements. Well established brood-stocks and
35
36 continuous supply of offspring is furthermore a prerequisite for successful RAS production of most
37
38 species. Successful operations of less intensive RAS such as aquaponic systems appear to be feasible
39
40 primarily when culturing more exotic species targeted for selected customers.

1. Introduction

1 While the aquaculture production is expanding rapidly in large parts of the world, it is more or less
2 stagnant or even slightly decreasing in the Nordic countries (Denmark, Faroe Islands, Finland,
3
4 Iceland, and Sweden) aside from Norway (FAO 2010; FEAP 2011). Part of this is due to differences in
5
6 natural environmental conditions, with prolonged low temperature periods challenging intensive
7
8 aquaculture production at high latitudes. Strict environmental regulations, limited access to
9
10 freshwater, focus on waste water management and animal welfare slows down growth in the
11
12 industry even further (Martins et al., 2010; Paisley et al., 2010). These issues are, or will soon
13
14 become, highly relevant in a global context, and there is need for development of cost-effective,
15
16 economically viable aquaculture production methods that minimize the environmental impact while
17
18 at the same time ensure optimal rearing conditions.

19 There is considerable growth potential for land-based intensive recirculating aquaculture systems
20
21 (RAS) as a means to mitigate these challenges. Intensive RAS make it possible to decrease water
22
23 consumption and significantly reduce nutrient outlet concentrations through continuous
24
25 technological improvements and developments. It is possible to control rearing temperatures along
26
27 with essential water quality parameters such as dissolved oxygen, carbon dioxide, ammonia, nitrite,
28
29 nitrate, pH, salinity, and suspended solids. This allows maintaining good rearing conditions for
30
31 optimized growth and feed utilization of a given species. It furthermore allows for a diversification of
32
33 species that may be cultured in RAS, which is a necessary prerequisite for ensuring a sustainable
34
35 development of the industry (Le François, 2010). Specific productions for targeted, niche or local
36
37 markets might provide additional opportunities for sustainable RAS productions.

38 On the downside to RAS, investment and operational costs are high compared to less intensive
39
40 systems, and increased technical complexity puts large demands on system management,
41
42 challenging the profitability of such systems even further. Commercial scale production in RAS is
43
44 therefore, apart from a few species, still rather limited (Martins et al., 2010).

45 Large scale commercial rearing in RAS in the Nordic countries includes Atlantic salmon smolt (*Salmo*
46
47 *salar*), rainbow trout (*Oncorhynchus mykiss*), and European eel (*Anguilla anguilla*), while minor scale
48
49 commercial productions of, e.g., Arctic char (*Salvelinus alpinus*), pike perch (*Stizostedion lucioperca*),
50
51 and sturgeon (order Acipenseriformes) also takes place. Pilot scale RAS are currently being
52
53 developed / tested for rearing of Nile tilapia (*Oreochromis niloticus*) and European lobster (*Homarus*
54
55 *gammarus*), and fry and fingerlings of many different species are produced in RAS.

56 Considerable hands-on experience has accumulated within the Nordic countries over the last 20-30
57
58 years in designing, constructing, and operating intensive land-based RAS. Denmark has been one of
59
60 the pioneering countries, contributing significantly to the development of both domestic systems
61
62

1 and RAS technology for export. Within the last 10-15 years, Norwegian companies have specialized
2 in the development of smolt RAS as well as RAS technology for export.

3 Much of the hands-on experience and existing knowledge concerning RAS setup and issues, such as
4 water quality parameters when rearing different species in practice, have never been published.

5 Moreover, if published the information may be hardly accessible as it is often present in
6 miscellaneous governmental and research institute reports, memorandums, etc. written in different
7 languages. For future growth in the sector, it is imperative to document this experience.

8 Furthermore, it is important to evaluate the performance of different species and systems in order
9 to support species diversification and improve system design and performance. The objective of this
10 study was therefore to exemplify ongoing activities, and to compile and assess existing published
11 literature along with un-published hands-on experiences with rearing different species in RAS in the
12 Nordic countries. Given the heterogeneity of the information, and the production of many species in
13 RAS being in an up-start phase with yet little experience gained, the level of details provided for each
14 species inevitable varies.

15 Table 1 summarizes water quality parameters observed under general conditions in commercial or
16 pilot scale RAS in operation. The information is largely obtained from farmers / managers, and
17 reflects their experiences with running RAS in practice. The values may deviate from scientifically
18 determined, optimal physiological values published in peer-reviewed journals, as the latter is often
19 based on short-term, single-factor, laboratory scale experiments rather than long-term, large scale,
20 commercial production systems (Colt, 2006).

TABLE 1

2. Atlantic salmon smolt (*Salmo salar*)

2.1. Current status

Atlantic salmon is the most produced species in the Nordic countries. Norway is by far the largest
producer, producing almost 1 million metric tons (MT) in 2010 (FEAP, 2011). There was 214 licensed
Norwegian hatcheries in 2009/2010 with an annual production of some 230 million smolts
(Drengstig et al., 2011a). Apart from additional production in Iceland and in the Faroe Islands there is
only limited production of farmed salmon in other Nordic countries (FEAP, 2011).

Grow-out mainly takes place in net cages at sea, while smolts traditionally have been produced in
land-based systems and in cages in lakes (Bergheim et al., 2009; Terjesen et al., 2009). The Faroe
Islands had seven smolt producing RAS farms in 2007 (Bergheim et al., 2009), and less than 10% of
Norwegian smolt farms have currently implemented RAS technology. However, many Norwegian

1 farmers plan to convert to RAS and most newly constructed Norwegian farms are built as RAS
2 (Drengstig et al., 2011b).

3 The increased focus on RAS for smolt production in Norway is due to: i) limitations in freshwater
4 resources especially during dry periods of the growing season; ii) problems associated to inlet water
5 quality as most water bodies have relatively soft water (low calcium) requiring liming or silicate to
6 increase alkalinity; iii) need for UV irradiation / ozone treatment for disinfection purposes; iv) need
7 for stripping off high levels of CO₂ (ground water); and v) the advantages of constant, optimized
8 temperature conditions offered in RAS in contrast to open systems (Kristensen et al., 2009). The
9 latter allows a faster and more flexible all year round production, i.e., including also cold seasons. By
10 utilizing RAS technologies, smolts can be ready for on-growing in sea cages in spring, summer, and
11 autumn. Furthermore, while smolts previously were grown to a size of 30-50 g, and lately to 140-170
12 g before stocking into net cages (Bergheim et al., 2009), future plans are to grow them even larger
13 (250-1,000 g) on land. Doing so will reduce the overall production time (rearing under highly
14 controllable conditions), reduce problems with sea lice (*Lepeophtheirus salmonis*) infestation
15 (smaller juveniles being particularly vulnerable), and expand the production area as most of the well
16 suited sites at sea / in fjords are already utilized.

29 **2.2. Rearing conditions**

30 There are many different commercial feed types available optimized for Atlantic salmon smolt, and
31 feed conversion ratios (FCR) are generally low, i.e., around 0.7-0.8 (Hevrøy et al., 2004; Opstvedt et
32 al., 2003).

33 Optimal water quality requirements and safety levels in smolt farms have been described by
34 Bergheim et al. (2009) and are listed in table 1. The required heat sum from fertilization to hatching
35 is approximately 500 day-degrees, while additional 2500-4000 day-degrees are required to reach
36 smoltification (Lekang, O.-I., 2008). Smoltification can be “scheduled” according to production plans
37 by controlling and optimizing light -and temperature regimes.

38 Studies indicate that smolts reared in RAS grow better and have a higher survival rate after transfer
39 to sea cages than traditionally reared smolts (Terjesen et al., 2009). This may relate to the optimized
40 temperature conditions in RAS and consequently larger smolts being produced before transfer to
41 sea.

42 Recent expansions in the smolt industry have resulted in a significant increase in fish densities in
43 many systems, necessitating the use of pure oxygen. Concomitant with this, CO₂ concentrations
44 have increased reaching levels up to 40 mg/L (Martens et al., 2006). Peak density in the systems
45 typically occurs just prior to transfer to sea with the risk of critical CO₂ levels reducing initial growth
46 in sea cages. Carbon dioxide levels should preferably not exceed 15 -20 mg/L (Fivelstad et al., 1999,
47
48
49

61
62
63
64
65

2003), and high levels may be avoided through the use of CO₂ stripping in tanks or by specific filters in RAS. More than one third of Norwegian farmers have installed equipment for stripping of CO₂ either as part of the water intake or within the system (Bergheim et al., 2009). In the Faroe Islands, a recent shift from flow-through systems to RAS including efficient CO₂ removal technology improved the water quality considerably, and smolt mortality has been reduced from 20% to less than 5% of the biomass (Joensen, 2008).

2.3. Existing RAS setups

Most smolt farms employ either single pass flow-through systems (with oxygenation), partial reuse systems (with aeration, oxygenation, and particle removal), or RAS (Bergheim et al., 2009). As mentioned in section 2.1, the number of Norwegian smolt RAS farms are increasing rapidly but information on how these systems affect performance and welfare in the salmon production industry, as well as their environmental impact, is fragmented (Terjesen et al., 2009).

Most Nordic salmon RAS with biofilters use circular tanks, microscreen filtration, and oxygenation technologies to increase carrying capacity. Moving bed biofilters appear to be preferred to fixed bed biofilters and trickling filters (Drengstig, 2011b). Moving bed biofilters are often more compact, use media with a larger specific surface area (500-800 m²/m³), do not require back-washing, and are generally considered easier to operate and maintain than fixed bed biofilters. A maximum feed loading of 2 kg feed/m³ make-up water is typically applied (Bjarne Hald Olsen, Billund Aquaculture, pers. comm.), and Fivelstad et al. (2003) found that smolts of 100-200 g can be produced with a make-up water intake of 0.02-0.04 L/min/kg fish at 10-12 °C. Smolts are typically feed round the clock (24 h light conditions) using automatic feeding systems.

A recently developed concept, based on a combination of smolt production and on-growing of market size Atlantic salmon in land-based RAS using seawater, is currently being implemented in Denmark. Here, a full-scale, land-based RAS (1,000 MT/year) integrates all production units needed for full life-cycle salmon production, i.e., an incubation unit, a separate RAS hatchery, a RAS smolt unit, and a grow-out RAS unit. The latter consists of four ø10 m tanks and four ø17 m tanks. Four additional ø10 m tanks are included for harvesting and purging potential off-flavor substances.

2.4. Future challenges and perspectives

Several new approaches are likely to be implemented within the salmon smolt industry in the coming years to improve overall processes and reduce investment and operation costs. In Norway, it is anticipated that 6-8 new, intensive RAS will be built each year along with reconstruction of existing flow-through systems into reuse systems (Drengstig et al., 2011a). The overall plan is to develop larger RAS farms as the industry currently experiences a deficit of smolts. Capacity building is of high

priority given that the Norwegian salmon industry aims at an annual production of 2 million MT to be reached within the coming 10 years. Depending on the experiences with system operation and the economy achieved within the coming years, production of 1,000 g smolts as well as of market sized fish (3-5 kg) in RAS may contribute to achieving this goal.

3. Rainbow trout (*Oncorhynchus mykiss*)

3.1. Current status

Next to Atlantic salmon, rainbow trout is the most produced species in the Nordic countries with a total production in 2010 of 105,600 MT (FEAP, 2011). Most of the production has until recently taken place in freshwater, land-based, traditional flow-through systems and in seawater net cages. An increasing number of especially Danish freshwater farms are, however, being reconstructed into so-called Model-Trout-Farms (MTFs), a concept that is characterized by the implementation of different cleaning devices and central elements from recirculation technology. By doing so, the farmers obtain operational advantages and can at the same time increase their production while still complying with a strict, national environmental legislation and new requirements related to implementation of the EU Water Framework Directive (WFD; Directive 2000/60 EC of the European Parliament and of the Council of 23 October 2000).

A comprehensive, 2-years monitoring program was carried out on eight MTFs with the aim of documenting their cleaning efficiency of N, P, and organic matter and the resulting discharge (Svendsen et al., 2008). Results showed that the MTFs were very efficient in removing N, P, and organic matter, and the specific discharge of nutrients (kg/MT fish produced) was concomitantly reduced (table 2).

TABLE 2

The Danish legislation was subsequently revised, and Danish trout farmers can now be regulated according to maximum nutrient emissions rather than fixed yearly feed quotas (Danish Ministry of Environment, 2012).

Total investment costs for completely rebuilding a traditional flow-through farm into a MTF are relatively high (approximately 2,800 €/MT produced/year). Rainbow trout is a low / medium value species, but given the new legislation there is no longer any upper limit to the amount of feed that a farmer may apply, and hence to the amount of fish that may be produced, as long as permitted nutrient emissions are not exceeded. As a consequence, there are now strong legislative incentives

1 for farmers to continuously improve and optimize system performance and effluent treatment
2 systems in order to produce more fish and improve the return of their investments.
3

4 **3.2. Rearing conditions**

5
6 There are many different commercial feed types available optimized for rainbow trout including
7 diets targeting on-growing in RAS, and feed conversion ratios are generally good. An average FCR of
8 0.91 (ranging from 0.80 to 1.05) was achieved at the eight MTFs discussed in section 3.1, rearing fish
9 (>50 g) at densities close to 50 kg/m³.
10

11 It typically takes 7-8 months to grow rainbow trout from 20 g to 300 g (portion size) in MTFs.
12

13 However, the actual growth rate depends on the water temperature which, unlike indoor RAS, may
14 vary considerably. Hence, although yearly temperature fluctuations in MTFs usually are less than
15 those observed in open flow-through systems, extremes of 1.6 and 21.0 °C (winter *versus* summer)
16 have been observed (table 1). The all year average temperature measured at the eight MTFs was
17 10.6 °C (Dansk Akvakultur, 2008), whereas the groundwater temperature (i.e., MTF intake water) in
18 Denmark is around 7-8 °C.
19

20 Water quality parameters within the recirculation flow differed both between as well as within the
21 eight monitored MTFs (Svendsen et al. 2008), representing the most intensive type MTFs (see
22 section 3.3). Total ammonia nitrogen (TAN) averaged 2.4 mg/L (average min/max concentrations of
23 0.3 and 7.5 mg/L, respectively), and according to the farmers, this concentration did not cause any
24 problems to the fish at the observed pH (averaging 7.8). NO₂-N averaged 0.15 mg/L (average
25 min/max concentrations of 0.1 and 1.7 mg/L, respectively), and NO₃-N averaged 7.2 mg/L.
26

27 The organic matter content was low to moderate compared to intensive RAS in general (Pedersen et
28 al., 2012), with BOD₅ and COD levels averaging 4.5 and 25 mg/L, respectively. The concentrations
29 were consistent with the good feed conversion generally obtained and indicate an efficient removal
30 of particulate matter (Dalsgaard and Pedersen, 2011). Furthermore, the modest feed loading applied
31 at the eight MTFs (averaging 0.21 kg feed/m³ make-up water) contributed to maintaining moderate
32 organic matter values given a correlation between feed loading and COD concentrations in RAS
33 (Pedersen et al., 2012).
34
35
36

37 **3.3. Existing RAS setups**

38 Feeding in MTFs is typically carried out using demand feeders or feeding continuously during
39 daylight hours using various automatic feeding systems.
40

41 Two types of MTFs are described in the new Danish legislation (Danish Ministry of Environment,
42 2012), referring to farm size prior to regulation by emission concentrations. Farms applying more
43 than 230 MT feed/year represent the highest degree of innovation, have the highest feed loading (≥
44
45
46
47
48
49

1 0.21 kg feed/m³ make-up water), the highest degree of recirculation ($\geq 95\%$), and use ground –or
2 drain water. In comparison, MTFs applying between 25 and 230 MT feed/year may continue to
3 pump in water from the nearby stream, may apply a lower feed loading (≥ 0.04 kg feed/m³ make-up
4 water), and may apply a lower degree of recirculation ($\geq 70\%$).
5

6
7 The use of groundwater reduces problems in maintaining biosecurity compared to using (untreated)
8 surface water. Furthermore, it ensures that year round temperature fluctuations are reduced,
9 minimizes the risk of introducing diseases into the system, and eliminates the risk of bringing in
10 polluted or poor quality water from the stream.
11

12
13 Raceways and self-cleaning circular tanks made in concrete are used. Raceways are equipped with
14 airlift pumps to pump and aerate the water. Decentralized sedimentation zones (typically in the
15 form of sludge cones) are applied for removal of particulate matter. Sludge is pumped to sludge
16 basins for sedimentation at least twice a week to reduce breakdown and mineralization (Pedersen et
17 al., 2008). Raceways may be equipped with drum filters (typically ≤ 74 μm mesh size) following the
18 sedimentation zone for removal of fine particulate matter before the water passes a biofilter. Both
19 fixed bed biofilters (bioelements typically having a specific surface area between 200-750 m²/m³)
20 and moving bed biofilters (media typically having a specific surface area of 750 m²/m³) exist. Fixed
21 bed biofilters must be back-washed at least once a week to remove particulate matter and reduce
22 the heterotrophic biomass in order to enhance nitrification processes (Jokumsen and Svendsen,
23 2010; Svendsen et al., 2008). In addition, optimal biofilter management requires careful monitoring
24 and adjustment of alkalinity, pH, and dissolved oxygen concentrations.
25

26
27 End-of-pipe treatment of outlet water from the production units and overflow from sludge basins is
28 carried out by constructed wetlands typically comprising the old earthen ponds from the former
29 flow-through system. Ponds are interconnected to form a meandering stream to optimize the
30 processes involved. A certain residence time in the constructed wetland is needed for efficient
31 nutrient removal, including degradation of organic matter, denitrification, and removal of
32 phosphorus through sedimentation and binding and incorporation into microbial biomass (Svendsen
33 et al., 2008). The minimum size of the constructed wetland must be at least 40 or 25 m²/MT
34 feed/year in MTFs applying 25 – 230 or > 230 MT feed/year, respectively. Furthermore, the hydraulic
35 retention time must be at least 12 or 36 h in MTFs applying 25 – 230 or > 230 MT feed/year,
36 respectively (Danish Ministry of Environment, 2012).
37

38
39 Sludge basins must be emptied regularly and FeCl or AlCl, often in combination with different
40 polymers, may be applied to increase phosphorus precipitation. Geotubes® may be used for sludge
41 dewatering.

3.4. Future challenges and perspectives

1
2 Model-Trout-Farm operation costs can be higher than that of traditional flow-through farms, and
3 efficient management requires well educated staff. The farms must be constantly optimized and
4 operated accordingly to ensure a permanently high production for economic viability. The removal
5 efficiency of nitrogen, which is lower than that of phosphorus and organic matter (cf. table 2), is
6 currently the major challenge to MTFs, largely preventing them from further increasing their
7 production. Cost-efficient ways of improving nitrogen removal by denitrification are therefore
8 needed.

9
10 The commercial success of MTFs has induced renewed interests in exploring the potential and
11 economic viability of farming rainbow trout in so-called FREA systems (fully recirculation systems),
12 defined as systems having a degree of recirculation of at least 99% (Dansk Akvakultur, 2007).

13
14 Although fully feasible from a technical point of view, new challenges may arise in such systems
15 including, e.g., accumulation of harmful substances that may impair fish growth and welfare (e.g.,
16 Martins et al., 2009). Furthermore, calculations on economic feasibility seem to render FREA systems
17 for trout production barely possible. However, market prices and variations in costs associated with
18 the production and other related costs might, at some point, change in favor of production in FREA.
19 In such a situation, farms based on the already existing recirculation technology may quickly be
20 established.

4. European eel (*Anguilla anguilla*)

4.1. Current status

21
22 Intensive farming of European eels started in the 1970s and was further developed during the 1980s
23 when FREA technology was introduced. Denmark played a leading part in the development of this
24 technology for eel, and still has a forefront position within commercial RAS eel farming among the
25 Nordic countries. There were eight commercial eel farms in Denmark in 2011 with a total annual
26 production of approximately 1500 MT (Christian Graver, Danish Eel Producer Association, pers.
27 comm.). In addition, there have been a few commercial eel farms in Norway and Sweden of which
28 one in Sweden is still in operation.

29
30 Recruitment of glass eels to the European coast has declined severely in the last decades, and it is
31 estimated that current recruitment is 1–9% of the recruitment observed in the 1970s (ICES, 2009a).
32 The sharp decline is an effect of a serious eel stock decline probably related to high fishing efforts,
33 loss of habitats, parasitic infections, and possible accumulation of PCBs and other contaminants
34 (ICES, 2009b). European eel was listed in CITES (the Convention on International Trade in
35 Endangered Species of Wild Fauna and Flora) Appendix II in 2007, with regulations coming into force

in 2009. This means that any import / re-export of live eels or processed eel products requires a CITES import / export permit. A European recovery plan was developed in 2007 (EU, 2007), and the International Council of the Seas (ICES) later stated that recruitment had come to a historical low level (ICES, 2009a). Growing demands by NGOs subsequently resulted in a boycott of eel and eel products from various retailers in Denmark, Germany, and Holland.

Prices on glass eels have recently risen and range at present between 520 and 650 €/kg (1 kg corresponding to approximately 2800-3300 individuals). In comparison, prices on market sized eels varied from 7.00 to 9.35 €/kg in January 2010 - 2012 (Christen Graver, Danish Eel Producer Association, pers. comm.).

4.2. Rearing conditions

On-growing European eels are typically reared at densities exceeding 120 kg/m³ (yielding up to 300 kg/m²/year), and optimum temperature requirements range between 23-28 °C. The species show relatively wide plasticity with respect to acceptable pH, NH₄-N, and CO₂ levels (table 1), all of which makes it very suitable for intensive RAS farming.

Juvenile and on-growing eel RAS systems may be designed similarly, but the stocking density of elvers (i.e., glass eels that have metamorphosed into adult like eels) should not exceed 25 kg/m³ (McCarthy et al., 1996). The survival from glass eel to pre-adult stages is typically very high (85-90%; Buchman et al., 2011).

Regular grading improves growth given high individual differences in growth rate and development of hierarchies (Garcia-Gallego and Akharbach, 1998). Quarantine RAS systems are typically stocked with wild caught glass eels at densities of 0.2-0.3 kg/m² (Huertas and Cerda, 2006). They are usually fed on cod roe and gradually weaned on to granulated, extruded dry feed (0.3-0.8 mm). They are subsequently sorted and reared to market size (200-400 g) on extruded pellets (1-2.5 mm). Belt feeders are typically used for smaller eels, while demand feeders or electrical feeders are used for larger eels. Eels are typically fed continuously for 8-10 h/day. Feed utilization improves by small meals followed by resting periods and stomach excretion (Mortensen, 1996; Seymour 1989). It takes on average 1.5 to 2 years to grow glass eels to market size.

4.3. Existing RAS setups

All European eel farms are based on RAS using FREA technology. Design and management practices vary from system to system. Both raceways, circular, and rectangular tanks exist. Tank design is of minor importance for self-cleaning in comparison to water flow and fish density. A daily water renewal (make-up water) of 4-8% of the system volume is typically applied, corresponding to feed loadings of 10-20 kg feed/m³ make-up water. Most RAS systems use mechanical drum filters with

40-80 µm mesh size for removal of suspended solids combined with submerged fixed bed biofilters (bioelements having a specific surface area between 150-250 m²/m³), and / or trickling filters for nitrification. Specific inline denitrification filters and phosphorus flocculation technology exist on a few intensive farms.

4.4. Future challenges and perspectives

Eel farming is capture-based with supply of juvenile based entirely on glass eels caught in the wild as the reproduction cycle of European eel has not yet been disclosed. An ongoing international research project (PRO-EEL) supported by the European Union through FP7 aims at breeding European eel in captivity (Tomkiewicz et al., 2012).

5. Pike perch (*Stizostedion lucioperca*)

5.1. Current status

Rearing of pike perch in extensive systems and ponds has existed for decades throughout Europe, while farming of pike perch in RAS is a relatively new industry. In Denmark, commercial intensive rearing of this species was initiated based on research projects financially supported by EFF (European Fisheries Fund), investigating the biological and technical challenges of rearing this species in RAS (Martin Vestergaard, Aquapri A/S, pers. comm.; Steinfeldt and Lund, 2008; Steinfeldt et al., 2010). Denmark has a few commercial pike perch RAS farms whereas the species is not reared commercially in RAS in other Nordic countries. A few commercial farms relying on recirculation technology exist in other parts of Europe.

5.2. Rearing conditions

Pike perch is a true piscivorous species with a high protein requirement. The feed applied is therefore rich in protein (typically ≥ 48%) and usually low in fat. The optimal ratio between digestible protein and digestible energy (DP:DE) has, however, not yet been established and no commercial feed is currently available.

Optimum growth rates and feed utilization require rearing temperatures of 22-25 °C, economically favoring closed, indoor RAS to outdoor facilities in which the fish typically grow more slowly (Steenfeldt et al., 2010). It takes on average 460 days to grow a pike perch from 1 g to 1 kg in RAS (Martin Vestergaard, Aquapri A/S, pers. comm.).

There is currently rather limited information on water quality parameters for pike perch in operating intensive RAS (table 1). The species appears to be quite robust to low oxygen concentrations, but it is recommended to keep oxygen levels above 50% saturation in rearing tank outlets to sustain

1 growth and optimal biofilter performance. Juvenile and on-growing pike perch are reared in
2 freshwater but tolerate brackish water, while larvae cannot survive salinities above approximately 5
3 ppt (Lozys, 2004). There are no published studies on the effects of salinity on pike perch
4 performance in RAS.
5

6
7 Optimal light intensities during on-growing are below 10 lux (Luchiari et al., 2006), and abrupt
8 changes in light intensity should be avoided to minimize severe stress and consequently loss of fish.
9 The dim light requirements may interact with daily management routines and inspection of the RAS.
10 Small juveniles (10-50 g) should be kept at densities below 15-30 kg/m² (Steenfeldt et al., 2010),
11 while larger juveniles (0.05-2.0 kg) can be kept at higher densities (30-60 kg/m²) without any obvious
12 increase in crowding stress parameters, suppressed growth, or increase in FCR (Steenfeldt et al.,
13 2010).
14

15
16 Successful brood-stock (preferably cultured rather than wild) maturation and spawning can be
17 obtained through adequate light -and temperature regulation combined with induced fish behavior
18 (Martin Vestergaard, Aquapri A/S, pers. comm.), eliminating the need for hormonal treatment and
19 artificial fertilization techniques (Steenfeldt and Lund, 2008). Each recirculation unit might preferably
20 be individually adjustable to prolong the spawning season in order that mature spawners can be
21 obtained throughout the year. This ensures a continuous production strategy involving year round
22 stocking and harvesting of fish. Second time spawners (i.e., 3 years of age) provide eggs / semen of
23 better quality than first time spawners (Martin Vestergaard, Aquapri A/S, pers. comm.), and eggs
24 solely from hatchery reared brood-stocks can now be obtained, providing eggs all year round.
25 Several independent brood-stock RAS minimize the risk of outbreak and spreading of diseases.
26 Hatchery conditions and larval management has been described in detail by Steenfeldt and Lund
27 (2008) and Steenfeldt et al. (2010).

34
35
36
37
38
39
40

41 **5.3. Existing RAS setups**

42 The high rearing temperature of pike perch increases energy costs associated with cleaning and
43 operation of recirculation pumps, or alternatively, increases costs associated with installation and
44 operation of heat pumps or heat exchangers.
45

46 Recirculating systems for pike perch typically include mechanical filters (40-80 µm mesh size),
47 submerged biological filters, and / or trickling filters for sludge removal and nitrification,
48 respectively. Both fixed bed and moving bed filters exist (specific surface area of the media typically
49 ranging between 150-750 m²/m³). Furthermore, filters for denitrification may be installed as in other
50 FREA systems for finfish farming. Tanks may be rectangular or circular for all production sizes.
51 However, pike perch are relatively shy and easily stressed (Martin Vestergaard, Aquapri A/S, pers.
52 comm.), and tanks should therefore not be too small (ø3-8 m) or shallow (≥ 1.5 m). In addition, sharp
53
54
55
56
57
58
59
60
61
62
63
64
65

edges or obstacles inside the tanks should be avoided as fish might easily get injured during situations of acute stress behavior.

Automatic feeders ensure the best feed intake by pike perch in RAS. It may be advantageous to use floating pellets to ensure a more uniform feed distribution and improve management (i.e., optimize estimates of feed consumption and avoid overfeeding) (Steenfeldt et al., 2010). However, juveniles (< 5 g) must be weaned using floating pellets, as they might otherwise not accept them at later stages (Martin Vestergaard, Aquapri A/S, pers. comm.).

Separate units of smaller on-growing RAS compared to a few larger units are advantageous in terms of daily management procedures, cleaning and disinfection, as well as maintenance and operation of biofilters (Martin Vestergaard, Aquapri A/S, pers. comm.). Using several separate systems furthermore ensures that pike perch from different cohorts and of different sizes can be kept apart, minimizing stress during grading, water treatment, etc. As a rule of thumb, pike perch should be graded (from 1 g onwards) at every doubling of the body weight to ensure a more uniform growth.

5.4. Future challenges and perspectives

Year round production of pike perch requires constant high temperatures, which is only feasible in intensive RAS. In the design of new RAS for this species, and to make the production economically sustainable, focus should be on cost reductions (i.e., investment and operational costs, fingerling expenses, energy costs, maintenance, etc.) as well as on improving growth and feed utilization. Furthermore, establishment of breeding or domestication programs might support commercial viability of pike perch farming.

6. Arctic char (*Salvelinus alpinus*)

6.1. Current status

Arctic char is a highly valued salmonid species renowned for its good texture and taste (Gunnarsson, 2006) and a fillet yield exceeding that of rainbow trout (Glandfeld, 1993). Arctic char farming is still a kind of niche industry with a global, annual production of about 5,000 MT of which approximately 60% takes place in Icelandic flow-through systems (Oddsson and Steindorsson, 2009). Minor productions take place in Norway, Sweden, and Canada some of which are in RAS, and there is increasing interest for farming Arctic char in Chile and Australia (Gunnarsson, 2006; Molleda, 2007; Oddsson and Steindorsson, 2009). The production of Arctic char in Iceland is expected to double within the next few years driven by increasing market demands, and the industry is anticipated to grow even further in the future.

1 Arctic char is sold as whole or fully trimmed fillets, either fresh or frozen. The main markets are
2 located in Europe (mainly Switzerland) and in the United States. Current wholesale prices for fillets
3 are about 10-13 €/kg.
4

5 6 **6.2. Rearing conditions**

7 Arctic char is the most cold-adapted salmonid species (Johnson, 1980) with an optimal rearing
8 temperature between 5-12 °C. The optimum rearing temperature for juveniles is slightly higher (8-15
9 °C, 20 – 500 g), although the growth advantages obtained when rearing at elevated temperatures
10 (15 °C) appear to be lost when producing fish > 1000 g due to maturation and subsequent growth
11 reduction (Gunnarsson et al., 2011; Ragnheidur Thorarinsdottir, pers. comm.). Arctic char typically
12 reaches market size 15-30 months post-hatch depending on the rearing temperature and
13 slaughtering size (800-1,300 g). It tolerates densities up to 130 kg/m³ (Summerfelt et al., 2004), and
14 is therefore considered very suitable for rearing in cold-water intensive RAS, where constant year-
15 round rearing temperatures can be maintained (Siikavuopio et al., 2009). There is, however, rather
16 limited information on water quality parameters for the species in operating intensive RAS (table 1).
17 Arctic char does not feed as aggressively as for example rainbow trout and multiple daily feeding
18 events are necessary to optimize the feed intake (Linnér and Brännäs, 2001). Several commercial fish
19 feed companies produce diets formulated specifically for Arctic char.
20
21
22
23
24
25
26
27
28
29
30

31 32 **6.3. Existing RAS setups**

33 Abundant sources of freshwater, seawater, and geothermal heat provide unique conditions for land-
34 based aquaculture in Iceland, and Icelandic land-based farms have so far not invested in RAS. Most
35 Icelandic farms use geothermal heat to maintain optimal rearing temperatures and reduce water
36 consumption by adding oxygen to the inlet water. Some farms reuse water after removing
37 suspended solids by simple filtration.
38

39 Compared to the production of Arctic char in flow-through or partial-reuse systems as in Iceland,
40 rearing of this species in intensive RAS is still in its infancy and very few systems exist. Summerfelt et
41 al. (2004) provided a thorough description of some intensive North American grow-out RAS including
42 both commercial -and demonstration facilities, and Siikavuopio et al. (2009) and Skybakmoen et al.
43 (2009) provided thorough descriptions of a commercial Norwegian Arctic char RAS.
44

45 The systems described have a high degree of recirculation (~ 95%) and use self-cleaning, circular
46 ('Cornell-type' dual-drain) or octagonal culture tanks attached with sludge collectors for rapid and
47 efficient solids removal, thereby reducing mineralization and concomitant deterioration of the water
48 quality (Summerfelt et al., 2004). Furthermore, outlet water from the culture tanks passes through
49 microscreen drum filters to ensure high water quality (Summerfelt et al., 2004). Pumping rates
50
51
52

54
55
56
57
58
59
60
61
62
63
64
65

1 should be high enough to exchange the culture tank volume once every 30-45 min, thereby
2 maintaining safe dissolved oxygen concentrations at high fish densities (Johannsson et al., 2010;
3 Summerfelt et al., 2004). The low rearing temperature of Arctic char can be a challenge in RAS as the
4 degree of recirculation increases, and may require installation of water chillers or increased use of
5 make-up water to maintain the temperature within the optimal range (Summerfelt et al., 2004).
6
7 The North American grow-out systems described by Summerfelt et al. (2004) primarily use fluidized
8 sand biofilters, which are relatively inexpensive and have a high specific surface area (8,000-12,000
9 m²/m³). These biofilters are efficient in removing TAN and oxidizing nitrite with typical outflow
10 concentrations of TAN between 0.1-0.5 mg/L and NO₂-N less than 0.1-0.3 mg /L. In comparison, the
11 Norwegian grow-out system described by Skybakmoen et al. (2009) uses a trickling biofilter. This
12 type of biofilter needs a high hydraulic flow-through (pumps working at 472 L/min/m²) to maintain
13 stable nitrification rates due to the short contact time in the filter. UV irradiation units or addition of
14 ozone prior to culture tanks may be used to maintain low levels of suspended solids and NO₂-N
15 (<0.01 mg/L) in the rearing tanks (Summerfelt et al., 2004).
16
17
18
19
20
21
22
23
24
25

26 **6.4. Future challenges and perspectives**

27 Most of the existing RAS technology and knowhow has been developed for rearing species at higher
28 temperatures than Arctic char and / or for rearing other salmonid species. More research and
29 development is therefore needed to ensure optimal rearing conditions for the species, although
30 significant improvements have already been achieved (Summerfelt et al., 2004).
31

32 In addition to system optimization, there is a need for systematic breeding programs and brood-
33 stock development selecting for fast growing strains. Wild caught fish are generally not suitable for
34 on-growing in intensive RAS due to high mortalities (often due to various pathogens) and seasonal
35 changes in growth and feed utilization, a trait that is typically not observed in hatcheries producing
36 Arctic char (Siikavuopio et al., 2009; Skybakmoen et al., 2009). Furthermore, there have been
37 problems with early sexual maturation, reducing growth rates and fillet quality before specimens
38 reaching market size (Summerfelt et al., 2004). An Icelandic breeding program was initiated in 1989
39 at Holar (Svavarsson, 2007) with emphasis on growth, sexual maturation, and resistance against
40 pathogens. In 1991, the Icelandic company Stofnfiskur similarly started a breeding program
41 (Gunnarsson, 2006) with support from the Icelandic Ministry of Agriculture and Fisheries, and results
42 from this ongoing work has been promising (Oddsson and Steindorsson, 2009).

7. Sturgeon (order Acipenseriformes)

7.1. Current status

Sturgeon (order Acipenseriformes) comprises more than 20 different species and a wide number of hybrids (Bronzi et al., 2011; Litvak, 2010). It is among the most valuable group of fish because of caviar, but the meat quality can also be quite high (Bronzi et al., 2011; Köksal et al., 2000). Sturgeons are, however, also among the most endangered group of fish due to overfishing, poaching, pollution, damming, habitat deterioration, etc. (Bronzi et al., 2011; Jaric and Gessner, 2012; Litvak, 2010). Since 1998, all extant species including those commercially reared have been listed in CITES Appendix I or II (i.e., threatened by extinction or in risk of becoming so), and trade of fish from the group has since been regulated under CITES.

Aquaculture production of sturgeon started in the 1960s in the former USSR (farming 'bester' - a hybrid between *Huso huso* and *Acipenser ruthenus*), while farming in Iran, North America, and Europe was initiated in the 1980s (Bronzi et al., 2011; Jaric and Gessner, 2010; Williot et al. 2001). Production took off in the beginning of the twenty-first century with China entering the industry, and the country currently accounts for approximately 75% of the global sturgeon meat production (Bronzi et al., 2011). Siberian sturgeon (*A. baerii*) is the most commonly reared species, but at least 12 species and 6 hybrids are farmed in more than 30 countries (Bronzi et al., 2011). The global production of caviar was estimated to be 110-120 MT in 2008 (close to the legal yield from fisheries), but has most likely increased considerably since then. In a foreseeable future, most caviar is anticipated to come from aquaculture. The most rare, top quality Beluga caviar sells for more than 10,000 €/kg, while caviar from commercial production sells for about 10% of this price (Bronzi et al., 2011).

Sturgeons are relatively easy to rear, and species cultured for production of meat could be potential candidates for substituting other commonly reared species such as rainbow trout (Köksal et al., 2000). On-growing may take place in flow-through raceways, tanks, earthen ponds, or in RAS (Paschos et al., 2008; Williot et al., 2001). Finland is currently the only Nordic country commercially engaged in sturgeon aquaculture, and farming of sturgeon in recirculation modules has taken place here since 2005. Sturgeon meat has been sold since 2007 at prices of 5-7 €/kg, while actual caviar production based on farming in RAS started in 2011.

7.2. Rearing conditions

Sturgeons are generally slow growing, late maturing fish. It takes for example 5-6 years for male and 6-8 years for female Siberian sturgeon to reach maturity in captivity, which is still far earlier than in the wild (FAO, 2012; Rachek et al., 2010; Williot et al., 2001). Sturgeons are reared in freshwater

1 throughout their life-cycle despite some species being semi-anadromous (Williot et al., 2001). They
2 generally tolerate high densities (up to 80–90 kg/m³ for fish weighing 10 kg; Kaj Arvonen, Arvotec,
3 pers. comm.), and show plasticity with respect to temperature and oxygen levels (table 1) (Williot et
4 al., 2001; Litvak, 2010). Water quality requirements are largely equal to that of other species,
5 although they appear to be more sensitive to NO₃-N (Kaj Arvonen, Arvotec, pers. comm.). A rearing
6 temperature of 20 °C appears to be suitable for on-growing, although slightly higher temperatures
7 speed up the maturation process.

8 Sturgeons are bottom feeders and commercial diets formulated for sturgeon are readily available.
9 Rearing conditions and feeding rates in farming aimed at caviar production must be carefully
10 adjusted to mature fish with optimal timing and to obtain high quality caviar, which is valued
11 according to color, firmness, fat content and taste. Caviar yields are typically about 10-15% of total
12 body weight, while fillet yields are about 40-50% (Litvak, 2010; Williot et al., 2001).

13 Hatchery conditions and brood-stock management is generally well known and has been described
14 for a few species (e.g., Hamlin et al., 2006; Litvak, 2010; Paschos et al., 2008; Williot et al., 2001).

25 7.3. Existing RAS setups

26 Caviar-oriented production requires extensive facilities for keeping enlarging stocks. A high intensive
27 RAS facility in Finland, rearing both Siberian sturgeon (*A. baerii*) and Beluga (*Huso huso*), is located
28 within a paper mill using waste heat from the plant to heat the water. The facility consists of several
29 separate modules each with their own recirculation system and each with a high degree of
30 recirculation (99.5%). Sludge is collected centrally from the circular tanks, and tank outlet water is
31 passed through drum filters (60 µm mesh size). Sludge is treated at the waste water treatment plant
32 associated with the paper mill. Water is degassed by aeration prior to being pumped through
33 fluidized sand-bed biofilters with a high specific surface area (typically 8,000-12,000 m²/m³), and
34 runs by gravity to oxygenation and ozone towers before returning to the tanks. Each module has a
35 volume of 250 m³ and a flow of approximately 100 L/s (360 m³/h), corresponding to a complete
36 module water exchange of 1.4 times/h. A maximum feed loading of 0.83 kg feed/m³ make-up water
37 is typically applied in sturgeon RAS (Bjarne Hald Olsen, Billund Aquaculture, pers. comm.).

38 Rearing conditions in the Finnish facility are controlled using a custom designed feeding system. The
39 system monitors temperature, oxygen, and pH in each module separately, while all necessary
40 adjustments are made manually to prevent problems arising from potential probe failures. The
41 feeding system furthermore controls the light conditions, and can simulate any season of the year.
42 An alarm system registers any failure or other anomalies in the systems, in which case feeding is
43 reduced or stopped.

7.4. Future challenges and perspectives

1
2 There is a huge and increasing worldwide market for caviar, but international trade is difficult due to
3 the strict legislation implemented to protect the endangered group of fish.

4
5 There is a risk that other gourmet products may override caviar. To avoid this, it must be ensured
6 that the organoleptic quality of caviar produced in aquaculture is excellent. Furthermore, promoting
7 the product as an extreme delicacy becomes even more important in the future. To avoid misuse of
8 the term caviar, the Codex Alimentarius Commission (CAC) of the Joint FAO/WHO Food Standard
9 Program has decided on a Standard for Sturgeon Caviar (Codex Stan 291 – 2010).

10
11 Geosmin is a general problem in RAS but even more so in the production of caviar due to its
12 renowned status as an exquisite delicacy (Kaj Arvonen, Arvotec, pers. comm.; Mogens Larsen,
13 Lyksvad Fiskefarm, pers. comm.). It is therefore of utmost importance that this problem is carefully
14 considered and ultimately eliminated in the farming process.

15
16 Systematic breeding programs are needed that select for all female fingerlings (when aiming for
17 caviar production), prevent unnecessary on-growing of males, and reduce the time to maturity
18 (Litvak, 2010).

8. Nile tilapia (*Oreochromis niloticus*)

8.1. Current status

19
20
21 There is an increasing interest for rearing tilapia in the Nordic countries, particularly in aquaponic
22 systems where nutrient rich effluent from culture tanks is used for green house production. Several
23 European companies, including a Swedish company, have thus started out with this relatively simple
24 and well-known green growth technology aiming at sustainable productions (e.g., Heeb et al., 2009).
25 Nile tilapia is a relatively fast growing, warm water species, offering new opportunities for RAS
26 productions utilizing waste heat from industries or geothermal heat which is available in many
27 countries. Focus is currently on small urban production units for local food production, but in areas
28 with geothermal heat or stable supply of waste heat the units could become of commercial scale.
29 Current operation costs of tilapia in RAS are high due to the limited production combined with a low
30 fillet yield (about 30-32%; Ragnheidur Thorarinsdottir, pers. comm.). On the upside, current market
31 prices are relatively high, i.e., about 10-20 €/kg for locally produced fresh fillets. Furthermore, the
32 costs of feed are relatively low, i.e., approximately half the cost of feed for salmonids.

Tilapia is a rapidly growing, high-density tolerating species enduring densities up to 120 kg/m³ making it well suited for aquaculture. It is omnivorous and can therefore feed on both plant and

1 animal products in contrast to most other aquaculture species cultured in the Nordic countries,
2 providing opportunities for sustainable productions based on local feed ingredients. A dietary
3 protein content of 32-36% and 28-32% is generally recommended for fingerlings and on-growing
4 fish, respectively (Riche and Garling, 2003). The fat content should not exceed 4-8% in diets for on-
5 growing fish (Riche and Garling, 2003), while it should be a little higher in feed for fingerlings
6 (Jauncey, 1998).
7

8
9
10 Given the right conditions, fry may increase their body weight by 50% every three days (Riche and
11 Garling, 2003), and tilapia may grow to approximately 1 kg in 8-9 months if reared at a temperature
12 of 27-28 °C and on a diet containing 30% protein (Ragnheidur Thorarinsdottir, pers. comm.). It is
13 recommended to feed on-growing tilapia at 4-5 hour intervals to improve feed utilization (Riche and
14 Garling, 2003).
15

16
17
18
19 There is currently limited information on water quality parameters for the species in intensive RAS in
20 operation (table 1). The optimal growth temperature ranges between 20-30 °C, and dissolved
21 oxygen concentrations should preferably be maintained above 5 mg/L at all times for optimal
22 growth. Feeding should be stopped if the level drops below 3 mg/L (Riche and Garling, 2003). As for
23 other fish species, unionized ammonia should be kept at an absolute minimum (Riche and Garling,
24 2003). Tilapia has high resistance against pathogens and low mortalities are generally observed.
25
26
27
28
29
30

31 **8.3. Existing RAS setups**

32
33 As mentioned in section 8.1, there are relatively few tilapia producers in Europe, and mostly with
34 relatively small production systems. A brood-stock of Nile tilapia was imported from North American
35 Tilapia Inc. (NATI, Lindsay, Ontario, Canada) to Iceland in 2008 and tested in a RAS at Keldnaholt,
36 Reykjavik. The system had an internal recirculation flow of 600 L/min (36 m³/h), and consisted of a
37 drum filter, combined aerator and low-head oxygenator, and a moving bed biofilter (Johannsson et
38 al., 2009). A commercial scale RAS production of tilapia based on this brood-stock was initiated in
39 2011, aiming for an annual production of 2,000 MT. The facility consists of a simple, semi-intensive
40 recirculation system (with a degree of recirculation of 70%) and no biofiltration. It contains both
41 indoor and outdoor tanks with geothermal heat used to maintain a rearing temperature of 27-28 °C.
42
43
44
45
46
47
48
49

50 **8.4. Future challenges and perspectives**

51
52 High capital costs are one of the biggest challenges for economically sustainable RAS production of
53 tilapia in the Nordic countries. The systems must become sustainable in terms of energy utilization
54 and cutting costs further by, e.g., using local feed ingredients.
55

56
57 Aquaponic systems are fetching increasing interest as a potential future technology for safe, local
58 food production, and also polycultures with other species might offer interesting possibilities.

64
65

9. European lobster (*Homarus gammarus*)

9.1. Current status

European lobster (*Homarus gammarus*) is among the most valuable and preferred seafood products. Despite a wide distribution from Northern Norway to Greece, annual landings are just about 2,000-2,500 MT (Agnalt, 2008). Norway was one of the major fishing nations for European lobster until 1960, but the annual landings declined by more than 90% between 1960 and 1980 to around 50 MT (Jørstad et al., 2001). Lobster stocks in Norway have not recovered since then, and the stock is at a historically low and critical level (Agnalt, 2008).

Farming of European lobster in RAS is still in its infancy, but incentives for land-based rearing are large. The species is subject to increasing market prices due to high market demands and the low and discontinuous wild catches.

9.2. Rearing conditions

Information on desirable water quality parameters and rearing conditions for European lobster are generally sparse (table 1). A thorough description of the currently best known rearing conditions and key water quality parameters for intensive production of European lobster in RAS can be found in Drengstig and Bergheim (this issue).

Recent research has shown that it is possible to rear lobster larvae, juveniles and plate-sized lobsters at high intensities, and major progress has been achieved on automation to support commercial rearing of full grow-out cultures (Drengstig et al., 2009). European lobsters can be farmed from hatching to market size (i.e., from approximately 20 cm to 300 g) in 24-30 months (i.e., Drengstig et al., 2003a, 2003b; Kristiansen et al., 2002, 2004; Wickins and Beard, 1991).

Ammonia is quite toxic to lobsters and seems to be the major limiting parameter in recirculation seawater systems, requiring a biological filter to mitigate the toxic effect. Lobster feed is high in protein, and ammonia excretion rates are correspondingly high. Average production rates of 0.1 – 0.5 g TAN/kg/day have been reported for adult lobster (Drengstig and Bergheim, 2010).

Protein is the main energy source for crustaceans and the diet of wild lobsters contains 40-60% protein (Leavitt et al., 1979). Crustaceans utilize carbohydrates better than lipids (Ackefors et al., 1992), and lobsters utilize complex carbohydrates better than simple ones (Cuzon and Guillaume, 1997). The optimal dietary DP:DE ratio has not yet been established. However, a formulated diet that can be used from I-stage larvae to market sized lobsters has been developed, substituting the need for live and / or natural feed.

Wild brood-stocks should be quarantined before introduced into a facility and proper water quality, adequate feed, and minimal stress should be ensured. In comparison to other lobster species,

1 *Homarus* species are characterized by a simple and abbreviated larval period. They feed readily on
2 natural and artificial food and exhibit rapid growth in heated water. The optimum growth
3 temperature is 18-20 °C.
4

5 European lobsters are generally quite resistant to diseases although they do seem susceptible to
6 Gaffkemia caused by the bacteria *Aerococcus viridians homari*. Intensive culture does not appear to
7 increase the risk of disease outbreaks, and with over a century of experimental and commercial
8 lobster hatchery operations only a few incidents of diseases have been recorded (Jørstad et al., 2001;
9 Kristiansen et al., 2004). Epizootic shell disease has been observed in some American lobster
10 (*Homarus americanus*) specimens discovered in Norwegian waters, but transmission to European
11 lobster has not been reported (Jørstad et al., 2001).

17

18 **9.3. Existing RAS setups**

19 European lobster is highly cannibalistic and needs to be reared in separated compartments.
20 Furthermore, the relatively high, optimal rearing temperature requires heating of seawater. Major
21 prerequisites for successful rearing in RAS therefore include development of highly advanced
22 technologies and effective conservation of water. There is currently only one producer farming
23 lobster in land-based RAS from egg to market size, and a detailed description of the system can be
24 found in Drengstig and Bergheim (this issue). The technique has been developed over the last 12
25 years, aiming at obtaining a viable farming solution and developing a technology that will be
26 economically, biologically, and technically suitable for industrial scale production. The facility
27 consists of a hatchery unit, a brood-stock section, and an on-growing unit. The principle in the
28 technology is that pelagic larvae after hatching (approximately 10 mm) are kept in upstream
29 incubators for approximately 14 days. The hatchery facility provides optimum conditions during this
30 stage by simulating the pelagic stage in the wild. After two weeks and three moults, the juveniles
31 (reaching approximately 20 mm) turn to benthic condition. At this stage, they are transferred to
32 single cages to prevent cannibalism. The lobsters change cages twice during the grow-out phase
33 according to size. Tanks and individual cages are self-cleaning given specific hydraulics.

48 **9.4. Future challenges and perspectives**

49 A genetic tagging program was launched in 2008 as a cooperation project between the Norwegian
50 Lobster Farm AS and the Institute of Marine Research in Bergen, Norway. The overall aim of the
51 program was to develop a genetic databank that can be used for screening and selecting the best
52 performing, wild caught brood-stock by monitoring offspring growth, survival, and feed utilization.
53 The genetic tagging program also included simulating seasonal changes by adjusting the ambient
54 temperature for 2 groups of brood-stock. As a result, it is possible to hatch juveniles from January
55
56
57
58
59
60
61
62
63
64
65

1 until December, and performance of these juveniles is currently being evaluated. Moreover,
2 successful attempts have been made to breed brood-stock in captivity. Monitoring of juvenile
3 performance was conducted in 2011, but the program was postponed until 2013 due to a fire in the
4 hatchery.
5

6
7 There is currently a lack of knowledge on respiration and excretion rates for lobster at all stages.
8 Based on the economic importance of these issues, current activities are carried out focusing on
9 identifying critical water quality values in order to dimension the technical equipment to sustain a
10 healthy RAS environment.
11
12
13
14
15

16 **10. Discussion**

17 Applications of RAS seem the most promising road ahead for boosting aquaculture production in the
18 Nordic countries, and there are many ongoing activities and possibilities for culturing different
19 species in RAS. Species that have not been embraced above, but where some preliminary
20 examinations have been carried out include for example common sole (*Solea solea*), perch (*Perca*
21 *flavescens*), turbot (*Scophthalmus maximus*), and whitefish (*Coregonus lavaretus*).
22
23
24
25
26

27 High capital costs are one of the biggest challenges to sustainable RAS calling for large scale
28 intensive productions to reduce investment and operation costs. Consistent with this, production of
29 Atlantic salmon smolts in indoor RAS and rainbow trout in outdoor MTFs have been the most
30 successful, commercial productions so far. Both of these production systems have: i) arisen from
31 traditional, well known and well established species and industries; ii) comprise large scale, intensive
32 production units; and iii) have had sufficient financial support from the start.
33
34
35
36

37 Much of the RAS technology applied is already well known (e.g., Crab et al., 2007; Eding et al., 2006;
38 Martins et al. 2010; Sindilariu et al. 2008; Timmons and Ebeling, 2007). It has been thoroughly tested
39 and is, as such, more or less ready to apply for culturing a variety of species. However, focusing
40 solely on technological solutions, while overlooking associated costs, may be risky and lead to non-
41 profitable productions.
42
43
44
45

46 The technology must be constantly optimized and assessed, and the systems operated and managed
47 accordingly in order to ensure economic viable returns in a fluctuating market. Furthermore, cost-
48 effective solutions for end-of-pipe treatment, including sludge handling and efficient nitrogen
49 removal, are still a challenge (Mirzoyan et al. 2010; van Rijn et al. 2006). Here, it may be beneficial to
50 learn from urban waste water treatment processes and management (Pedersen et al., 2012). In
51 addition, it is essential to develop production methods and routines that ensure high product quality
52 and reduce general problems in RAS such as off-flavors caused by for example geosmin and 2-
53 methylisoborneol (Houle et al., 2011; Krishnani et al., 2008; Schrader and Summerfelt, 2010; Tucker,
54
55
56
57
58
59
60

62
63
64
65

1
2
3
4
5
6
7
8
9
2000). Treatment of diseases is another ubiquitous issue in RAS. While some diseases might more or less disappear when rearing in RAS, others may aggravate. An example of the latter is white spot disease caused by the protozoan parasite *Ichthyophthirius multifiliis*. Outbreaks are typically treated with formalin, although less environmentally harmful and health hazardous substances are becoming available (e.g., Pedersen et al., this issue). It is, however, outside the scope of this paper to get further into diseases and disease treatment.

10
11
12
13
14
15
16
17
18
Given that the technology is more or less in place, successful production of “new” fish species in RAS depends largely on identifying biological requirements such as the specific water quality conditions of the specific species including different life-stages, and designing the RAS to fulfill and support these specific requirements. Large scale production of crustaceans in RAS is more challenging, still requiring development and optimization of the necessary technology.

19
20
21
22
23
24
25
26
27
It is a prerequisite for successful RAS production of most species to have well established brood-stocks rather than relying on supply from the wild. Cultured brood-stocks reduce the risk of introducing diseases into the systems, ensure a steady (all year round) supply of progeny, and allow for carrying out domestication and breeding programs selecting for desired traits such as enhanced growth and improved feed utilization.

28
29
30
31
Successful operations of less intensive RAS including aquaponic systems appear to be feasible primarily when culturing more exotic species targeted for selected customers.

Table 1. Water quality parameters observed under general conditions in operating, commercial or pilot scale RAS^a

Parameter	Temperature (°C)	O ₂ ^b (mg/L)	CO ₂ (mg/L)	pH	Salinity (ppt)	TAN (mg/L)	NO ₂ -N (mg/L)	NO ₃ -N (mg/L)	Density (kg/m ³)	References ^c
Arctic char	5-12	9-11	≤22	6.5-8.5	<24-26	≤1.0	<0.50	<10	85-130	1-4
Atlantic salmon smolt	12-14	10	≤12	6.8-7.3	0	<0.2	<0.20	≤90	45-50	5-7
European eel	23-28	6-8	10-20	5.0-7.5	0-5	0.0-5.0	0-1.50	50-100	50-120	8-9
European lobster	18-20	>6	n.a.	7.8-8.2	28-35	<0.3	n.a.	n.a.	n.a.	10-11
Pike perch	22-25	6-8	10-20	6.5-7.5	0	0-10.0	0-1.50	≤56	15-60	12-13
Rainbow trout	2-21	6-8	≤15	6.5-8.0	0-30	<7.5	<1.00	<200	50-80	5, 14-17
Sturgeon	18-25	8	n.a.	7.0-8.0	0	<3.0	<0.50	<25	80-100	18-23
Tilapia	20-30	4-6	≤30-50	6.5-8.5	≤10-15	<3.0	0.05-1.00	100-200	85-120	1, 24-26

^a The table represents values for commercial or pilot scale RAS for on-growing (excepting Atlantic salmon smolt) as observed primarily by farmers / managers. The values may deviate from scientifically validated research results or scientifically determined, optimal physiological values typically obtained under laboratory scale experiments.

^b Oxygen concentrations at typical rearing temperatures.

Table 2. Average net removal efficiencies (R_N , %)^a of eight Model-Trout-Farms and the concomitant specific discharge (kg/MT fish produced) of nitrogen, phosphorus and BOD₅ (Svendsen et al. 2008)

Nutrient	Total nitrogen	Total phosphorus	BOD₅
R_N obtained (%)	50	76	93
Specific discharged (kg/MT fish produced)	20.0	1.1	5.6

^a R_N (%) = $((P - U_N) / P) * 100$, where P = contribution of a given nutrient from fish production

(Dalsgaard and Pedersen, 2011), and U_N = net discharge of a nutrient from the farm (i.e., discharge concentration minus the contribution from intake water).
