#### Abstract

Safi, Zeineb, Masters: June: 2017, Master of Science Computing Title: A CONCEPTUAL HEURISTIC FOR SOLVING THE MAXIMUM CLIQUE PROBLEM

Supervisor of Thesis: Prof. Ali Jaoua The maximum clique problem (MCP) is the problem of finding the clique with maximum cardinality in a graph. It has been intensively studied for years by computer scientists and mathematicians. It has many practical applications and it is usually the computational bottleneck. Due to the complexity of the problem, exact solutions can be very computationally expensive. In the scope of this thesis, a polynomial time heuristic that is based on Formal Concept Analysis has been developed. The developed approach has three variations that use different algorithm design approaches to solve the problem, a greedy algorithm, a backtracking algorithm and a branch and bound algorithm. The parameters of the branch and bound algorithm are tuned in a training phase and the tuned parameters are tested on the BHOSLIB benchmark graphs. The developed approach is tested on all the instances of the DIMACS benchmark graphs, and the results show that the maximum clique is obtained for $70 \%$ of the graph instances. The developed approach is compared to several of the most effective recent algorithms.

## Dedication

For my parents.

## Acknowledgements

First and foremost, I would like to thank my parents. I thank my mother for her unconditional love and support. My father for being such a great idol and setting an example for me to follow. I thank them both for believing in me and pushing me to always give my best. My deepest thanks and gratitude to my supervisor Prof. Ali Jaoua, who I learned a lot from, and who's door was open for me whenever I needed. I would also like to thank my team, Eman Rizk for her valuable advice, Dr. Abdelaali Hassaine, Fahad Islam and Abubakr Aqle for their feedback and support.

This contribution was made possible by NPRP grant \#06-1220-1-233 from the Qatar National Research Fund (a member of Qatar Foundation). The statements made herein are solely the responsibility of the authors.

## Chapter 1: Introduction

### 1.1 Overview

Optimization is very important in our human life. We constantly strive to optimize our productivity, our time consumption and even the roads we take. Factories seek optimization of their production by optimizing their production chains. Governments make great efforts to optimize the allocation of their resources. As possibilities grow larger and the number of choices increases, optimization becomes harder and harder to achieve. All of these problems are related to what is known in information theory as "Combinatorial Optimization", which is a set of problems in which an optimal object is sought from a set of objects.

The maximum clique problem has been researched intensively for decades as an important combinatorial optimization problems. The k-clique problem, checking if a clique of size k exists in a graph, is one of the 21 original NPComplete problems introduced by Karp [28]. The maximum clique problem is not just hard to solve but also approximate solutions for it are hard to find [6]. It has many generalizations and relaxations. In the maximum weight clique problem, graph edges have weights associated to them and the clique with the highest weight needs to be found. The k-plex, quasi-clique, k -subgraph problems, are all relaxations of the constraints on the density and the number of adjacent vertices of the maximum clique to be found. All of these have
important applications in different domains, and because of their difficulty, efficient exact and heuristic solutions need to be developed.

In applied mathematics, Formal Concept Analysis is the field that is concerned with deriving a conceptual hierarchy from a collection of objects and their corresponding attributes. The survey conducted by Singh et. al. [47], illustrates the usefulness of formal concept analysis in solving problems in various fields of applications including Software Engineering, Social Network Analysis, Information Retrieval, Security Analysis etc. The sound mathematical foundation of conceptual methods, can be applied to devise solution to problems like the maximum clique, and that is what we attempt to explore in the scope of this thesis.

### 1.2 Maximum Clique Applications

The maximum clique problem is motivated by its significance in solving practical problems in various fields, that are both interesting and important. In bioinformatics, the comparison of protein structures is an important task that can help in developing medical treatments that are based on proteins. Some methods that compare protein structures can be represented as a maximum clique problem as in the work done by Malod-Dognin et. al. [34], Ravetti and Moscato [40] and Strickland et. al. [50].

Determining the maximum size of a code satisfying a minimum Hamming distance is a challenging coding theory problem. One of the solution approaches is to construct a Hamming graph such that two sequences of length $n$ are vertices and they have an edge conncting them only if their hamming distance is larger than or equal to $d$. Sloane [48] and Etzion and Östergård [14] formulated the bound on the hamming distance as a maximum independent set problem.

The maximum clique and its equivalent problems also have applications in economics. One of which is analyzing the stock market and drawing conclusions from it. The stock market is represented by a market graph, where stocks are vertices and a correlation between pairs of stocks is marked by an edge. An example of this is the work done by Boginski et. al. [8].

In the field of wireless networks and telecommunication, Chen et. al. [13] modeled the task of estimating path available bandwidth in multirate and multihop wireless network as a weighted maximum clique problem. Similarly, Jain et. al. [26] modeled inference between neighboring nodes in a network as a conflict graph and modeled the problem of finding a lower bound on the optimal throughput as a maximum independent set problem.

Social network analysis is an emerging field that is gaining a lot of popularity. A social network graph has actors or users as nodes and ties between them as edges. The maximum k-plex problem is one of the relaxations of the maximum clique problem, that entails finding subgraphs with high density and not necessarily complete. Many social network analysis problems can be modeled as the maximum k-plex problem, such as the work done by Balasundaram et. al. [4]. k-plexes have also been used for data mining and graph-based clustering applications as in the work done by Balasundaram [3].

### 1.3 Thesis Objective

The focus of this thesis is the extraction of maximum cliques from a simple unweighted graph using conceptual methods. The following are the objectives of the thesis:

- Design a heuristic solution, that uses formal concept analysis as a foundation, for solving the maximum clique problem.
- Design a new efficient greedy algorithm that is based on formal concept analysis.
- Escape the local optimality of the greedy algorithm using a backtracking design.
- Explore a larger portion of the hyper concept tree using a branch and bound design.
- Investigate the use of different algorithm design approaches in developing an efficient and effective solution.
- Compare the performance of the developed method to other published results using benchmark graphs.

### 1.4 Thesis Outline

In Chapter 2 we present the necessary background information and formal definitions for the maximum clique and related problems, and conceptual methods, which we base our solution on. In Chapter 3 a review of developed exact and approximate solutions of the maximum clique and other NP-Hard problems is presented. Our developed solution and its different variations are presented in Chapter 4, and the obtained results are discussed in Chapter 5. Chapter 6 concludes the thesis and presents some future work.

## Chapter 2: Background

Here we presents the background needed for the reminder of the thesis. In Section 2.1 we present the maximum clique problem and other problems that are equivalent to it with examples. Section 2.2 presents a few of the main complexity classes and the one under which the maximum clique problem falls. Section 2.3 presents the formal concept analysis background and Section 2.4 contains a brief description of the different algorithm design methods.

### 2.1 Maximum Clique and Related Problems

Graph theory is a very diverse and rich field. Many different types of graphs exist and are useful for different applications. For the purpose of this work we are interested in studying a specific type of graphs that has the following characteristics [10]:

- Finite: Contains finite vertex and edge sets.
- Simple: An edge always has unique ends. Two vertices can be connected by only one edge.
- Connected: Every vertex is reachable from any other vertex.
- Undirected: Edges have no directions.
- Unweighted: Edges have no weights assigned to them.

Definition 1 "A graph is defined by $G=(V, E)$ where $V=\{1, \ldots, n\}$ is a set of vertices and $E=\left\{e_{1}, \ldots, e_{m}\right\}$ is a set of edges. An edge $e=(u, v)$ where $u, v \in V$. If $e \in E u$ and $v$ are said to be adjacent. [10]"

Figure 2.1 shows a finite, simple, connected, undirected and unweighted graph.

Figure 2.1: Finite Simple Connected Undirected and Unweighted Graph

Definition 2 " $\bar{G}$ denotes the complement of the graph $G=(V, \bar{E})$, where $\bar{E}$ is the complement of $E$. If $e \in E$ then $e \notin \bar{E}$ similarly, if $e \notin E$ then $e \in \bar{E}$."

Figure 2.2 shows the complement of the graph in Figure 2.1

Figure 2.2: Graph Complement

Definition 3 " $A$ subgraph of $G$ is the graph $G^{\prime}=\left\{V^{\prime}, E^{\prime}\right\}$ where $E^{\prime} \subseteq E$ and $V^{\prime} \subseteq V$. "

Definition 4"The cardinality of a graph or a subgraph is the number of its vertices."

Definition 5"A subgraph $C$ of $G$ is a clique if it is complete (all its vertices are pairwise adjacent). Figure 2.1 contains a few cliques, the vertices $\{2,4,5\}$ for example form a clique of cardinality 3."

It is important to distinguish between maximal and maximum cliques.

Definition 6 "A clique is maximal if it cannot be enlarged by adding more vertices to it. A clique is maximum if it has the maximum cardinality."

In Figure 2.1 vertices $\{0,1,6\}$ form a maximal clique, while vertices $\{2,3$, $4,5\}$ form the maximum clique of the graph.

Definition 7 "The clique number $\omega(G)$ is the cardinality of the maximum clique in a graph G."

The clique number in Figure 2.1 is $\omega(G)=4$.

Definition 8 "An independent set of the graph $G$ is a subset of the vertices of the graph $I \subseteq V$ where for any two vertices $u, v \in I,(u, v) \notin E$."

If $C$ is a clique in $G$, then $C$ is an independent set in $\bar{G}$. Similarly, if $C$ is a maximum clique in $G, C$ is a maximum independent set in $\bar{G}$.

Definition 9 "The independence number $\alpha(G)$ is the cardinality of the maximum independent set in the graph $G$."

Definition 10 "If $V^{\prime}$ is a subset of $V$ and every edge $(u, v) \in E$ has at least one end point in $V^{\prime}, V^{\prime}$ is called a vertex cover. "

In Figure 2.3 graph (c) to the right of shows a maximum clique colored in blue. Graph (b) is the complement of (c) and the corresponding maximum independent set is highlighted in blue, the vertex cover on the complement is highlighted in graph (a).

Figure 2.3: (a) Vertex Cover (b) Independent Set (c) Clique

More information and theoretical background about these problems can be found in [9].

### 2.2 Complexity Classes

We here present a brief overview of some complexity classes and the complexity class under which the maximum clique problem falls.

Definition 11 "For any problem $\Pi$, if a polynomial time algorithm exits to solve $\Pi$ with a time complexity of $O\left(n^{k}\right)$, where $n$ is the size of the input and $k$ is a non-negative integer then $\Pi$ is called tractable, otherwise $\Pi$ is called intractable."

Definition 12 "A decision problem can only have one of two outcomes yes or no, while in an optimization problem the concern is to minimize or maximize a certain quantity."

The k-clique problem is a decision problem that takes a graph $G$ and a non-negative integer $k$ as input and returns a decision of whether or not $G$ contains a clique of size $k$. The optimization version of it is the maximum clique problem, it requires determining the maximum value of $k$ in $G$ such that the graph contains a clique of size $k$ and no cliques of size $k+1$.

Figure 2.4 shows the relationship between the 4 complexity classes.

Figure 2.4: Complexity Classes

The class of problems NP (Nondeterministic Polynomial) is the set of problems $\Pi$ the solution of which is verifiable in polynomial time using a deterministic algorithm. A deterministic algorithm is presented with only one choice at each step of its execution. The algorithms used to solve problems in the class NP are nondeterministic. There are two phases to a deterministic algorithm. The guessing phase, where an arbitrary candidate solution is generated in polynomial time. The verification phase, where the generated solution is verified using a deterministic algorithm[17].

The class P (Polynomial) is a subclass of NP. It consists of decision problems that can be solved using a polynomial deterministic algorithm.

NP-Complete problems are a subclass of intractable problems. Hundreds of problems fall under the class of NP-Complete, and if one of these problems has a polynomial time solution, then a polynomial time solution for all the other problems also exists.

Formally, NP-Complete problems can be defined as:

Definition 13 "An NP-Complete decision problem $\Pi$ must satisfy two conditions:"

1. $\Pi \in N P$
2. $\forall \Pi^{\prime} \in N P, \quad \Pi^{\prime} \propto_{\text {poly }} \Pi$
$\Pi^{\prime} \propto_{\text {poly }} \Pi$ symbolizes that the problem $\Pi$ is reducible to $\Pi^{\prime}$ in polynomial time. An instance of the problem $\Pi$ can be transformed into and instance of the problem $\Pi^{\prime}$ using an algorithm that runs in polynomial time.

Definition 14 "A problem $\Pi$ is in the class $\boldsymbol{N P}$-Hard if $\forall \Pi^{\prime} \in N P, \Pi^{\prime} \propto_{\text {poly }}$ П"

A problem is NP-Hard, if it is at least as hard as the NP-Complete problems.
The k-clique problem is an NP-Complete problem because:

1. k -clique $\in$ NP since a solution to the problem can be verified using a deterministic algorithm.
2. $\mathrm{SAT} \propto_{\text {poly }} \mathrm{k}$-clique

The optimization version, the maximum clique problem is NP-Hard [17].

### 2.3 Formal Concept Analysis

Formal Concept Analysis (FCA) is the field of applied mathematics that mathematizes the underlying philosophical notion of "concepts". Traditionally used for knowledge processing and knowledge discovery, we here present another application of FCA as basis for solving some NP-Complete and NP-Hard problems. In this section, we present the mathematical foundations of Formal Concept Analysis, and hyper concepts in particular, necessary for the remainder of this thesis. The FCA background is in the most part is taken from the first chapter of Ganter and Wille's book [16].

### 2.3.1 Context, Concept and Concept Lattice

Definition 15"A formal context is a triplet $K=(G, M, R)$ where $G$ is a set of objects, $M$ is a set of attributes, and $R$ is a relation between $G$ and $M$. $(g, m) \in I$ indicates that object $g \in G$ is in a relation with attribute $m \in M$ and it is read as object $g$ has the attribute $m$. "

A context may be represented by a matrix. The matrix rows are objects and the columns are attributes. If $(g, m) \in I$, the value ' 1 ' is placed in the cell corresponding to row $g$ and attribute $m$, ' 0 ' otherwise.

Figure 2.5 shows an example of a formal context where the set of objects $G=\{0,2,3,4,5,6,7\}$ and the set of attributes $M=\{a, b, c, d, e, f, g, h\}$.

|  | a | b | c | d | e | f | g | h |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 0 | 1 | 0 | 0 | 0 | 0 | 1 | 0 | 0 |
| 1 | 1 | 0 | 0 | 0 | 0 | 1 | 1 | 0 |
| 2 | 1 | 1 | 0 | 0 | 0 | 1 | 1 | 0 |
| 3 | 0 | 1 | 0 | 0 | 0 | 1 | 1 | 1 |
| 4 | 1 | 0 | 0 | 1 | 1 | 0 | 0 | 0 |
| 5 | 1 | 1 | 1 | 0 | 1 | 0 | 0 | 0 |
| 6 | 0 | 1 | 1 | 1 | 0 | 0 | 0 | 0 |
| 7 | 0 | 1 | 1 | 0 | 1 | 0 | 0 | 0 |

Figure 2.5: Formal Context Example

Definition 16 " $A$ formal concept is a pair $(A, B)$ with $A \subseteq G, B \subseteq M$, $A^{\prime}=B$ and $B^{\prime}=A . A^{\prime}$ is the set of attributes common to all objects in $A . B^{\prime}$ is the set of objects common to all attributes in B. "

$$
\begin{aligned}
A^{\prime} & :=\{m \in M(g, m) \in I \forall g \in A\} \\
B^{\prime} & :=\{g \in G(g, m) \in I \forall m \in B\}
\end{aligned}
$$

A formal concept is also referred to as a maximal rectangle or a non-enlargeable rectangle.

Figure 2.6 shows the formal context of the previous example with a highlighted formal concept where the set of objects $A=\{1,2\}$ share the set of attributes $B=\{a, f, g\}$.

|  | a | b | c | d | e | f | g | h |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 0 | 1 | 0 | 0 | 0 | 0 | 1 | 0 | 0 |
| 1 | 1 | 0 | 0 | 0 | 0 | 1 | 1 | 0 |
| 2 | 1 | 1 | 0 | 0 | 0 | 1 | 1 | 0 |
| 3 | 0 | 1 | 0 | 0 | 0 | 1 | 1 | 1 |
| 4 | 1 | 0 | 0 | 1 | 1 | 0 | 0 | 0 |
| 5 | 1 | 1 | 1 | 0 | 1 | 0 | 0 | 0 |
| 6 | 0 | 1 | 1 | 1 | 0 | 0 | 0 | 0 |
| 7 | 0 | 1 | 1 | 0 | 1 | 0 | 0 | 0 |

Figure 2.6: Formal Concept Example

Definition 17 "The concept lattice is a hierarchical organization of all concepts extracted from a context ( $G, M, I$ ) in subconcept, superconcept relation. Given two concepts $\left(A_{1}, B_{1}\right)$ and $\left(A_{2}, B_{2}\right),\left(A_{1}, B_{1}\right)$ is a subconcept of $\left(A_{2}, B_{2}\right)$ if $A_{1} \subseteq A_{2}$. Consequently, $\left(A_{2}, B_{2}\right)$ is a superconcept of $\left(A_{1}, B_{1}\right)$. This is written as $\left(A_{1}, B_{1}\right) \leq\left(A_{2}, B_{2}\right)$. The relation $\leq$ is the hierarchical order of concepts."

### 2.3.2 Hyper Concepts

Extracting all concepts from a formal context is a very time consuming process. In addition, the concept lattice is a large structure that requires a lot of storage space, and that grows exponentially as the size of the formal context grows. In practice, most applications do not require the full set of concepts. Minimal conceptual coverage aims to cover the given context by a smaller number of concepts while preserving the knowledge. The hyper concept algorithm developed by Hassaine et. al. [22] is one such attempt where the context is covered by optimal "hyper concepts". In $[23,22]$ hyper concepts are used as textual
features for classification of Islamic advisory opinions [22] and classifying news articles [23]. In [38] Otaibi el. al. used the hyper concept algorithm for feature extraction combined with conceptual reasoning for detecting inconsistencies in text.

Definition 18 " $A$ relation $R$ is a subset of the Cartesian product of two sets $X$ and $Y "$

Definition 19 " $R^{-1}=\left\{\left(e, e^{\prime}\right)\left(e^{\prime}, e\right) \in R\right\}$ is the converse of the relation $R$."

Definition 20 " $m . R=\{x \in G(x, m) \in R\}$ is the image of $m$ by the relation R."

Definition 21 " $I(A)$ is called the identity relation. It is a subset of the Cartesian product $A \times A$ such that $\forall m \in M, m \cdot I(M)=\{m\}$ "

Definition 22 " $R \circ R^{\prime}=\left\{\left(e, e^{\prime}\right) \exists t((e, t) \in R) \&\left(\left(t, e^{\prime}\right) \in R^{\prime}\right)\right\}$ is the relative product or composition of two binary relations. "

Definition 23 "Given a formal context $K=(G, M, R)$ and $m \in M$ an arbitrary attribute. A hyper concept denoted as $H_{m}(R)=I\left(m \cdot R^{-1}\right) \circ R$."

A hyper concept corresponding to an attribute $m \in M$ is the union of all concepts containing the attribute $m$.

Figure 2.7 shows the formal context and the hyper concept corresponding to attribute $a$. The image of attribute $a$ by the relation $R^{-1}$ is $a \cdot R^{-1}=$ $\{0,1,2,4,5\}$. The hyper concept shown in the figure correspond to $I\left(a \cdot R^{-1}\right) \circ R$.

Definition 24 "The"importance" of a hyper concept $H_{m}(R)$ is measured by its weight $W\left(H_{m}(R)\right)$."

The calculation of the different weights depends on the following attributes:

|  | a | b | c | d | e | f | g | h |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 0 | 1 | 0 | 0 | 0 | 0 | 1 | 0 | 0 |
| 1 | 1 | 0 | 0 | 0 | 0 | 1 | 1 | 0 |
| 2 | 1 | 1 | 0 | 0 | 0 | 1 | 1 | 0 |
| 3 | 0 | 1 | 0 | 0 | 0 | 1 | 1 | 1 |
| 4 | 1 | 0 | 0 | 1 | 1 | 0 | 0 | 0 |
| 5 | 1 | 1 | 1 | 0 | 1 | 0 | 0 | 0 |
| 6 | 0 | 1 | 1 | 1 | 0 | 0 | 0 | 0 |
| 7 | 0 | 1 | 1 | 0 | 1 | 0 | 0 | 0 |$\quad \rightarrow$|  | a | b | c | d | e | f | g |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 0 | 1 | 0 | 0 | 0 | 0 | 1 | 0 |
| 1 | 1 | 0 | 0 | 0 | 0 | 1 | 1 |
| 2 | 1 | 1 | 0 | 0 | 0 | 1 | 1 |
| 4 | 1 | 0 | 0 | 1 | 1 | 0 | 0 |
| 5 | 1 | 1 | 1 | 0 | 1 | 0 | 0 |

Figure 2.7: Hyper Concept Corresponding to Attribute a

- d: The domain cardinality of $H_{m}(R)$
- c: The codomain cardinality of $H_{m}(R)$
- r: The cardinality of $H_{m}(R)$ "

Definition 25 "The economy of a binary relation (gain in storage space) is given by the formula: $W(R)=\frac{r}{d \times c} \times(r-(d+c))$ "

The quantity $\frac{r}{d \times c}$ is the density of the relation, while the quantity $(r-(d+c))$ is the economy of information [21].

The hyper concept tree is a hierarchical organization of hyper concepts. The hyper concepts at each level are extracted from the hyper concept of the previous level. The hyper concepts at each level are organized by weight in a non-increasing order. Assuming that the weight of the hyper concept is just "d", the cardinality of the domain, Figure 2.8 shows the first level of the hyper concept tree constructed from the formal context of Figure 2.5.

The hyper concept with the highest weight in the first level is the one corresponding to attribute a, since a has the highest domain cardinality. Figure 2.9 shows the second level hyper concepts extracted from the hyper concept corresponding to attribute a.

Figure 2.8: Hyper Concept Tree First Level

Figure 2.9: Hyper Concept Tree Second Level

### 2.4 Algorithm Design Methods

Different variations of our proposed solution use different algorithmic design methods. Here we introduce a few basic exact and approximate design methods.

### 2.4.1 Exact Design Methods

## Divide and Conquer

A powerful algorithm design method that operates by dividing the problem instance into p subinstances and recursively solves each instance separately. Merging, or combining the solutions of the sub-instances results in a solution to the problem [1].

## Dynamic Programming

Dynamic programming is similar to divide and conquer in that algorithms that employ it are usually stated in the form of recursive functions. Unlike divide and conquer, dynamic programming algorithms operate in a bottomup manner. Smaller problem instances are solved first, and their intermediate solutions are saved to be used in computing the final result [1].

## Backtracking

A systematic searching technique in which the search space is organized as a tree and the tree is traversed in a depth first manner. The search stops when a certain criterion is met [1].

## Branch and Bound

A very similar design strategy to backtracking that is typically used for designing solutions to optimization problems. Like backtracking, the search space is orgranized in the form of a tree, but it does not impose any constraints on how the tree is traversed. In a branch and bound algorithm, each node in the tree has a bound to determine if the node is promising or not [1].

### 2.4.2 Approximate Design Methods

## Greedy Method

Greedy algorithms are usually iterative algorithms that are also used for solving optimization problems. Greedy algorithms make decisions that will result in the maximum immediate gain without worrying about the future. The resulting solution is a local optimum, which might be translate to a global optimum [1].

## Evolutionary Algorithms

Evolutionary Algorithms are inspired by the process of natural selection (increasing the existence of favorable traits in future generations) and evolution (changing the genetic makeup of populations). One type of Evolutionary algorithms is genetic algorithms. It operates by first randomly initializing a population that consists of individuals, where each one is an encoding of a possible solution to the problem instance. Crossover (exchanging substrings of the solution between pairs of individuals) and Mutation (adding, deleting or replacing a part of the individual by another) are performed recursively. The solution is evaluated in each iteration and the algorithms stop when a certain criteria is met [37].

## Chapter 3: Literature Review

The maximum clique problem has many exact and approximate solutions. A few comprehensive surveys of these approaches were conducted. The first dates back to 1994 by Pardalos and Xue [39], followed by the survey of Bomze et. al. [9]. The most recent survey for the maximum clique algorithms is the work done by Wu and Hao [56], which is a comprehensive review of mathematical formulations, enumerative algorithms, exact solution approaches, and heuristic approaches for the maximum clique problem and a few other generalizations and relaxations of it. In our review, we focus on recent exact and approximate solution approaches of the unweighted maximum clique and related problems.

### 3.1 Exact Algorithms for the Maximum Clique Problem

Most of the exact solutions of the maximum clique and the related problems are based on a branch and bound algorithms. The algorithm enlarges an initial small clique until one with a maximum cardinality is found. Given a graph $G=(V, E)$, the algorithm maintains a list $Q$ for the vertices of the current clique and a list $Q_{\max }$ for the largest clique already found, both of which are intially empty, and a candidate list $R \subseteq V$ that is initially set to $V$. The algorithm operates by adding a vertex $p \in R$ to $Q, p$ is then removed from $R$ along with all the vertices that are not connected to it. When $R=\emptyset$, if
$Q>Q_{\max }, Q_{\max }$ is replaced by $Q$. The algorithm then backtracks and another vertex $p$ is selected.

Most algorithms start from the general framework above and add improvements to the branching and pruning strategies, some approaches use approximate coloring to color the candidate set of vertices. $\chi(G)$ is the chromatic number of a graph. A clique in any given graph can never be larger than the chromatic number. This set of solutions uses approximate graph coloring of the candidate set of vertices as an upper bound.

Tomita and Seki [53] presented MCQ, an improvement to the basic algorithm that an approximation of $\chi(G)$ to set an upper bound and prune the search space. Colors are greedily assigned to vertices of the candidate set $R$. Each color class $C_{k}$ is represented by an integer k. Colors are assigned to vertices as follows. A vertex $v_{1}$ is assigned a color $k=1$, if vertex $v_{2}$ is adjacent to $v_{1}$ then $v_{2}$ is assigned a color $k=2$, otherwise $v_{2}$ is assigned $k=1$. Vertices in R are sorted based on their assigned colors in ascending order. The vertex selected from $R$ to be added to $Q$ is the one with the maximum color value. If adding the vertex of maximum value to $Q$ will result in a clique that is smaller in size than $Q_{\max }\left(Q+\operatorname{Max}\{k\} \leq Q_{\max }\right)$ then the branch is disregarded.

The vertices in MCQ [53] before coloring are sorted in descending order of their degree in the graph $G$. MCR [52] developed by Tomita and Kameda, improves the initial ordering of vertices. Vertices are ordered into a list $L=$ $\left\{v_{1}, v_{2}, \ldots, v_{n}\right\}$ such that $v_{n}$ has the lowest degree of $G, v_{n-1}$ has the lowest degree of $G \backslash\left\{v_{n}\right\}, v_{n-2}$ has the minimum degree in $G \backslash\left\{v_{n}, v_{n-1}\right\}$ and so on. The remaining steps operate as in MCQ. In MCR, vertices chosen to expand the current clique are those that have the maximum color. As stated earlier, vertices that have colors that are smaller than a threshold will not produce a maximum clique eventually and the corresponding branches are pruned.

To further improve MCR, Tomita et. al. introduced MCS [54] that further reduces the search space for a maximum clique by employing a recoloring strategy. Not all vertices with colors greater than the threshold are promising. Vertices that do not fit a certain criteria and will not lead to a maximum clique, but still have colors greater than the threshold are recolored to have colors smaller than the threshold to prevent them from being selected.

The order by which the vertices are introduced to the coloring algorithm is important. While Tomita and Seki [53] order the vertices by their color in the candidate set R, Konc and Janezic [30] present an improvement to the algorithm in which the current clique is enlarged by vertices with large color number. The vertices are reordered by their degree in a decreasing order, keeping the vertices that have color numbers below the threshold in their original order. This makes the new developed approach, MaxCliqueDyn, faster than Tomita and Seki's original MCQ algorithm.

An improvement to MaxCliqueDyn is presented in the work of Segundo et. al. [41]. BB-MaxClique is an efficient bit parallel implementation, that uses basic operations between bit strings to obtain induced subgraphs during the search. The main contribution of the algorithm is that the order of the vertices in the set $R$ does not change. The vertices are ordered in an increasing order of their degree and then presented to the coloring algorithm. The authors also present an improvement to the coloring algorithms, BB-Color, which obtains a color class in each iteration instead of assigning colors to vertices independently.

BB-MaxClique was later improved by Segundo et. al. [44] by integrating the recoloring strategy introduced in MSC into the bit parallel implementation.

Segundo and Tapia [42] introduced a relaxation to the basic coloring algorithm [53] in which they only compute $k_{\text {min }}-1$ color classes at each iteration, where $k_{\text {min }}$ is the minimum order of hidden clique in the induced subgraph that might lead to a clique larger than $Q_{\max }$ in the branch.

MCT is a final, recent improvement to MCS by Tomita et. al. [51] which is based on the observations that the algorithm used to find an initial clique from which the lower bound of the solution is obtained is important for the efficiency of the algorithm. The algorithm they used for finding an initial solution is k-opt local search [29] developed by Katayama et. al., that will be discussed later in Heuristic Solutions section. While the algorithm does not always produce the best solutions, it is used because of its high speed. The numbering and renumbering process used in MSC reduces the search space, but also introduces an overhead to the running time of the algorithm. MCT uses a three stage operation technique. In the first stage, the vertices are sorted based on their degree. At certain level of the tree, the algorithm switches to the regular sorting based on numbering (coloring). Finally, near the leafs of the tree, the ordering of the vertices is inherited from previous levels. The level at which the switching occurs depends on the density of the graph at that level.

The work introduced by Segundo et. al. [45] presents an improvement to the initial sorting of vertices that is intended to work with different algorithms. The paper presents the NEW_SORT algorithm that automatically switches between two novel sorting strategies, a degree based sorting and a color based sorting based on the density of the given graph. The degree based sorting operates by first sorting the vertices based on their width, and then sorting the fist $k$ vertices in descending order based on their degrees. The color based ordering operates as follows. Initially, all vertices of the set $V$ are copied to a set $w_{1}$. Iteratively, a vertex $v \in W_{1}$ is removed and assigned to a color $C_{k}$. Vertices connected to $v$ are removed from $W_{1}$ and copied to $W_{2}$. When $W_{1}=\emptyset$ the next color class is built.

The maximum clique problem is reducible to maximum satisfiablity problem, but max sat solvers are not very useful when it comes to finding maximum cliques. However, they can be used to improve the value of the upper bound.

Li and Quan presented the first attempt to use max sat and propositional logic as an upper bound in [33]. In their approach, MaxCLQ, Li and Quan first partition the graph into independent sets, and an independent set based encoding of the maximum clique into max sat is devised. A set of soft and hard clauses are extracted from each independent set. If the graph contains $k$ independent sets in the graph, and the independent set MaxSat encoding contains $s$ disjoint soft clauses, it is proven that $\omega(G) \leq k-s$.

Improvements to MaxCLQ are presented by Li and Quan [32] that adopts the incremental computation of the maximum clique degree presented in MaxCliqueDyn [30], and a relaxation of the soft clauses which allows the detection of more inconsistent subsets of clauses. Further improvements presented by Li et. al. [31] consist of incremental upper bound computation resulting in a more efficient algorithm.

A combination of MCS, and MaxSat [54, 32, 33] is presented by Maslov [36], resulted in an efficient exact maximum clique algorithm.

Cliquer is an algorithm developed by Östergård [49] that uses a completely different approach for finding maximum cliques. The algorithm starts by trying to find the maximum clique in a subset of the vertices of size $S_{n}=\left\{v_{n}\right\}$, and then proceeds to finding the maximum clique in $S_{n-1}=\left\{v_{n}, v_{n-1}\right\}$ the $S_{n-2}=\left\{v_{n}, v_{n-1}, v_{n-2}\right\}$ and so on until the maximum clique in $S_{1}$, which is the original graph is found. The algorithm uses information from the previously found larger graphs as a bound. This algorithm is not as fast as other developed approaches.

Exact algorithms guarantees extracting the maximum clique from any given graph but are usually very time consuming. In some applications, efficiency is more important than the size of the obtained cliques.

### 3.2 Heuristic Approaches for the Maximum Clique Problem

Some maximum clique applications are more sensitive to time constraints, and can tolerate some error in the size of the maximum cliques founds. For this purpose, many heuristic approaches have been developed, that use different strategies for finding maximum cliques, we present some of these approaches in this section.

### 3.2.1 Greedy Algorithms

Very few greedy algorithms for the maximum clique and related problems exist in the literature. Greedy algorithms are generally efficient but not very effective in finding maximum clique and in most cases face the problem of local optimality. The general framework for greedy algorithms is to either begin with an empty set of vertices and add vertices to it in a greedy manner until a maximum clique is found. Or starting with the full set of vertices, greedily remove vertices until a maximum clique is found. To avoid finding locally optimal solutions, some algorithms use a multi-start strategy. An example of this is the approach developed by Jagota and Sanchis [25], in which an initial, possibly empty clique $C$ is expanded by adding vertices from the set $S=\{v \in G \backslash C v$ is adjacent to every vertex in $C\}$. Positive integer weights are associated to vertices in $S$ which determine the probability by which the vertex $v_{i}$ can be added to the current clique. Vertices with larger weight values have higher probability of being selected. In the nonadaptive version (NA), the algorithm restarts $k$ times with the same set of weights, and the largest clique in all iterations is recorded. In the adaptive weights (AW) version of the algorithm, the weights are modified between restarts. The last version is the adaptive initial
state (AI) version, in which the initial state of each iteration is influenced by whether or not a larger clique was found in the previous iteration.

The deep adaptive greedy search approach (DAGS) developed by Grosso et. al. [18] is a greedy approach that is based on swap moves and vertex weights. The swap moves are used to replace the current clique by another, more promising clique of equal size. As in [25], the vertecies are weighted and the weights are adaptively adjusted in each iteration.

### 3.2.2 Search Heuristics

Search heuristics are the most successful approach used for solving the maximum clique and related NP-Complete problems. The general framework of search heuristics is trying to satisfy an evaluation function by exploring a defined search space using a neighborhood function.

STABULUS [15] is one of the earliest attempts for utilizing tabu search as a solution to the maximum independent set problem. In their approach Friden et. al. first fix an upper bound $k$ for the cardinality of the independent set $\alpha(G)$ to be obtained. A feasible solution partitions the set of nodes $V$ into two sets, $S$, the set of nodes that are independent or almost independent, and $\bar{S}$, the set of remaining nodes. The neighborhood $N(s)$ of a solution $s=(S, \bar{S})$ is the set of all solutions that can be obtained as a permutation of one node $x \in S$ with one node $y \in \bar{S}$. The new solution $s^{\prime}$ is obtained from the initial solution $s$ such that $s^{\prime}=(S \backslash\{x\} \cup\{y\}, \bar{S} \backslash\{y\} \cup\{x\})$. A Tabu list $T$ is maintained, it contains the $T$ last solutions. The selected pair $(x, y)$ at each step is the pair that has the smallest value of $E(S \backslash\{x\} \cup\{y\})$, and that is not a member of $T$. If after nbmax iterations an independent set was not found, another initial solution is randomly generated and the procedure is applied on it, where nbmax is an
preset parameter. If after $q$ initial solutions an independent set of size $k$ is still not found, the size of $k$ is reduced by 1 and the process is repeated.

Adaptive Multistart Tabu Search (AMTS) is a more recent approach developed by Wu and Hao [55] for solving the maximum clique problem. It is based on STABULUS and introduces a few improvements to it. The neighborhood in $N(s)$ is replaced by the constrained neighborhood $C N(s)$ that is restricted to permutations of vertices $u \in A$, where A contains the nodes that have the smallest degrees relavent to the subset S , and that do not appear in the tabu list. And $v \in B$, where B the nodes of $S \backslash V$ not in the tabu list T and that have the largest degree relevant to the subset S . This improvement allows for a more focused search space that is smaller in size than the one used in STABULUS. Some probabilistic move selection rules are applied when the search is stuck in local optimum to allow the exploring the search space.

Swap-Based Tabu Search (SBTS) developed by Jin and Hao [27] has one the best performances in the literature, it successfully finds the maximum independent set for all instance of the two most used benchmarks. The general idea of the algorithm is to randomly generate an initial solution $S$ and then improve it using a set of intensification and diversification steps. The basic operation of this approach is the $(k, 1)-s w a p$, where $(k=0,1,2, \geq 2)$. The swap operation consists in swapping a vertex from $V \backslash S$ with $k$ adjacent vertices from current maximal independent set $S$. The set $V \backslash S$ is divided into 4 subset $N S_{0}, N S_{1}, N S_{2}$ and $N S_{>2}$ where the subscript corresponds to number of vertices $v_{j} \in S$ that are adjacent to vertex $v_{i} \in V \backslash S$. When the value of $k$ in a $(k, 1)-$ swap is 0 or 1 , the performed operation is called an intensification step, it aims at obtaining a local optimum from the current solution by either adding a randomly selected vertex from the set $N S_{0}$ to S or replacing one vertex of $N S_{1}$ by one vertex of $S$ following a set of rules that will guarantee an improvement to the current result. When the value of $k$ in a $(k, 1)-\operatorname{swap}$ is

2 or $>2$, the performed operation is called an diversification step, it aims at perturbing the current solution to explore other search regions by replacing 2 or more vertices of $S$ by one vertex of $N S_{2}$ or $N S_{>2}$. The vertices removed from the set $S$ are added to the tabu list to ovoid cycling. Intensification operations are preferred over diversification operations and are given priority. A diversification operation is only performed when the sets $N S_{0}$ and $N S_{1}$ are empty, or when the vertices in them are members of the tabu list.

Reactive Local Search (BLS) by Battiti and Protasi [5] is a local search heuristic that dynamically determines the amount of diversification using historical information.

Variable Neighborhood Search (VNS) by Hansen et. al. [20] is a combination of a greedy heuristic and a local search heuristic that changes the neighborhood by computing choosing a solution with a closer distance.

Hoos and Pullan [24] presented a Dynamic Local Search (DLS) algorithm that alternates between two phases. During the iterative improvement phase the algorithm adds vertecies to the current clique to enlarge it. During the plateau search phase, swap operation with vertices outside the clique occur.

Breakout Local Search (BLS) developed by Benlic and Hao [7] is a local search strategy that can be used as a solution to the maximum weight clique and the maximum clique problems. BLS generates an initial solutions greedily by randomly selecting a vertex $v$ and adding it to the set $C$. Vertices $u \in V \backslash C$ are iteratively added to the set $C$ such that $\forall c \in C\{u, c\} \in E$. This process ends when no nodes can be added to $C$, it requires no initial upper bound on the size of the clique to be found, and it results in a valid clique. The proposed approach first uses local search to find a local optimum from the initial solution C by either adding $v$ to the set $C$ such that $\forall c \in C\{v, c\} \in E$, by adding a vertex $v$ to $C$ such that $v$ is connected to all vertices of $C$ except for one vertex $u$ which is then excluded from $C$, or by just removing a vertex $v$ from $C$. The
move that will result in a more improved solution is the one that is considered. The previously mentioned three moves are called directed perturbations to the initial solution $C$. The purpose of directed perturbations is to move the search from one local optimum to another. When no improved result is found after a certain number of iterations, the search is said to be stagnating, and stronger random perturbation is applied. The purpose of the random perturbation is to restart the search and explore another unseen area of the search space. The probability of performing one type of perturbation or another is determined by the search state, the probability of performing a random perturbation becomes higher as the number of non-improving local optima visited increases.

### 3.2.3 Evolutionary Algorithms

Evolutionary Algorithms are very efficient in practice but they do not give good results when used on their own and are usually paired with other approaches.

In 1993 Carter and Park [12] conducted an experiment to evaluate the usefulness of genetic algorithms in solving the maximum clique problem. They came to the conclusion that at the time, genetic algorithms are not as powerful as other general purpose heuristics. Since then, genetic algorithms have been used in combination with statistical information and search heuristics and produced acceptable results.

Marchioni's algorithm [35] GENE is a hybrid genetic algorithm, local search approach, When a local optimal solution is obtained, genetic operators, crossover and mutation, are applied to it. The stopping criteria of the algorithm is when a solution is reached or when a preset maximum number of iterations is exceeded.

Guturu and Dantu's [19] algorithm is another more recent example of the combination of evolutionary algorithms with search heuristics. The algorithm integrates several features of previous, successful approaches.

Zhang et. al. [57] developed an approach that outperformed GENE, that combines a genetic algorithm with statistical information. The algorithm introduced an evolutionary algorithm guided mutation (EA/G) operator, which uses global statistical information and the location of the current solution to make more informed decisions in the generation of the offsprings.

Singh and Gupta's Algorithm [46] consists of genetic algorithm where a steady state population replacement method is used, a greedy heuristic and an exact algorithm. While their algorithm outperformed some of the best genetic algorithms of the time, it did not perform better than heuristics that are not based on evolutionary methods.

## Chapter 4: Methodology

Three main algorithm design approaches were used in our solution, a greedy approach, a partial backtracking approach and a partial branch and bound approach, all of which are based on the hyper concept algorithm presented earlier with some minor alterations made to it. Here we present the general framework used 4.1 and the details of each approach 4.2, 4.3 and 4.4.

### 4.1 General Framework

The first step of the solution is mapping the graph to a formal concept. The graph is initially stored in a text file that contains some metadata about the graph, like the method of generation, the density, the number of vertices and edges. The file also contains all edges of the graph in a two column format that indicate the source vertex and the destination vertex, proceeded by the letter "e" to indicate that the line corresponds to a graph edge. The file is read line by line and the formal context is built from it. The formal context is represented by a two dimensional array $C$ in which both the rows and columns represent vertices of the graph. $C_{i, j}=1$ in the produced context signifies that there is an edge between the nodes, $C_{i, j}=0$ signifies that an edge does not exist. Even though the graphs are simple and they do not contain loops, the diagonal is set to 1 to facilitate the extraction of hyper concepts. Figure 4.1 shows the representation of the graph in the input file, and the formal context constructed from the input file.

Figure 4.1: Graph to Formal Context

The hyper concept tree is constructed from the generated formal context by computing the hyper concept corresponding to each attribute and sorting them according to their weights. To maintain the symmetry of the relations, vertices that are not contained in the domain of the resulting hyper concept are also removed from the co-domain. Figure 4.2 shows the formal context built from the graph on the left, the hyper concept corresponding to attribute " 1 " in the middle, and the modified hyper concept on the right. The vertices in the domain of the original hyper concept are $\{1,2,3,7\}$ and the vertices in the co-domain are $\{1,2,3,4,5,6,7\}$. Because vertices " 4 ", " 5 ", and " 6 " are not contained in the domain, they are also removed from the co-domain.

Figure 4.2: Hyper Concept from Graph

Hyper concepts are prioritized by their weight as presented earlier. Different weight formulas have been used. The weight formulas are summarized in Table 4.1.

Table 4.1: Hyper Concept Weights

| Weight ID | Original Formula | Modified Formula |
| :--- | :--- | :--- |
| weight1 | $d$ | $d$ |
| weight2 | $r$ | $r$ |
| weight3 | $\frac{r}{d \times c} \times(r-(d+c))$ | $\frac{r}{d \times d} \times(r-(d+d))$ |
| weight4 | $\log _{10}\left(\frac{r}{d \times c}\right) \times(r-(d+c))$ | $\log _{10}\left(\frac{r}{d \times d}\right) \times(r-(d+d))$ |
| weight5 | $3+\frac{\sqrt{9-8 *(d-r)}}{2}$ | $3+\frac{\sqrt{9-8 *(d-r)}}{2}$ |

Weight1 and weight2 are the cardinality of the domain and of the relation respectively. Weight1 gives priority to hyper concepts corresponding to vertices with higher cardinality, while weight2 give priority to hyper concepts containing the largest number of edges. Weight3 is the gain of a relation defined earlier. In weight4, the quantity $\frac{r}{d \times c}$ in the gain formula is replaced by $\log _{10}\left(\frac{r}{d \times c}\right)$. The change made gives less value to the density of the relation than the economy of information. Finally, weight5 is a theoretical upper bound to the size of the maximum clique in a graph defined in [2]. Weight5 prioritizes hyper concepts that might contain larger cliques.

Due to the symmetry in the resulting hyper concept, the cardinality of the domain is equal to the cardinality of the co-domain $(d=c)$. " c " is replaced in weight3 and weight 4 by "d". Figure 4.3 shows the hyper concept tree corresponding to the context of Figure 4.1 and taking the cardinality of the domain as a weight (weight1). The leaf node of each branch is represents by a maximal clique. The graph contains three maximal cliques $\{3,4,5,6\},\{1,2,3\}$ and $\{1,2,7\}$, all of which are extracted by the hyper concept algorithm at different levels of the tree. Each node is represented by the nodes that are contained in the domain and codomain of the hyper concept. Some redundancy between hyper concepts might occur. For example, the hyper concept corresponding to
both node " 1 " and node " 2 " is $\{1,2,3,7\}$. Only the hyper concept corresponding to node " 1 " is added to the tree.

Figure 4.3: Hyper Concept Tree

Algorithm 1 shows the pseudocode of the hyper concept extraction procedure, which is the main step of the developed approach.

The algorithm takes a context or a hyper concept as and a "tabuList". At the first level of the tree, the context is passed to get_HC and the hyper concept with the highest weight is returned. At any given level $l$ of the tree, the hyper concept with the highest weight extracted from the current hyper concept in level $l+1$ is returned. The method also takes a tabu list of vertices as input. The tabu list contains vertices that have already been chosen as vertices with highest weight in previous levels, and prevents them from being chosen again. In lines 2 to 8, the cardinality of the domain of hyper concepts corresponding to all vertices are computed and the values are stored in the array d. Lines 11 to 16 , show the computation of the value of " r ". The index with the highest weight is recorded and the rows are copied from the context to the new hyper

```
Algorithm 1: Hyper Concept Extraction
    get_HC(context,tabuList);
    Input : A formal context in the form of a 2D Integer array and a Tabu
                list
    Output: The hyper concept with the highest weight
    for columnIndex \(\in\) columns do
        for rowIndex \(\in\) rows do
            if \(C[\) columnIndex \(][\) rowIndex \(]==1\) then
                countd + +;
            end
        end
        \(d[i]=\) count \(d ;\)
        countd \(=0\);
    end
    for columnIndex \(\in\) columns do
        for rowIndex \(\in\) rows do
            if \(C[\) columnIndex \(][\) rowIndex \(]==1\) then
                \(r+=d[i] ;\)
            end
        end
        //use value of r and \(\mathrm{d}[\mathrm{i}]\) to compute weight[i] according to the
        selected formula
        if weight \([i]>\) largestWeight and tabuList \([i]!=1\) then
            largetWeight \(=\) weight \([i]\);
            largestWeightIndex \(=i_{1}\)
        end
    end
    TabuList[largestWeightIndex] = 1
    //Copy HC rows and return HC
```

concept. If two vertices have the same value for any given weight value the one that occurs first is selected.

Taking the operation at line 14 " $r+=d[i]$ " as basic operation, the worst case time complexity of this procedure is $O\left(n^{2}\right)$ where n is the number of attributes in the hyper concept.

Figure 4.4 shows how the computation of the cardinality of the relation is computed in a graphical form. The table in the middle shows the computation of the domain cardinality of each vertex, which is done by lines $2-10$ of the
algorithms. The second table shows the computation of an $r$ value of a specific vertex in each iteration of the loop starting at line 11.

|  | 1 | 2 | 3 | 4 | 5 | 6 | 7 |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 1 | 1 | 1 | 0 | 0 | 0 | 1 | d[1] | 4 |  | r[1] | d[1] $+\mathrm{d}[2]+\mathrm{d}[3]+\mathrm{d}[7]=19$ |
| 1 | 1 | 1 | 1 |  |  |  | 1 | d[2] |  |  | r[2] | $\mathrm{d}[1]+\mathrm{d}[2]+\mathrm{d}[3]+\mathrm{d}[7]=19$ |
| 2 | 1 | 1 | 1 | 0 | 0 | 0 | 1 | d[3] | 6 |  | r[3] | d[1]+d[2]+d[3]+d[4] + [ 53$]+d[6]=31$ |
| 3 | 1 | 1 | 1 | 1 | 1 | 1 | 0 | d[4] | 4 | $r$ computation | r[4] | d[3]+d[4]+d[5] $+\mathrm{d}[6]=19$ |
| 4 | 0 | 0 | 1 | 1 | 1 | 1 | 0 | d[5] |  |  | r[5] | d[3]+d[4]+d[5] $+\mathrm{d}[6]=19$ |
| 5 | 0 | 0 | 1 | 1 | 1 | 1 | 0 | d[6] |  |  | r[6] | $d[3]+d[4]+d[5]+d[6]+d[7]=23$ |
| 6 | 0 | 0 | 1 | 1 | 1 | 1 | 1 | d[7] |  |  | r[7] | d[1] $+\mathrm{d}[2]+\mathrm{d}[6]+\mathrm{d}[7]=17$ |
| 7 | 1 | 1 | 0 | 0 | 0 | 1 | 1 |  |  |  |  |  |

Figure 4.4: Graphical Representation of Algorithm1

In some cases a list of hyper concepts with highest weights needs to be returned instead of a single hyper concept. In this case, the process of recording extracting the highest weight index in lines 18 to 21 is discarded. The array weights is sorted and a list of the highest weight indecies is returned. The time complexity of the sorting process is $O(n \operatorname{logn})$, this makes the time complexity of get_HCList $O\left(n^{2}+n l o g n\right)$ which is equivalent to $O\left(n^{2}\right)$.

Three different approaches have been used for extracting maximum cliques from a graph that are based on the hyper concept algorithm. The first is the greedy approach, which is our baseline, and the two improvements made to it, a partial backtracking approach, and a partial branch and bound approach.

### 4.2 Greedy Approach

The greedy algorithm is designed to provide a conceptual basis for solving the maximum clique problem and investigate the usefulness of the hyper concept algorithm in solving the maximum clique problem. Other greedy methods do exist in the literature, but a conceptual greedy algorithm is needed as a basis for further development of the solution.

The greedy approach is a depth first traversal of the tree, that only considers the first branch. At each level of the tree, the hyper concept with the highest
weight is selected. Figure 4.5 shows a depth first traversal of the hyper concept tree that starts with a formal context and ends with a clique in the leaf of the first branch. Here we use "d" as the weight of the hyper concept. The hyper concept corresponds to a clique when the cardinality of the relation is equal to the number of vertices squared $r=d^{2}$.

|  | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 1 | 1 | 1 | 1 | 0 | 0 | 0 | 1 |
| 2 | 1 | 1 | 1 | 0 | 0 | 0 | 1 |
| 3 | 1 | 1 | 1 | 1 | 1 | 1 | 0 |
| 4 | 0 | 0 | 1 | 1 | 1 | 1 | 0 |
| 5 | 0 | 0 | 1 | 1 | 1 | 1 | 0 |
| 6 | 0 | 0 | 1 | 1 | 1 | 1 | 1 |
| 7 | 1 | 1 | 0 | 0 | 0 | 1 | 1 |

Figure 4.5: Clique Extraction Using the Greedy Approach

Algorithm 2 shows the recursive procedure followed for finding the maximum clique using the greedy method. Line 2 of the algorithm checks if the current context is a clique, in which case the size of the clique found is returned and the algorithm terminates. If it is not a clique, the function get_HC(context) is called in line 5. get_HC(context) extracts all hyper concepts from the context, computes their weights according to the selected formula and returns the
hyper concept with the highest weight. greedy_getClique(context) procedure is then called recursively until a clique is found. The worst case time complexity of the greedy approach is equivalent to $O\left(n^{3}\right)$

```
Algorithm 2: Finding the largest clique using the greedy approach
    greedy_getClique (context);
    Input : A formal context in the form of a 2D Integer array
    Output: the size of the maximum clique
    if isClique(context) then
        return clique_size;
    else
        context \(=\) get_HC(context, tabuList);
        greedy _getClique(context);
    end
```

### 4.3 Partial Backtracking

The greedy method often falls in the trap of local optimality. The backtracking method was designed to escape the local optimum and extract cliques from different branches.

Partial backtracking is an improvement to the greedy approach. Based on the assumption that the first clique obtained using the greedy approach is not necessarily the largest in the graph. After the largest clique is obtained, a normal backtracking algorithm would backtrack to the first node with an unvisited child, in our case, we backtrack all the way to the first level of the tree and select the node with the next highest weight. Figure 4.6 shows the order in which the nodes of the hyper concept tree are traversed in the backtracking approach. This approach entails traversing all the nodes of the first level, and for each node, the hyper concept with the highest weight is extracted and the algorithm proceeds similar to the greedy method. At each level of the tree at most n nodes are traversed and get_HC(context) is called in each node, where n is the cardinality of a graph.

Figure 4.6: Backtracking Illustration

The backtracking procedure is explained in Algorithm 3. First, the indecies of the hyper concepts of the first level of the hyper concept tree are sorted according to their weights and stored in indexList using sortCliques(context). greedy_Cliques(index, context) in line 4 is used to get the clique at the leaf of the branch corresponding to the first level hyper concept of the current index. The index is a parameter that can be used to limit the number of branches traversed. In each iteration, the largest clique of each branch is returned, and the largest clique obtained from all iterations is reported by backtracking_getClique(context). The worst case time complexity of the backtracking approach is $O\left(m n^{3}\right)$, where m is the number of branches to be explored.

```
Algorithm 3: Finding the largest clique using the backtracking approach
    backtracking_getClique (context);
    Input : A formal context in the form of a 2D Integer array
    Output: The size of the maximum clique
    indexList \(=\) sortCliques \((\) context \()\);
    for index \(\in\) indexList do
        cliqueSize \(=\) greedy_getClique(index, context) ;
        if cliqueSize \(>\) largestClique then
            largestClique \(=\) cliqueSize ;
        end
    end
    return largestClique ;
```

### 4.4 Partial Branch and Bound

The branch and bound method was developed to escape the local optimum faced by the greedy method by exploring a larger area of the hyper concept tree.

Branch and bound is traditionally used for finding exact solutions for optimization problems. We here explore its use for obtaining an approximate solution by exploring only a portion of the tree by limiting the depth and the width at which the branching stops. In Figure 4.7 the depth is set to 2 and the width is set to 3 . The nodes that are visited are highlighted in gray. For level 1 and level 2 , the 3 nodes with the highest weight are considered, for the rest of the tree only the node with the highest weight is considered. It is clear here that the number of node that will be visited is significantly larger than that of the backtracking approach, and it grows fast as the values of depth and width increase.

Figure 4.7: Branch and Bound Illustration

Algorithm 4 presents the branch and bound procedure. The algorithm uses a priority queue data structure that orders hyper concepts according to their weight in each level of the hyper concept tree. The queue is populated by objects of type "HC" which have the level, weight and a list the hyper concept vertices as attributes. For each hyper concept that is popped from the priority queue, one or more hyper concepts are extracted from it depending on the preset
depth and width parameters. If the level of the hyper concept is less than or equal to a preset value of the maximum level $l$, a list of $w$ hyper concepts are extracted, where $w$ is a preset value of the width. The extracted hyper concepts are added to the priority queue only if the size of the hyper concept is greater than the size of largest hyper concept obtained so far. If the size of the hyper concept is smaller than the largest clique, it is guaranteed that a larger clique cannot be obtained from it and it is pruned from the tree. If the hyper concept is at a level that is larger than the preset level $l$, then only one hyper concept with the highest weight is extracted from it. The extracted hyper concept(s) is added to the queue if it is not a clique. If it is a clique however, its size is checked, if larger than the current largest clique, it replaces it. The worst case time complexity of the branch and bound approach is $O\left(w d n^{3}\right)$ where w is the value of the width and $d$ is the value of the depth of the hyper concept tree.

Algorithm 4 starts by pushing the passed context to the priority queue in line 2 . The context is popped from the queue in line 4 and its level is checked. If the level is less than " 1 ", a list of "w" hyper concepts are extracted. Each of the extracted hyper concepts is checked whether it is not a clique and whether its size is greater than the largest clique found so far, if that's the case then the hyper concept is added to the clique. If the hyper concept is a clique, and its size is greater than the current largest size, then its size is recorded as the largest in line 11. If the level is greater than l, only one hyper concept with the highest weight needs to be extracted, it is added to the queue if it is not a clique and if its size is greater that the current clique. This process is repeated until the queue is empty.

```
Algorithm 4: Finding the largest clique using the branch and bound
approach
    branchAndBound_getClique(context);
    Input : A formal context in the form of a 2D Integer array
    Output: The size of the maximum clique
    HCQueue.push(context) ;
    do
        \(\mathrm{HC}=\mathrm{HCQueue} . \operatorname{pop}()\);
        if \(H C\).level ()\(<=l\) then
            \(H C L i s t=\operatorname{get}_{-} H C L i s t(H C, w) ;\)
            for \(H C \in H C\) List do
                if HC.size () > largestClique and !isClique \((H C)\) then
                    HCQueue.puch \((H C)\);
                else if HC.Size ()\(>\operatorname{largestClique}\) and \(\operatorname{isCliqe}(H C)\) then
                    largestClique \(=\) HC.Size ()\(;\)
            end
        else
            \(H C=\) get_HC(HC);
            if HC.size ()\(>\) largestClique and !isClique \((H C)\) then
                HCQueue.puch \((H C)\);
            else if HC.Size ()\(>\) largestClique and isCliqe \((H C)\) then
                largestClique \(=\) HC.Size () ;
            end
    while ! HCQueue.isEmpty ();
```

## Chapter 5: Evaluation and Discussion

In this chapter we present the set up of the experiment 5.1 followed by a description of the used benchmark instances 5.2. After that we present the results of the greedy approach 5.3, the backtracking approach 5.4 and the branch and bound approach 5.5. Finally we present a comparison between the developed approach and the best published results 5.6.

### 5.1 Experimental Setup

The experiments have been performed on an HP envy laptop running windows 8.1. The PC has an $\operatorname{Intel}(\mathrm{R})$ Core i7-4702MQ processor and 16GB RAM. The implementation of all algorithms is sequential, written in Java programming language.

### 5.2 Benchmark

The 3 different variations of the algorithm are tested on DIMACS benchmark. DIMACS is the Center for Discrete Mathematics and Theoretical Computer Science that is a collaborative project of different institutions. The center held a few challenges, one of which focused on three NP-Hard problems: Satisfiability, Graph Coloring, and Maximum Clique. The graphs used during the challenge became the most widely benchmark for testing algorithms for the maximum clique, maximum weighted clique and even for the maximum independent set and vertex cover problems since 1992. The benchmark contains 80 different
cliques belonging to 12 different families. The families differ in the method by which the clique are generated which provides a wide variety of graphs. The graph sizes range between 28 to 4000 vertices. The following is a summary of the families.

- brock: Based on the work done by [11] which attempts to hide large cliques in graphs between smaller size cliques.
- C: Randomly generated graphs.
- c-fat: Generated from fault diagnosis data.
- DSJC: Randomly generated graphs.
- gen: Artificially generated graphs by Sanchis [43]
- hamming: Graphs that are based on the hamming distance between words. If the words are at least a hamming distance apart an edge is formed between them.
- johnson: Undirected graphs generated from systems of sets. An edge is formed if the intersection of the sets contains at lease k-1 elements.
- keller: Graphs based on Keller's conjecture on tilings.
- MANN: Graphs generated from converting the set covering formulation.
- p-hat: Randomly generated graphs.
- san: Randomly generated graphs.
- sanr: Randomly generated graphs.

The BHOSLIB benchmark was used to evaluate the optimal parameters for the branch and bound algorithm. The benchmark instances are transformed from a SAT benchmark where the vertices correspond to variables and the edges correspond to binary clauses.

### 5.3 Results of Greedy Approach

In this experiment, we tested the greedy algorithm previously presented on the full set of benchmark files using the 5 different weight values. The obtained results are summarized in Table 5.1. Weight, refers to the weight formula presented in Table 4.1. The second column, Clique Count, shows the number of maximum cliques found in the 80 benchmark files, and the percentage between parenthesis. When the maximum clique is not found, we use the distance between the largest clique found by the algorithm and the clique number of the graph $\omega$ as an indication of the quality of the given weight. We report here the maximum, minimum and average distance. Time ( s ) is the total time in seconds needed to find solutions to all the graphs.

Table 5.1: Greedy Method Results

| Weight | Clique Count(\%) | max distance | min distance | avg distance | Time (s) |
| ---: | :---: | :---: | :---: | :---: | :---: |
| weight1 | $17(21.25)$ | 26 | 1 | 6.60 | 186.39 |
| weight2 | $18(22.5)$ | 28 | 1 | 7.01 | 116.44 |
| weight3 | $13(16.25)$ | 50 | 3 | 13.61 | 93.44 |
| weight4 | $19(23.75)$ | 28 | 1 | 7.16 | 174.32 |
| weight5 | $18(22.5)$ | 28 | 1 | 7.01 | 182.60 |
| All Weights | $19(23.75)$ | 26 | 1 | 6.40 | 489.72 |

Weight4 produced the best result for the greedy approach which is the modified gain formula that gives more importance to the economy of information. using weight4, 19 out of 80 maximum cliques were extracted, and the average distance from the maximum clique is 7.16 nodes. weight1, weight 2 and weight 5 , produced results that are close to that given by weight1. Weight1 has a smaller minimum distance and smaller average distance. The last row is the result of sequentially running the greedy algorithm with all possible weight values, and reporting the largest clique found. The number of cliques is the same as that found using weight4, but it results in a smaller distance average. The time taken to extract cliques from all the benchmark graphs is 489.72 seconds,
which is acceptable. The full results of each weight on all benchmark graphs are listed in the Appendix.

### 5.4 Results of Partial Backtracking

A similar experiment has been conducted to test the backtracking approach. The results in Table 5.2 correspond to backtracking 50 times to the first level for each given weight.

Table 5.2: Partial Backtracking Results

| Weight | Clique Count(\%) | max distance | min distance | avg distance | Time (s) |
| ---: | :---: | :---: | :---: | :---: | :---: |
| weight1 | $32(40.0)$ | 26 | 1 | 4.33 | 4323.81 |
| weight2 | $33(41.25)$ | 25 | 1 | 4.77 | 4323.81 |
| weight3 | $15(18.75)$ | 32 | 1 | 9.68 | 3760.69 |
| weight4 | $33(41.25)$ | 26 | 1 | 4.81 | 4235.93 |
| weight5 | $33(41.25)$ | 25 | 1 | 4.79 | 4538.24 |
| All Weights | $33(41.25)$ | 25 | 1 | 4.78 | 56964.89 |

Weight2, weight4, weight5 and weight1 produce the best results of this approach, with 33 or 32 maximum cliques extracted out of 80 benchmark graphs, which presents a slight improvement to the greedy approach. Weigh3 produces worse results. The time taken by this approach is significantly larger than that taken by the greedy algorithm. Performing the same experiment by sequentially trying all weights results in the same number of maximum cliques, which indicates that one weight is sufficient to find all the maximum cliques. The detailed set of obtained results on all graphs is listed in Appendix.

### 5.5 Results of Branch and Bound

This is the last modification made to basic approach. We tested the method on the different benchmark files, using the different weight measures and with varying values of depth and width for branching. We tested the approach with
depths 1 and 2, and width values 10 to 100 with increments of 10 . Figures 5.1, 5.2, 5.3, 5.4, and 5.5 show the summary of the results obtained using each weight formula. In each figure, the horizontal axis represents the corresponding depth and width values, the value $1-10$ signifies depth 1 and width 10 . The primary vertical axis represents the total number of maximum cliques found at each depth and width values out of the 80 benchmark cliques. The secondary vertical axis represents the total time in seconds. Two values for the total time are reported, the total time taken by algorithm for the 80 benchmark graphs, shown in red, and the total time needed to find the maximum clique in a graph, shown in green.

Figure 5.1: Branch and Bound Summary for Weight1

Weight1 shows good performance for this approach. The number of maximum cliques obtained by weight1 ranges from 28 at depth 1 and width 10 , to 56 at depth 2 width 80 .

The maximum number of maximum cliques obtained by weight2 is slightly lower than than obtained by weight1, 54 out of 80 , but is still presented a good overall performance.

Weight3 shows a poor performance, with only 28 out of 80 maximum cliques are extracted at most.

Figure 5.2: Branch and Bound Summary for Weight2

Figure 5.3: Branch and Bound Summary for Weight3

Weight4 and weight5 both have a similar acceptable performance with 47 out of 80 cliques extracted, but not as good as the results obtained by weight1 and weight2.

The maximum number of maximum cliques is found using weight1 at depth 2 and width 70 , where 57 cliques are found out of 80 ( $70 \%$ of the graphs).

Table 5.3 summarizes the results obtained from all the weights. The average distance obtained using weight1, weight2, weight4 and weight5 is less than 5 nodes. This means that even when the largest clique is not obtained, the size of the clique is close.

Figure 5.4: Branch and Bound Summary for Weight4

Figure 5.5: Branch and Bound Summary for Weight5

Table 5.3: Branch and Bound Results

| Weight | Clique Count (\%) | max distance | min distance | avg distance |
| :--- | :---: | :---: | :---: | :---: |
| weight1 | $56(70.0)$ | 22 | 1 | 4.75 |
| weight2 | $54(67.5)$ | 21 | 1 | 4.27 |
| weight3 | $28(35.0)$ | 219 | 1 | 12.94 |
| weight4 | $47(58.7)$ | 21 | 1 | 4.27 |
| weight5 | $47(58.7)$ | 21 | 1 | 4.27 |

The time needed to find the maximum clique increases, the running time of the algorithm also increases as the values of depth and width increase. But the time needed for finding the maximum clique increases at a much smaller rate, and is always much lower than the running time of the algorithm. This
means that the clique is found in the first few branches of the hyper concept tree, but the algorithm keeps searching until all the branches are explored.

Initially, the a time limit of 2000 seconds was used. If a solution was not found withing the first 2000 seconds of running the algorithm, the largest clique size is reported and the algorithm is forced to stop. The selected time limit was not very tight, and resulted in a the running time of the algorithm being very high, especially that the first clique if found usually found a lot before. We also observed that the time at which the first clique is found by the algorithm is indicative of the time needed to find the largest clique. Similarly, graphs with higher density are more likely to have a longer running time. Based on these observations, multivariate regression was used to obtain a dynamic estimation of the time that the largest clique will be found based on the time that the first clique was found and the graph densities.

As weight1 gave the best results using a depth of 2 and width of 70 , we used the time values of obtaining the first clique output by this configuration along with the graph densities as input to the multivariate regression, and the output was coefficients of the time and density parameters along with the intercept shown in Table 5.4.

Table 5.4: Regression Parameter Coefficients

| intercept | -66.395 |
| :---: | :---: |
| density | 188.65 |
| first clique time | 5.74 |

The experiments conducted so far in this section can be seen as a parameter tuning phase, to devise the best value of the weight, depth, width and time limit for the running time of the algorithm. To evaluate the effectiveness and efficiency of the tuned parameters, we tested these setting on some the graphs of the BHOSLIB benchmark. Table 5.5 is a summary of the obtained results.

Table 5.5: BHOSLIB Benchmark Results

| graph | $\omega(G)$ | density | with time limit |  | without time limit |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | clique size | run time | clique size | run time |
| frb30-15-1 | 30 | 0.82 | 29 | 91.49 | 29 | 83.63 |
| frb30-15-2 | 30 | 0.82 | 29 | 91.15 | 29 | 104.51 |
| frb30-15-3 | 30 | 0.82 | 28 | 90.38 | 28 | 103.81 |
| frb30-15-4 | 30 | 0.82 | 28 | 90.55 | 28 | 89.22 |
| frb30-15-5 | 30 | 0.82 | 28 | 89.85 | 28 | 95.98 |
| frb35-17-1 | 35 | 0.84 | 32 | 94.86 | 32 | 191.22 |
| frb35-17-2 | 35 | 0.84 | 32 | 98.18 | 33 | 159.42 |
| frb35-17-3 | 35 | 0.84 | 32 | 95.70 | 33 | 189.27 |
| frb35-17-4 | 35 | 0.84 | 32 | 93.86 | 32 | 167.53 |
| frb35-17-5 | 35 | 0.84 | 32 | 93.57 | 33 | 180.94 |
| frb40-19-1 | 40 | 0.86 | 36 | 101.50 | 36 | 504.01 |
| frb40-19-2 | 40 | 0.86 | 36 | 98.96 | 37 | 546.28 |
| frb40-19-3 | 40 | 0.86 | 36 | 98.29 | 37 | 531.90 |
| frb40-19-4 | 40 | 0.86 | 37 | 98.62 | 37 | 467.40 |
| frb40-19-5 | 40 | 0.86 | 37 | 97.20 | 37 | 466.56 |

In most cases, the cardinality of the obtained cliques without setting a time limit is the same as the size of the clique obtained using the time limit except for graphs frb35-17-2, frb35-17-3, frb40-19-2 and frb40-19-3, where the size of the clique found is one node smaller than that found after applying the limit. The running time on the other hand, is much lower when a time limit is applied.

### 5.6 Comparison with Other Approaches

Table 5.6 compares the best results obtained from the developed approach, branch and bound method using weight1 at depth 2 and width 70 , to the most effective results in the literature as reported by [56]. The table shows the performance on the hardest instances of the benchmark. The reported times of all the algorithms are the times reported in the respective publications. The times are relative and only listed for comparison purposes. All the reported results are of sequential algorithms. The reported results correspond to [5, 35, $18,20,29,57,24,46,19,55,7,27]$.

Table 5.6: Comparison Between Approaches

| Instance | brock400_2 |  | brock400_4 |  | brock800_2 |  | brock800_4 |  | C2000.9 |  | C4000.5 |  | MANN_a45 |  | MANN_281 |  | keller6 |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

The results show that the maximum clique found by the hyper concept algorithm (in the last row) using the branch and bound design approach always has a size that is in the same range as some of the best approaches in the literature, the running time however, is slightly higher in most cases. Some of the approaches rely on randomization, the results between parenthesis are the average of 100 runs. The reported running time results are obtained without applying the learning approach. The time needed to find the largest clique is presented between parenthesis, it is usually a lot lower than the running time, and it can be obtained using regression. Furthermore, the hyper concept algorithm is implemented in Java, while most of the other solutions are implemented in lower level languages like C and $\mathrm{C}++$.

## Chapter 6: Conclusion

In the scope of this thesis, a heuristic conceptual approach for solving the maximum clique problem that runs in polynomial time has been developed. Several algorithm design approached have been designed and tested on the DIMACS benchmark graphs. The developed greedy approach is very efficient but the obtained results are not satisfactory in terms of obtained clique sizes. The backtracking approach slightly improved the greedy approach in terms of clique sizes but still does give the desired results. The branch and bound approach was the most successful in terms of obtained clique sizes but proven to no to be efficient. The parameters of the branch and bound approach have been optimized in a learning phase and tested on the BHOSLIB benchmark graphs.

The best obtained results we compared to the best result in the literature. The actual running time was high when compared to other approaches, but the time needed for finding the largest clique by the algorithm is much smaller and can be predicted through regression using historical information for obtaining previous cliques.

In the future, many improvements can be made to the algorithm to improve its performance. The current solution is implement in Java programming language, an implementation in a lower level language, like C might be much more efficient. Further improvements can be done to the data structures used. Conceptually, better upper and lower bounds to the branch and bound approach can be used to increase the efficiency of the algorithm. Learning through the re-
gression method can be extended to include the learning from the times needed to find the first two or three cliques instead of just the first clique to obtain a better estimation of the time time needed for finding the largest clique.

An improvement to the obtained results can be done by considering a sub ordering method when the vertices have equal weights for the main weight formula. For example, when the weight formula used is $\frac{r}{d \times c} \times(r-d-c)$, and two hyper concepts have equal highest weights, giving selecting the hyper concept with the higher value of $\frac{r}{d \times c}$ might result in obtaining a better results values faster. More consideration can be given to special numerical situations that could be causing a disadvantage for some of the weight formulas. For example, if the value of $(r-(d+c))$ is negative, the $\log$ of it will be undefined. In addition, squaring the matrix immediately after obtaining the vertex of the highest weigh then checking if the obtained hyper concept is clique will decrease the running time even further for the greedy approach. The performance of the developed approach might be assessed using many other weight formulas, for example the formula $\frac{r}{d}$ might produce better results.
