50 **ABSTRACT**

51 The purpose of the study was to examine the relationship between vertical stiffness, leg  
52 stiffness and maximal sprint speed in a large cohort of 11-16-year-old boys. Three-hundred  
53 and thirty-six boys undertook a 30 m sprint test using a floor-level optical measurement  
54 system, positioned in the final 15 m section. Measures of speed, step length, step frequency,  
55 contact time and flight time were directly measured whilst force, displacement, vertical  
56 stiffness and leg stiffness, were modeled from contact and flight times, from the two fastest  
57 consecutive steps for each participant over two trials. All force, displacement and stiffness  
58 variables were significantly correlated with maximal sprint speed ( $p \leq 0.05$ ). Relative vertical  
59 stiffness had a very large ( $r > 0.7$ ) relationship with sprint speed, while vertical center of  
60 mass displacement, absolute vertical stiffness, relative peak force, and maximal leg spring  
61 displacement had large ( $r > 0.5$ ) relationships. Relative vertical stiffness and relative peak  
62 force did not significantly change with advancing age ( $p > 0.05$ ), but together with maximal  
63 leg spring displacement accounted for 96% of the variance in maximal speed. It appears that  
64 relative vertical stiffness and relative peak force are important determinants of sprint speed in  
65 boys aged 11-16 years, but are qualities that may need to be trained due to no apparent  
66 increases from natural development. Practitioners may wish to utilize training modalities  
67 such as plyometrics and resistance training to enable adaptation to these qualities due to their  
68 importance as predictors of speed in youth.

## 75 INTRODUCTION

76           The natural development of speed throughout childhood and adolescence is  
77 thought to follow a non-linear process (8), with fluctuating improvements in sprint  
78 performance occurring in preadolescent and adolescent periods (24). The physiological  
79 factors that influence the development of speed in childhood have been explored from both  
80 an age- and maturity-related perspective (8,11). Prior to the onset of puberty, boys show  
81 accelerated improvements in sprint performance, which are primarily attributed to  
82 neurological adaptations, such as improved motor recruitment and coordination patterns (8).  
83 Peak gains in sprint speed performance are reported to coincide with circa- and post-peak  
84 height velocity (PHV), and circa- Peak Weight Velocity (PWV) around the time of the  
85 adolescent growth spurt (11,17). Owing to the increases in limb-length, muscle mass, and  
86 hormonal levels during this stage of development, which are associated with improved  
87 muscular strength and power output (24), a maturational influence of speed development  
88 appears likely (5). Unfortunately, while data on the developmental trends in maximal running  
89 speed in boys exist, there is a paucity of research that has examined the determinants of  
90 maximal running speed in youth.

91

92           Stiffness is thought to be a determinant of sprint speed in youth (3,6,20) and  
93 adults (1,2). The spring-mass model is often used to calculate vertical and leg stiffness  
94 measures, with the lower limb acting as the “spring” and the center of mass serving as the  
95 “mass” (4). Vertical stiffness is used to describe the vertical motion of the center of mass  
96 during ground contact at the middle of the stance phase, and is defined as the ratio of the  
97 maximal force to the vertical displacement of the center of mass as it reaches its lowest point  
98 (15). However, during running the leg contacts the ground at an angle when the center of  
99 mass is not directly over the foot (9). In order to quantify this measure of stiffness when

100 horizontal motion is involved, leg stiffness has been calculated using the force-time curve  
101 sine method based on flight times, contact times, leg length, body mass and running velocity  
102 (15). Having greater vertical stiffness is thought to enhance running performance by aiding  
103 the lower body's ability to resist large displacements of the center of mass during the landing  
104 (eccentric) phase, while also increasing the rate of force development during the push-off  
105 (concentric) phase (2). Previous research has investigated the relationship between vertical  
106 stiffness and sprint running performance in a small sample ( $n = 11$ ) of 16 year old males, and  
107 found that vertical stiffness measured during hopping was significantly correlated ( $r = 0.68$ )  
108 with maximal velocity but not with acceleration (3). Furthermore, significant positive  
109 relationships ( $r = 0.56$ ) have been reported between vertical stiffness and running speed in a  
110 small mixed gender sample ( $n = 10$ ) of 5 – 10 year old children (6), however the participants  
111 were only instructed to run "fast" or "slow" during the assessment and therefore maximal  
112 velocity may not have been achieved. Though there is supporting evidence that leg stiffness  
113 is a key determinant of maximal sprint velocity in adult populations (1,2) but not in youth (6),  
114 the small sample sizes and methodological limitations of studies in the current body of  
115 literature may mask the true contribution of leg stiffness to maximal running speed in youth.

116

117           While it is known that sprint speed is influenced by age and maturation (11),  
118 literature that specifically focuses on the natural development of stiffness characteristics  
119 throughout childhood and adolescence remains scarce. Rumpf and colleagues (20) showed  
120 that both vertical and leg stiffness contributed to maximal sprint velocity in a sample of male  
121 athletes of contrasting maturity status. However, the reported maximal running velocities,  
122 which were collected on a non-motorized treadmill, were approximately 50 percent slower  
123 than data reported recently in a similar large cohort of boys during overground sprinting (11).  
124 Thus, it remains to be determined how vertical and leg stiffness contribute to overground

125 sprint performance in male youth. Therefore, the aim of the study was to examine the  
126 relationship between force, vertical stiffness and leg stiffness with maximal sprint speed in a  
127 large cohort of 11-16-year-old boys.

128

## 129 **METHODS**

### 130 **Experimental approach to the problem**

131 A large sample of school-aged boys were grouped according to age and  
132 subsequently tested for maximal running speed using an optical measurement system  
133 (Optojump, Microgate, Italy). Sprint performance variables directly measured during sprint  
134 trials included running speed, step length, step frequency, contact time and flight time.  
135 Additional variables were modeled from the spatiotemporal data including maximal ground  
136 reaction force ( $F_{max}$ ), center of mass displacement ( $\Delta y_c$ ), leg spring compression ( $\Delta L$ ),  
137 vertical stiffness ( $K_{vert}$ ) and leg stiffness ( $K_{leg}$ ).

138

### 139 **Subjects**

140 Three hundred and seventy-five boys aged 11–16 years agreed to participate in  
141 the study. Descriptive details (means and standard deviations) for all anthropometric  
142 variables per chronological age group are provided in *Table 1*. Maturation was determined  
143 using a sex-specific maturity offset prediction equation (13) derived from anthropometric  
144 variables, including body mass, standing height, and sitting height. Subsequently, leg length  
145 was derived from the difference between standing and sitting heights. Participants reported  
146 no injuries at the time of testing and were all regularly participating in bi-weekly physical  
147 education classes, however, none of the participants were engaged in formal strength and  
148 conditioning programs. Physical education classes followed national curriculum guidelines  
149 and were 60 minutes in duration. Participants were instructed to wear school-issued physical

150 education clothing, refrain from physical activity 24 hours prior to testing, and avoid food  
151 consumption one hour prior to testing. All testing sessions occurred during scheduled  
152 physical education classes and within the same indoor facility, with the equipment orientated  
153 in the same positions. All participants were provided the opportunity to familiarize  
154 themselves with the test protocols prior to commencing data collection. The institutional  
155 ethical committee, in accordance with the declaration of Helsinki, granted ethical approval,  
156 and subsequently parental/guardian consent as well as child assent were obtained before  
157 testing. The study conforms to the Code of Ethics of the World Medical Association  
158 (approved by the Ethics Advisory Board of Swansea University).

159

160 \*\*\*Table 1 near here\*\*\*

161

162 **Procedures**163 *Sprint test*

164 The sprint test followed the same procedures as those previously utilized in male  
165 youth (10–12), requiring participants to sprint maximally along a 30 m track. Participants  
166 began the sprint in a split stance on a line 0.5 m behind the start line and were instructed to  
167 sprint with maximal effort down the testing track. A finish line was placed at 35 m in order to  
168 encourage participants to sprint maximally throughout the 15-30 m section of the track where  
169 the data were collected. Initiation of the test protocol was consistent throughout; “ready”  
170 informed participants to adopt the split stance ready position, while “go” was the verbal  
171 stimulus to start sprinting. All participants completed two trials of the protocol and verbal  
172 encouragement was provided throughout each trial. A minimum of four minutes passive rest  
173 was given between trials to ensure sufficient recovery.

174

175 *Sprint test variables*

176           The assessment of vertical and leg stiffness measures were calculated from  
177 spatiotemporal sprint characteristics via an optical measurement system (Optojump,  
178 Mircrogate, Italy), positioned at floor level in the 15-30 m section of the track. Data for the  
179 sprint characteristics were instantaneously collected at a sampling rate of 1000 Hz using a  
180 Windows XP laptop via specialist software (Optojump, Microgate, Italy), and subsequently  
181 exported to Microsoft Excel for data processing. Data obtained from the optical measurement  
182 system were used to automatically calculate the following variables:

183

- 184       • *Speed*: Calculated by dividing the distance (in meters) between alternate foot contacts  
185       (step length) and the time taken (in seconds) between these contacts (flight time +  
186       contact time), with units expressed as distance per unit of time ( $\text{m}\cdot\text{s}^{-1}$ ).
- 187       • *Step length*: The distance (in meters) between the foot tip of alternate foot contacts  
188       (i.e., the distance between left and right foot contacts).
- 189       • *Step frequency*: The rate (in Hertz) of lower limb movements as defined by the  
190       number of steps taken per second.
- 191       • *Contact time*: The amount of time (in seconds) the participant spends during the  
192       stance phase of the sprint, where the foot is in contact with the floor.
- 193       • *Flight time*: The amount of time (in seconds) between alternate foot contacts, where  
194       the participant is not in contact with the floor.

195

196           Using the methods previously identified by Morin and colleagues (15,16), force,  
197 displacement as well as vertical and leg stiffness components were calculated from contact  
198 and flight times from the two fastest consecutive strides for each participant over two trials.  
199 The variables were processed with equations 1-5 and defined as the following:

200

- 201 • *Peak ground reaction force ( $F_{max}$ ):* The maximal ground reaction force during the  
 202 contact phase (kN) where  $m$  is the subjects body mass (in kg),  $g$  is gravity,  $t_c$  is  
 203 contact time (in s) and flight time is  $t_f$  (in s).

$$204 \quad F_{max} = m \cdot g \cdot \frac{\pi}{2} \cdot \left(\frac{t_f}{t_c} + 1\right) \quad (1)$$

- 205 • *Peak vertical center of mass displacement ( $\Delta y_c$ ):* The vertical displacement of the  
 206 center of mass to its lowest point during contact.

$$207 \quad \Delta y_c = -\frac{F_{max}}{m} \cdot \frac{t_c^2}{\pi^2} + g \cdot \frac{t_c^2}{8} \quad (2)$$

- 208  
 209 • *Maximal leg spring displacement ( $\Delta L$ ):* The difference between leg length when  
 210 standing and leg length when the center of mass is at its lowest point, where  $L$  is leg  
 211 length.

$$212 \quad \Delta L = L - \sqrt{L^2 - \left(\frac{v_c \cdot t_c}{2}\right)^2} + \Delta y_c \quad (3)$$

- 213  
 214 • *Absolute vertical stiffness ( $K_{vert}$ ):* The ratio ( $\text{kN} \cdot \text{m}^{-1}$ ) of the modeled peak ground  
 215 reaction force ( $F_{max}$ ) over the modeled vertical displacement of the center of mass  
 216 ( $\Delta y_c$ ).

$$217 \quad K_{vert} = F_{max} \cdot \Delta y_c^{-1} \quad (4)$$

- 218  
 219 • *Absolute leg stiffness ( $K_{leg}$ ):* The ratio ( $\text{kN} \cdot \text{m}^{-1}$ ) of the modeled peak ground reaction  
 220 force ( $F_{max}$ ) over the modeled leg length variation ( $\Delta L$ ) during ground contact

$$221 \quad K_{leg} = F_{max} \cdot \Delta L^{-1} \quad (5)$$

222

223 This modelling approach was taken owing to its non-invasive nature as well as  
224 the low level of mean error bias in all variables ( $F_{max} = 3.24\%$ ;  $\Delta y_c = 2.34\%$ ;  $\Delta L = 0.67\%$ ;  
225  $K_{vert} = 2.30\%$ ;  $K_{leg} = 2.54\%$ ) and significant regressions between modelled stiffness  
226 characteristics ( $K_{vert} = p < .01, r^2 = .98$ ;  $K_{leg} = p < .01, r^2 = .89$ ) and force-plate measures  
227 during overground running (15). Relative vertical and leg stiffness measures were quantified  
228 by normalizing data to both leg length and body mass (kg) (9).

229

### 230 *Sprint test data processing*

231 Data for all steps completed within the 15-30 m data collection zone were  
232 instantaneously recorded for participants over their two sprint trials. Subsequently all data  
233 corresponding to the fastest two consecutive steps from either trial were extracted and  
234 averaged for analysis. If a participant was deemed to have obtained their fastest steps from  
235 the last or first foot contact recorded in the 15–30 m data collection zone, then their data were  
236 excluded from the analysis. This exclusion was enforced to remove those participants who  
237 had already achieved maximal speed before the data collection zone and also those who were  
238 still accelerating at the end of the data collection zone ( $n = 22$ ), thereby resulting in data from  
239 only those participants achieving maximal speed between 15–30 m being included for  
240 subsequent analysis ( $n = 375$ ). The approach to data processing adopted in this study has  
241 been previously shown to be reliable for the assessment of the spatiotemporal characteristics  
242 (intraclass correlations: 0.66 – 0.86; coefficient of variation: 3.8 – 5.0%) in boys (12). Due to  
243 the novel modeling approaches in this study, the reliability of all force, displacement and  
244 stiffness variables, as well as the estimations of contact and flight length, was assessed with a  
245 cohort of 49 boys (age:  $14.1 \pm 0.7$  years, range: 12.9 – 15.7 years) over three trials during a  
246 two week period alongside the main study. Data revealed moderate-very large levels of  
247 reliability related to all modeled variables for intraclass correlation ( $F_{max} = 0.96$ ; relative  $F_{max}$

248 = 0.66;  $\Delta y_c = 0.77$ ;  $\Delta L = 0.99$ ;  $K_{vert} = 0.92$ ;  $K_{leg} = 0.94$ ; relative  $K_{vert} = 0.85$ ; relative  $K_{leg} =$   
249 0.93) and coefficient of variation values ( $F_{max} = 4.99\%$ ; relative  $F_{max} = 4.99\%$ ;  $\Delta y_c = 7.61\%$ ;  
250  $\Delta L = 2.29\%$ ;  $K_{vert} = 7.53\%$ ;  $K_{leg} = 6.33\%$ ; relative  $K_{vert} = 7.53\%$ ; relative  $K_{leg} = 6.33\%$ ).

251

## 252 **Statistical analyses**

253 Descriptive statistics (means  $\pm$  standard deviations) were calculated for all force,  
254 displacement, stiffness and spatiotemporal characteristics for each chronological age group.  
255 The assumption of normality was assessed via the Kolmogorov-Smirnov test. A one-way  
256 analysis of variance (ANOVA) was conducted to determine differences between the age  
257 groups. Homogeneity of variance was assessed via Levene's statistic and where violated,  
258 Welch's adjustment was used to correct the F-ratio. The location of significant differences  
259 between groups was identified by either using Bonferroni or Games-Howell post-hoc  
260 analysis, where equal variances were and were not assumed, respectively. Pearson correlation  
261 coefficients were used to determine the strength of relationships between all sprint test  
262 variables and maximal running speed, with the strength of relationships classified as either;  
263 almost perfect ( $r = >0.9$ ), very large ( $r = 0.7- 0.9$ ), large ( $r = 0.5 - 0.7$ ), moderate ( $r = 0.3-$   
264  $0.5$ ), small ( $r = 0.1-0.3$ ) or trivial ( $r = <0.1$ ) (7). Stepwise multiple regression analyses were  
265 employed to establish the contribution of stiffness-related determinants of speed across the  
266 entire sample, and separately for those participants deemed to be Pre- ( $< -0.5$  years) and Post-  
267 PHV ( $> 0.5$  years) according to the maturity offset. This approach facilitated the examination  
268 of the role of maturation whilst accounting for the measurement error of the prediction  
269 equation for maturity offset (13). The assumption of independent errors during the multiple  
270 regression analyses was tested via a series of Durbin-Watson tests, whilst multi-collinearity  
271 was tested using variance inflation factor (VIF) and tolerance diagnostics. All statistical

272 analyses were conducted in SPSS Statistics v. 20 for Mac, with statistical significance set at  
273 an alpha level of  $p < 0.05$ .

274

## 275 **RESULTS**

276 The results in *Table 2* indicate no significant differences ( $p > 0.05$ ) in maximal  
277 speed between the under 12 years (U12) and under 13 years (U13) age groups. However, the  
278 under 14 years (U14) and under 15 years (U15) groups were significantly faster ( $p < 0.05$ )  
279 than the U12 boys, while under 16 years (U16) were significantly faster ( $p < 0.05$ ) than the  
280 boys in all of the younger age groups. Similarly, step length was significantly longer ( $p <$   
281  $0.05$ ) in U14 and U15 compared to the U12 and U13 group, while U16s had significantly  
282 longer steps ( $p < 0.05$ ) than all other groups. Step frequency and flight time did not differ  
283 significantly across all groups ( $p > 0.05$ ), whilst the only significant differences for contact  
284 time were between the U12 and U15 groups ( $p < 0.05$ ).

285

286 \*\*\*Table 2 about here\*\*\*

287

288 The results in *Table 3* shows there were no significant differences ( $p > 0.05$ ) in  
289 relative  $F_{max}$  for boys across any of the age groups. While no significant differences ( $p >$   
290  $0.05$ ) in absolute  $K_{leg}$  were observed, absolute  $K_{vert}$  significantly increased with age ( $p <$   
291  $0.05$ ). No significant between-group differences in relative  $K_{vert}$  or vertical displacement  
292 ( $\Delta y_c$ ) characteristics were observed across the age groups. However, there were significant  
293 decreases in relative  $K_{leg}$  between the U12s and the U15s, while the U16s had significantly  
294 lower relative  $K_{leg}$  than the U12-U14 age groups. Furthermore, both the U14 and U15 groups  
295 had significantly greater ( $p < 0.05$ ) leg spring displacement ( $\Delta L$ ) than the U12s and U13s. In  
296 addition, the U16s displayed significantly greater ( $p < 0.05$ )  $\Delta L$  than all other age groups.

297

298 \*\*\*Table 3 near here\*\*\*

299

300 All force, displacement and stiffness related variables had significant  
301 relationships ( $p < 0.05$ ) with speed, however, the magnitudes of these relationships varied  
302 (*Table 4*). Speed had a very large positive relationship with relative  $K_{vert}$  ( $r^2 = 0.53$ ;  $p < 0.05$ ).  
303 Absolute  $K_{vert}$ ,  $\Delta y_c$ , relative  $F_{max}$ , and  $\Delta L$  were all moderately related to speed ( $r^2 = 0.16 -$   
304  $0.24$ ;  $p < 0.05$ ), while all of the other variables had small relationships ( $r^2 = 0.03$ ;  $p < 0.05$ ).  
305 Furthermore, a moderate relationship was found between leg length and  $\Delta L$  ( $r = 0.45$ ;  $p <$   
306  $0.05$ ), whilst contact time was found to have a very large negative relationship with both  $\Delta L$   
307 and relative  $F_{max}$  ( $r = -0.78$ ;  $p < 0.05$  and  $r = -0.77$ ;  $p < 0.05$ , respectively). An almost perfect  
308 negative relationship existed between  $\Delta y_c$  and step frequency ( $r = -0.96$ ;  $p < 0.05$ ), whilst  
309 relative  $F_{max}$  had a very large relationship with step length ( $r = 0.79$ ;  $p < 0.05$ , respectively).

310

311 \*\*\*Table 4 near here\*\*\*

312

313 Multiple stepwise regression analysis across the whole sample showed that  
314 variation in maximal running speed was best explained by relative  $K_{vert}$ ,  $\Delta L$  and relative  $F_{max}$ ,  
315 which accounted for 96% of the total variance. The addition of absolute  $F_{max}$ , absolute  $K_{leg}$   
316 and absolute  $K_{vert}$  marginally improved the predictive ability of the regression equation to  
317 97%. When examined separately for Pre- and Post-PHV sub-groups, relative  $K_{vert}$ ,  $\Delta L$  and  
318 relative  $F_{max}$  remained the strongest predictors of speed, accounting for 96% and 98% of the  
319 total explained variance, respectively.

320

321 \*\*\*Table 5 near here\*\*\*

322

323 **DISCUSSION**

324           The aim of this study was to examine the natural development of stiffness  
325 properties during maximal sprint speed in a large sample of young boys of contrasting age. It  
326 was observed that relative vertical stiffness, relative peak force and maximal leg spring  
327 displacement explained 96% of the variance of sprint speed. Despite significant increases in  
328 sprint speed with age, relative force and relative vertical stiffness did not significantly  
329 change; while maximal leg spring displacement did increase with age.

330

331           In the current study, maximal sprint speeds were similar in the youngest two age  
332 groups and increased significantly in the U14-U16's. Based on descriptive data, this would  
333 suggest that speed was stable in the pre-PHV age groups, but increased around and beyond  
334 the period of PHV (11,17). The results also indicated that step frequency was constant across  
335 groups, whilst step length increased across age groups. This may indicate that changes in  
336 speed were proportional to changes in step length (22); however, it has been suggested that  
337 when boys are divided into maturation groups that step frequency decreases and contact time  
338 increases across pre-pubertal groups of advancing maturity, and only once these decrements  
339 in performance stabilize around the period of PHV are significant increases in sprint speed  
340 observed (11). A similar pattern was observed in this study, although the age-group rather  
341 than maturation-group analysis appears to have influenced the results of the between-group  
342 significances observed. While it may therefore be concluded that sprint speed is influenced  
343 by age and maturation (11,17,21), literature that specifically focuses on the natural  
344 development of stiffness characteristics throughout childhood and adolescence is limited.

345

346           The results from the between-group analysis in the current study revealed that  
347 increases in speed coincided with increases in absolute vertical stiffness across all age  
348 groups. Similar results have previously been found across boys of a similar age during a pre-,  
349 mid- and post-PHV analysis (20). Significant increases in absolute peak force were observed  
350 from U13 with advancing age. Increases in absolute vertical force across boys of a similar  
351 age and maturation status have been previously reported and were largely attributed to  
352 increases in body mass, however increases in relative vertical force were only observed for  
353 those post-PHV (21). In the current study, both relative vertical stiffness and relative peak  
354 force measures remain unchanged across all age groups. Collectively, these results may  
355 suggest that absolute increases in peak forces can be expected as a result of natural increases  
356 in muscle cross-sectional area during growth (23). Furthermore, with no observed differences  
357 in relative force production in the current study, a negative influence of increased body mass  
358 during sprint performance cannot be ruled out (10). On this basis, neurological sources of  
359 increased force production such as motor unit activation, coordination, recruitment and firing  
360 (18) may be considered important for sprint performance in boys. Furthermore, it is also  
361 likely that the significant increases in body mass associated with the older age groups would  
362 require a greater level of overall stiffness to maintain the magnitude of center of mass  
363 displacement during ground contact (9).

364

365           Analysis revealed that absolute leg stiffness remained constant in boys with  
366 advancing age, yet relative leg stiffness decreased significantly in the U15s and U16s.  
367 Increases in mass have been shown to be associated with increases in relative leg stiffness in  
368 children aged 5-10 years (6), and therefore it might be expected that the increases in mass  
369 seen across age groups may continue to exert this influence. This proposition was not  
370 supported in the current study, however the comparative values (6) may not have been

371 derived from maximal sprinting, resulting in a relative stiffness values that were ~67% lower  
372 than the current study. The results of the present study ascertain that the concomitant  
373 significant increases in absolute maximal force and leg spring displacement resulted in  
374 absolute leg stiffness remaining unchanged with age. Furthermore, the decrements in relative  
375 leg stiffness experienced by the more mature boys, likely reflect changes in body size that  
376 occur around and after the pubertal growth spurt. Specifically, significant increases in leg  
377 length may have resulted in reduced leg stiffness due to greater compression of the leg as a  
378 ratio of leg length. Conversely, previous research has found leg stiffness increased  
379 significantly with maturation during sprinting on a non-motorized treadmill (20). However, it  
380 should be noted that making comparisons between these studies is problematic, given the  
381 different methodologies adopted to measure speed and stiffness properties. Data from a study  
382 of boys of similar age and maturity during non-motorized treadmill sprinting (20) reported  
383 maximal velocities between 46-58% slower, and relative leg stiffness values 62-80% lower  
384 than those of the current study. These differences may be in part be explained by the  
385 influence of treadmill inertia, meaning those younger participants with a lower body mass  
386 would be placed at a disadvantage in overcoming the initial treadmill resistance,  
387 consequently altering their sprint kinematics and kinetics (19). These observations further  
388 reinforce the importance of assessing spatiotemporal and stiffness characteristics during  
389 overground running in order to elicit true maximal values for each variable of interest.

390

391           The results of the study revealed that both absolute and relative leg stiffness had a  
392 small relationship with speed and were not predictors of maximal sprinting velocity, which  
393 differs from previous literature (20). Conversely, relative vertical stiffness had a very large  
394 relationship with maximal sprint speed ( $r = 0.73$ ) and was the most important predictor of  
395 speed in the regression analyses, explaining over 50% of the variance. It is thought that those

396 who possess greater stiffness have a more rapid release of elastic energy during fast SSC  
397 activities such as sprinting, where angular joint displacement is minimal (1). Furthermore, the  
398 results of this study highlighted that vertical displacement had an almost perfect negative  
399 relationship with step frequency ( $r = -0.96$ ), emphasizing the importance of limited  
400 displacement of the center of mass upon step frequency in male youth. Researchers have  
401 reported increases in vertical stiffness with increasing running velocity in adult populations  
402 (1,2,15), as well as in children (6) and adolescent populations (3). Chelly and Denis (3)  
403 previously identified muscular power as a key determinant of both acceleration and maximal  
404 speed, but found that only vertical stiffness was correlated with maximal sprinting velocity in  
405 16-year-old boys. The findings of the current study are the first to demonstrate that relative  
406 vertical stiffness has a major role in determining sprint speed. Interestingly, although the  
407 present study revealed that relative vertical stiffness is a quality that does not significantly  
408 change between ages 11 and 16 years as a result of natural development, this is contrary to  
409 the known increases in muscle-tendon stiffness with advancing age (25). If age-related  
410 increases in muscle-tendon stiffness do contribute to increases in speed, this must be due to  
411 an increase in step length, as there are only minimal changes in step frequency with  
412 advancing age; however further research is needed to confirm this.

413

414           Studies in adults (1,14,26,27), and more recently in youth (3,21), have shown that  
415 force production has a major role in determining sprint speed. In the current study, relative  
416 measures of peak force were related ( $r = 0.42$ ) to sprint speed and were a better predictor of  
417 maximal sprint velocity than absolute peak force. While absolute peak force appears to be  
418 influenced by age, measures of relative peak force are not. Furthermore, relative force  
419 production had a very large positive relationship with step length ( $r = 0.79$ ), and a very large  
420 negative relationship ( $r = -0.77$ ) with contact time, highlighting the importance of force

421 production over a short period of ground contact to achieve greater distance between foot  
422 contacts during sprinting (27). Therefore, our results support the existing evidence regarding  
423 the importance of relative force for the propulsive component of developing maximal sprint  
424 velocity in youth, whilst also highlighting that relative forces do not improve as part of  
425 natural growth and development. Consequently, it is suggested that male youth should also  
426 engage with training modalities to enhance relative force production.

427

428           Interestingly, maximal leg compression had a moderate relationship to, and was  
429 an important predictor of maximal sprint speed. This finding may reflect the importance of  
430 contact length during the ground contact phase of sprinting (26), whereby boys with greater  
431 leg compression may also have travelled a further distance when in contact with the ground.  
432 Interestingly, only 20% common variance was observed between leg length and leg  
433 compression. This result may highlight the independent effects that leg length and leg  
434 compression have upon contact length and the possible role of technical factors such as lower  
435 limb angles at touchdown. It has been suggested that leg stiffness decreases with a less  
436 vertical orientation of the leg at touchdown (greater limb angle from the vertical) (9),  
437 however at this stage these inferences remain speculative as these other mediating factors  
438 were not assessed in this study. Novel findings from the current study demonstrate that  
439 maximal leg compression and relative force production have an important role in developing  
440 maximal sprint speed in young boys. However, it should be noted very large negative  
441 relationships were observed between ground contact time and relative leg compression ( $r = -$   
442  $0.78$ ). That is, those who exhibited greater leg compression are likely to have also utilized  
443 shorter period of ground contact. This may highlight that increases in compression does not  
444 impose a negative impact upon contact times and concomitant step frequency. Conversely,  
445 the relationships between contact time and leg compression with relative force production ( $r$

446 = -0.77 and 0.47, respectively) suggest that those producing more relative force were doing  
447 so in shorter periods of ground contact but with less leg compression. This may highlight  
448 differential strategies employed by male youth to manage the period of ground contact;  
449 however, further research is required to explore these concepts.

450

451 Collectively, these findings would seem to provide contradictory  
452 recommendations; firstly the need to compress the legs more to potentially allow for greater  
453 contact length; whilst secondly the need to produce greater relative force over shorter periods  
454 of ground contact to increase step length; and thirdly, the need to minimize center of mass  
455 displacement and increase vertical stiffness for enhanced step frequency. The results of the  
456 study also indicate that leg compression increases with age, whilst relative vertical stiffness  
457 and center of mass displacement do not. Furthermore, given the increases in absolute force  
458 production and vertical stiffness observed in this study, the negative influence of increases in  
459 stature and particularly mass cannot be ignored (10). It may therefore be postulated that  
460 whilst additional leg compression may offer some beneficial effects to sprint performance in  
461 youth, the enhancement of relative force production and relative vertical stiffness may be  
462 qualities that deserve more attention during training. This approach should ensure enhanced  
463 SSC function and step frequency, whilst synergistically enhancing step length to maximize  
464 sprint performance in male youth.

465

466 The propositions made in this study should be viewed in the context of the  
467 limitations associated with the study. It should be acknowledged that the validity of the  
468 modeling equations for force, displacement and stiffness have been previously reported (15),  
469 these variables are not directly measured. Given the limitations of non-motorized treadmills  
470 (19), and the substantial financial outlay required for a series of in-ground force plates, the

471 method presented here offers practitioners a practical alternative to assess force, displacement  
472 and stiffness during sprinting.

473

#### 474 **PRACTICAL APPLICATIONS**

475           The results of this study indicate that relative vertical stiffness, relative peak  
476 force, and maximal leg spring displacement are the most important determinants of maximal  
477 sprint speed in boys, explaining 96% of performance. While maximal leg spring  
478 displacement increases naturally with growth and maturation during childhood, this is not the  
479 case for relative vertical stiffness and relative peak force. Cumulatively, this suggests that to  
480 facilitate increases in sprint speed, boys will benefit from varied resistance training  
481 interventions that are targeted to enhance relative force production, rate-of-force  
482 development, and relative stiffness properties.

$F_{max}$	0.001	0.967
Absolute $k_{leg}$	-0.054	0.972
Absolute $k_{vert}$	-0.008	0.973

**Key:**  $\Delta L$  = modeled leg length variation during ground contact;  $K_{vert}$  = vertical stiffness;  $F_{max}$  = Maximal force;  $K_{leg}$  = leg stiffness
