Abstract

The equilibration of hot and dense nuclear matter produced in the central cell of central Au+Au collisions at RHIC ($\sqrt{s} = 200A$ GeV) energies is studied within a microscopic transport model. The pressure in the cell becomes isotropic at $t \approx 5$ fm/c after beginning of the collision. Within the next 15 fm/c the expansion of matter in the cell proceeds almost isentropically with the entropy per baryon ratio $S/A \cong 150$, and the equation of state in the (P, ε) plane has a very simple form, $P = 0.15\varepsilon$. Comparison with the statistical model of an ideal hadron gas indicates that the time $t \approx 20$ fm/c may be too short to reach the fully equilibrated state. Particularly, the creation of long-lived resonance-rich matter in the cell decelerates the relaxation to chemical equilibrium. This resonance-abundant state can be detected experimentally after the thermal freeze-out of particles.

I. INTRODUCTION

The assumption that strongly interacting hadronic (or rather partonic) matter, produced in nucleus-nucleus collisions at high energy, can reach a state of local equilibrium (LE) [1–3] is one of the most important topics in relativistic heavy-ion program [4]. The degree of equilibration can be checked by fitting the measured particle yields and transverse momentum spectra to that of the thermal model in order to extract the conditions of the fireball at the chemical and thermal freeze-out (see, e.g., [5–12] and references therein). Here the equilibrium particle abundances, which correspond to a certain temperature, T , baryon chemical potential, μ_B , and strangeness chemical potential, μ_S , can be determined. However, the analysis is complicated, e.g., by the presence of collective flow of particles and the non-homogeneity of the baryon charge distribution in the reaction volume. The volume of the fireball is also taken as a free parameter in the thermal model. Various non-equilibrium microscopic transport-, string-, partonic-, etc. models have been applied to verify the appearance of at least local equilibrium in the course of heavy-ion collisions at relativistic and ultrarelativistic energies [13–24]. To reduce the number of unknown parameters and simplify the analysis it has been suggested [20,21] to examine the equilibrium conditions in the central cell of relativistic heavy-ion collisions, simulated by one of the microscopic models. For these purposes we employ the microscopic Ultra-relativistic Molecular Dynamics (UrQMD) transport model, which nicely describe the available experimental data on hadron-hadron and nucleus-nucleus collisions in a broad energy range [22].

The central cell of symmetric heavy-ion collisions is a convenient system because the velocity of its center of mass is essentially zero. The cell should be neither too small nor too large. Previous studies at energies from $10.7A$ GeV (AGS) to $160A$ GeV (SPS) [20,21] have shown that the cubic cell with volume $V = 5 \times 5 \times 5 = 125 \text{ fm}^3$ is well suited for the analysis. The aim of the present paper is to study the relaxation of hot nuclear matter, simulated within the microscopic model, in the central cell in Au+Au interactions at RHIC ($\sqrt{s} = 200A$ GeV) energy.

The paper is organized as follows. The conditions of kinetic equilibrium in the cell are discussed in Sec. II. Section III describes the statistical model (SM) of an ideal hadron gas employed for the comparison with the microscopic calculations. The relaxation of hot nuclear matter in the cell to thermal and chemical equilibrium is studied in Sec. IV. Finally, conclusions are drawn in Sec. V.

II. KINETIC EQUILIBRIUM

First, the kinetic equilibrium has to be verified. The collective flow in the cell should be isotropic and small, so it cannot significantly distort the momentum distributions of particles. As shown in Fig. 1, the average longitudinal velocity in the central cell at RHIC energies reaches its maximum at $\approx 1 \text{ fm}/c$ after the Lorentz-contracted nuclei have completely passed through each other. The longitudinal flow rapidly drops and converges to the developing transverse flow. The longitudinal collective velocity of particles becomes smaller than $v_{flow} = 0.15c$ at $t = 5 - 6 \text{ fm}/c$ at RHIC, while the similar process takes $t = 8 - 10 \text{ fm}/c$ at the AGS and SPS energies. This gives a small correction, only $\langle m_N v_{flow}^2/2 \rangle \approx 7 \text{ MeV}$ for the

nucleon spectra, and less than a MeV for pions, whereas the characteristic temperatures are around 140 MeV.

Velocity distributions of hadron species become isotropic and nearly Maxwellian quite soon [20,21]. Isotropy of the velocity distributions results in pressure isotropy. The pressure in the longitudinal direction in the cell, calculated according to virial theorem [25], is compared in Fig. 2(a) with the transverse pressure. The time of convergence of longitudinal pressure to the transverse one decreases from 10 fm/c to 5 fm/c with rising incident energy from AGS to RHIC, respectively. Thus, the kinetic equilibrium in the central cell in Au+Au collisions at RHIC energy is reached at $t \approx 5$ fm/c.

III. STATISTICAL MODEL OF AN IDEAL HADRON GAS

To verify that the matter in the cell is in thermal and chemical equilibrium one has to compare the snapshot of hadron yields and energy spectra in the cell with the equilibrium spectra of hadrons obtained in the statistical model (SM) of an ideal hadron gas containing essentially the same number of baryonic and mesonic degrees of freedom [23]. We recall the procedure briefly: the values of energy density, ε , baryon density, ρ_B , and strangeness density, ρ_S , extracted from the microscopic calculations in the cell, are used as an input to the system of nonlinear equations of the SM

$$\varepsilon^{\text{mic}} = \frac{1}{V} \sum_i E_i^{\text{SM}}(T, \mu_B, \mu_S), \quad (1)$$

$$\rho_B^{\text{mic}} = \frac{1}{V} \sum_i B_i \cdot N_i^{\text{SM}}(T, \mu_B, \mu_S), \quad (2)$$

$$\rho_S^{\text{mic}} = \frac{1}{V} \sum_i S_i \cdot N_i^{\text{SM}}(T, \mu_B, \mu_S), \quad (3)$$

containing the baryon charge, B_i , and strangeness, S_i , of the hadron species i . This procedure enables one to determine temperature, T , baryon chemical potential, μ_B , and strangeness chemical potential, μ_S . If the set of three parameters (T, μ_B, μ_S) is fixed, all macroscopic characteristics of the equilibrated system can be determined unambiguously. For instance, the particle yields, N_i^{SM} , total energy, E_i^{SM} , and pressure, P^{SM} , are calculated within the SM via the Gibbs distribution function

$$f_i(p, m_i) \propto \exp\left(-\sqrt{p^2 + m_i^2}/T + \mu_i/T\right), \quad (4)$$

where p and m_i are the momentum and the mass of the hadron species i , respectively. Namely,

$$N_i^{\text{SM}} = \frac{V g_i}{(2\pi\hbar)^3} \int f(p, m_i) d^3p, \quad (5)$$

$$E_i^{\text{SM}} = \frac{V g_i}{(2\pi\hbar)^3} \int (p^2 + m_i^2)^{1/2} f(p, m_i) d^3p, \quad (6)$$

$$P^{\text{SM}} = \sum_i \frac{g_i}{(2\pi\hbar)^3} \int \frac{p^2}{3(p^2 + m_i^2)^{1/2}} f(p, m_i) d^3p, \quad (7)$$

with g_i being the degeneracy factor. The entropy density $s = S/V$ can be determined either via the distribution function (4)

$$s = - \sum_i \frac{g_i}{(2\pi\hbar)^3} \int_0^\infty f(p, m_i) [\ln f(p, m_i) - 1] d^3p, \quad (8)$$

or directly from Gibbs thermodynamical identity

$$Ts = \varepsilon + P^{\text{SM}} - \mu_B \rho_B - \mu_S \rho_S. \quad (9)$$

The chemical potential μ_i of the i th hadron is determined by its baryon and strangeness charge, $\mu_i = \mu_B B_i + \mu_S S_i$. Thermal and chemical equilibrium is assumed to occur in the cell when the spectra of hadrons in the microscopic cell calculations become close to the spectra predicted by the SM.

IV. RELAXATION TO CHEMICAL AND THERMAL EQUILIBRIUM

At the isotropic stage the total microscopic pressure is close to the grand canonical pressure, P^{SM} , as shown in Fig. 2(a). Both pressures converge at about $t = 5$ fm/ c , which is chosen as a starting point for the comparison with the SM. The input, $\{\varepsilon, \rho_B, \rho_S\}$, and output, $\{T, \mu_B, \mu_S\}$, parameters are listed in Table I together with the microscopic pressure, entropy density, and entropy per baryon in the cell. The final time of the calculation, defined from conventional freeze-out conditions $\varepsilon \approx 0.1$ GeV/fm³ or $\rho_{tot} \approx 0.5\rho_0$ [21], corresponds to $t = 20 - 21$ fm/ c . One may see that in spite of different initial conditions the freeze-out time in the central cell in heavy-ion collisions at RHIC energies is similar to corresponding freeze-out times at AGS [20] and SPS [21] energies. In accordance with general estimates [8,26] the baryochemical potential at RHIC energies is small while the temperatures are well above the anticipated temperature for the QCD phase transition, $T \approx 160 \pm 10$ MeV. The entropy per baryon in the cell varies slightly after the beginning of the kinetic equilibrium stage. A comparison with s/ρ_B at lower energies is shown in Fig. 2(b). The hadron-string matter in the central cell seems to expand isentropically with $s/\rho_B \equiv S/A \approx 12$ (AGS), 32 (SPS), and 150 (RHIC). Note that the results of the simulations at AGS and SPS energies are intriguingly close to the entropy per baryon values extracted from the thermal model fit to experimental data, namely, $(S/A)^{\text{AGS}} \approx 14$ and $(S/A)^{\text{SPS}} \approx 36$ [8]. It is most interesting to compare the predicted value $(s/\rho_B)^{\text{RHIC}} = 150 - 170$ to the upcoming RHIC data. Together, isotropy in the pressure sector, isotropic and nearly Maxwellian velocity distributions of hadrons, and almost isentropic expansion of matter in the central cell strongly support the idea that a hydrodynamic regime is established after a certain time. In the following, we extract the equation of state (EOS) of hadron-resonance-string matter from the microscopic simulations at the quasi-equilibrium stage of nuclear collisions, which is part of this hydrodynamic picture.

The evolution of the pressure with the energy density is depicted in Fig. 3(a) for AGS, SPS, and RHIC energies in the central cell, respectively. Several interesting facts can be gained from this figure. First, the pressure drops linearly with the decreasing energy density for all three energies. It means that the ratio P/ε remains constant for the whole time interval of the (quasi)equilibrium stage. Thus the equation of state in the (P, ε) plane has a

very simple form: $P = 0.12 \varepsilon$ at AGS, and $P = 0.15 \varepsilon$ at SPS and RHIC. We see that despite the significant difference in the center-of-mass energy of the nuclei, colliding at $\sqrt{s} = 17A$ GeV vs. $\sqrt{s} = 200A$ GeV, the ratio P/ε in the central cell is saturated already at SPS energies.

Figure 3(b) presents the evolution of the EOS in the (T, μ_B) plane. The baryon chemical potential in the cell increases with decreasing temperature at AGS and SPS energies, but remains almost constant (and small) at RHIC. Also, all three curves can be well approximated by a simple linear dependence. This fact deserves explanation. Substituting $P = a\varepsilon$ in Eq. (9) and omitting the term $\mu_S \rho_S$, because the net strangeness density in the cell is quite small, we get

$$T \frac{s}{\rho_B} = \frac{\varepsilon(1+a)}{\rho_B} - \mu_B . \quad (10)$$

If the ratio ε/ρ_B is constant, then the temperature T would depend linearly only on the baryon chemical potential μ_B , and vice versa. However, the energy per baryon slightly decreases within the considered time interval for all three energies. At the final stage it drops to approximately 80-90% of its initial value. Therefore, from Fig. 3(b) it follows that the evolution of temperature as a function of ε/ρ_B and μ_B is mainly determined by the change of energy per baryon, and not the baryon chemical potential.

Energy spectra, $dN/(4\pi p E dE)$, of π 's, N 's, Λ 's, Δ 's and K 's in the cell at the stage of kinetic equilibrium are shown in Fig. 4 at two different times, $t = 5$ fm/c and $t = 10$ fm/c at RHIC energies. At $t = 5$ fm/c the spectra of baryons seem to be in a reasonable agreement with those of the SM, while the slopes of the meson spectra are steeper compared to the predictions of the statistical model. This means, that the apparent temperatures of mesons, especially pions, are lower than the temperature given by the SM. Moreover, the energy spectra of pions can be decomposed on two components representing low and high energy pions. At $t = 5$ fm/c the fit by two exponents to the pion spectrum yields the temperatures $T_{low}^\pi \approx 114$ MeV and $T_{high}^\pi \approx 158$ MeV, while at $t = 10$ fm/c the results of the fit are $T_{low}^\pi \approx 100$ MeV and $T_{high}^\pi \approx 150$ MeV, respectively. Although the apparent temperature of pions from the high energy tail of the energy spectrum is closer to the temperature given by the SM, $T_{t=10}^{SM} = 171$ MeV, one may conclude that the thermal equilibrium in the central cell is not reached yet. The slopes of baryon spectra in the microscopic calculations at $t = 10$ fm/c are also steeper than the SM slope. Since the energy density ε is the same in both models, the lower temperatures of hadronic spectra in the microscopic case indicate that the hot matter in the cell is not in chemical equilibrium. Therefore, one might expect that the fractions of mesons and resonances in the UrQMD cell are overpopulated. These extra-particles consume significant part of the total energy and effectively "cool" the hadron cocktail. The reheating proceeds via the absorption of mesons in the processes like $\pi\pi \rightarrow \rho$, $\rho\rho \rightarrow \pi\pi$, or $\pi N \rightarrow \Delta$, $\Delta N \rightarrow NN$, etc. Thus, our next step is to study the time evolution of hadron abundances in the cell. Note also that the difference between the temperatures of meson and baryon spectra can be explained by the fact that baryons experience many more elastic collisions and interactions with the resonance production per particle, which drive the system toward thermal equilibrium, than mesons. The mean number of interactions per, e.g., nucleon or delta increases from 5 interactions at $t = 5$ fm/c to 10 interactions at $t = 10$ fm/c. In contrast, pions (kaons), which are readily absorbed and produced by the

resonance-string hadron matter, suffer only 0.5 (1) elastic collision per particle at $t = 5$ fm/ c and 1.8 (2.5) ones at $t = 10$ fm/ c .

Figure 5 depicts the yields of the main hadron species in the cell within the time interval $5 \text{ fm}/c \leq t \leq 19 \text{ fm}/c$. It is interesting that microscopic spectra of pions, which are underestimated by the SM in the central cell at lower energies [21], converge to the SM predictions at $t \approx 15 \text{ fm}/c$. Also, the statistical model overestimates yields of nucleons, lambdas, and kaons, while the yields of both baryon and meson resonances are reproduced quite well. Since the baryon number and the strangeness are conserved in strong interactions, where is the rest of the hypercharge, $Y = B + S$, in the UrQMD calculations in the cell? As seen from Table II, where the partial densities of baryons R_B and antibaryons $R_{\bar{B}}$ in the microscopic and macroscopic model are listed (the net values $\rho_B \equiv R_B - R_{\bar{B}}$ are listed in Table I), the total yields of baryons and antibaryons in the SM are larger than those of the UrQMD. The hadron-resonance-string matter in the cell is not in chemical equilibrium; that is why the density of antibaryons is 2-3 times smaller than the equilibrium values. The results on strangeness densities are listed in Table III for the strange baryons, mesons, and their antiparticles, respectively. Here the net strangeness is $\rho_S \equiv R_S^B + R_{\bar{S}}^B + R_S^M + R_{\bar{S}}^M$. In line with the previous observation, the SM predicts significantly larger abundances of both strange baryons and strange antibaryons at $5 \leq t \leq 11 \text{ fm}/c$ in the cell, while the densities of strange mesons are pretty similar. It is worth noting here that strangeness is underpredicted by the UrQMD if compared to experimental data at SPS energies, see [27]. At $t \approx 12 \text{ fm}/c$ the situation turns around: microscopic yields of strange baryons become closer to those of the SM, but the predictions for strange mesons diverge. Note also that up to $t = 13 \text{ fm}/c$ the net strangeness of baryons in microscopic calculations is larger compared to the net strangeness of baryons in the SM at the expense of the net mesonic strangeness. After $t = 13 \text{ fm}/c$ the fractions of the net strangeness deposited in baryonic and mesonic sectors in the microscopic calculations coincide with the SM results.

Finally, the ratios of hadronic abundances are studied (see Fig. 6). Here the results are presented separately for non-strange and strange baryons and mesons. In the baryon sector the resonances dominate over the strange and non-strange baryons until the end of the simulations. This can be taken as an indication of the creation of long-lived resonance-rich matter. Recall that the formation of resonance abundant matter plays an important role in the evolution of the system produced in nuclear collisions at lower bombarding energies [28]. It has been suggested that the significance of the resonances, mainly Δ 's, for the system development should be diminished with rising center-of-mass energy of the collisions. This assumption is not confirmed in our simulations. The fraction of baryon resonances is almost 70% of all baryons in the cell at RHIC at $5 \leq t \leq 19 \text{ fm}/c$, while at SPS and AGS the number of baryon resonances decreases from 70% to 35%, and from 60% to 25%, respectively. The meson fractions of resonances shrink within the time interval $5 \leq t \leq 19 \text{ fm}/c$ from 60% to 30% (RHIC), 50% to 20% (SPS), and 40% to 15% (AGS). But at RHIC energies the hot hadronic matter in the cell as well as in the whole volume of the reaction is meson dominated. The mesons, baryons, and antibaryons carry 90%, 7%, and 3% of the total number of particles in the RHIC cell at $t \geq 10 \text{ fm}/c$ (cf. 85%, 14.5%, 0.5% at SPS and 50%, 50%, 0% at AGS). The microscopic ratios for mesons (Fig. 6, right panels) seem to be very close to the SM ratios. However, one has to keep in mind that the temperatures given by the SM fit are 40-50 MeV higher than the apparent temperatures of meson species. Since the

freeze-out occurs at $t \approx 21$ fm/ c in the central cell at RHIC energies, the matter in the cell is frozen before reaching thermal and chemical equilibrium. This circumstance significantly complicates the extraction of the chemical and thermal freeze-out parameters by means of the standard thermal model fit.

But can the formation of the resonance-abundant matter be traced experimentally? To answer this question the rapidity distributions of baryon resonances are plotted in Fig. 7 for central ($b = 3$ fm) Pb+Pb collisions at $E_{lab} = 160A$ GeV and Au+Au collisions at $\sqrt{s} = 200A$ GeV, respectively. (The UrQMD predictions for other global observables at RHIC energies can be found in [29]). Here only those resonances that decay into ground state hadrons, i.e. no final state interactions, have been accounted for. The rapidity distributions of baryon resonances at SPS energies have a characteristic Gaussian-like shape, while the dN/dy distributions of those at RHIC energies are nearly flat in the rapidity interval $|y| \leq 3.5$ resembling the Bjorken scaling picture of nuclear matter expansion at ultra-relativistic energies [3]. More than 80% of the baryon non-strange resonances at RHIC energies are still Δ 's (1232). One can see that the density of directly reconstructible baryon resonances, especially Δ 's and Λ 's + Σ 's, per unit rapidity at RHIC energies is quite high. Therefore, the resonance-rich hadron matter produced in central Au+Au collisions at $\sqrt{s} = 200A$ GeV can be detected.

V. CONCLUSIONS

In summary, the microscopic transport model UrQMD is applied to study the equation of state of the hot meson-dominated hadron-string matter produced in the central cell ($V = 125$ fm³) of Au+Au collisions at $\sqrt{s} = 200A$ GeV. After the restoration of the isotropy of pressure gradients, the hadron spectra in the cell are compared with those of the statistical model of an ideal hadron gas. It is found that the expansion of matter in central collisions proceeds with constant entropy per baryon ratio in the central cell, $S/A = s/\rho_B \cong 150$. Since the S/A ratios for the central cell in A+A collisions, calculated at AGS and SPS energies, are very close to the ratios extracted from the analysis of the experimental data, the expected value of the entropy per baryon ratio at RHIC lies within the range $150 \leq s/\rho_B \leq 170$. The microscopic pressure in the cell is also close to the SM pressure. It shows a linear dependence on the energy density in the cell, $P = 0.15 \varepsilon$, which is similar to the $P(\varepsilon)$ dependence in the central cell at SPS energies [21]. The obtained result is in accord with the EOS $P \cong 0.2 \varepsilon$, derived for an ideal gas of hadrons and hadron resonances [30]. The temperature T^{SM} in the cell at RHIC energies is shown to be nearly independent of the baryon chemical potential μ_B .

The further comparison of the energy spectra and yields of hadrons with the SM predictions shows that the full thermal and chemical equilibrium is not reached even at the late stage of the reaction. This means that the times $t \approx 20$ fm/ c may be too short for the relaxation process. Particularly, the deceleration of the relaxation to equilibrium is attributed to the creation of the long-lived resonance-abundant matter. For instance, pions which are frequently absorbed and produced in various inelastic processes, including formation and decay of resonances, experience on average only two elastic collisions per particle. This appears to be insufficient to reach thermal equilibrium in the system of strongly interacting particles. In turn, inelastic collisions try to restore chemical equilibrium in the cell. Non-equilibrium

densities of strange and non-strange baryons, like N 's, Λ 's, Σ 's, etc, and their antiparticles are still lower than the equilibrium values. Amazingly, the yields of resonances are in accord with the SM values from the very early times $t \approx 5 \text{ fm}/c$. Even the abundances of pions are equalizing after $t \geq 15 \text{ fm}/c$. However, this result should be taken with a grain of salt. The fitting temperature of the thermal model is higher than the inverse slope parameters of the energy spectra of particles in the cell, i.e., the temperature of the chemical freeze-out will be overestimated by the SM fit.

According to microscopic calculations, resonance-rich matter survives until the thermal freeze-out when the contact between the hadrons is lost. It remains a challenging task to verify the formation of long-lived resonance-abundant matter in heavy-ion collisions at $\sqrt{s} = 200A \text{ GeV}$ experimentally.

FIGURES

FIG. 1. Time evolution of the velocities of longitudinal (solid lines) and transverse (dashed lines) flows of baryons (left panels) and mesons (right panels) in an asymmetric cell $0 \leq \{x, y, z\} \leq 2.5$ fm of central heavy-ion collisions at $E_{lab} = 10.7$ AGeV (upper row), $E_{lab} = 160$ AGeV (middle row), and $\sqrt{s} = 200$ A GeV (bottom row), respectively. Arrows indicate the times t_{cr} needed for Lorentz-contracted nuclei to pass through each other.

FIG. 2. (a) The longitudinal (solid lines) and the transverse (dashed lines) diagonal components of the pressure tensor P in the central cell of heavy-ion collisions at AGS, SPS, and RHIC energies compared to the SM results (dotted lines).

(b) Time evolution of the entropy per baryon ratio, $s/\rho_B = S/A$, in the central cell with $V = 125 \text{ fm}^3$ in heavy-ion collisions at AGS, SPS, and RHIC energies, respectively. Solid lines denote microscopic calculations with the UrQMD model, dashed lines show the predictions of the statistical model.

(b)

FIG. 3. (a) The evolution of pressure P and baryon density ϵ in the central cells of the heavy-ion collisions at AGS, SPS, and RHIC energies. (b) The same as (a) but for the (T, μ_B) -plane. Solid symbols correspond to the stage of kinetic equilibrium, open symbols indicate the preequilibrium stage. The hatched area shows the expected region of the quark-hadron phase transition.

(b)

FIG. 4. Energy spectra of N (circles), Λ (squares), π (triangles up), K^+ (open stars), K^- (triangles down) and Δ (solid stars) in the central cell of Au+Au collisions at RHIC at $t = 5 \text{ fm}/c$ (upper panel) and $t = 10 \text{ fm}/c$ (bottom panel). Dashed lines show the predictions of the SM.

FIG. 5. The yields of main hadron species in the central cell of Au+Au collisions at $\sqrt{s} = 200A$ GeV as a function of time as obtained in the model UrQMD (circles) together with the predictions of the SM (stars).

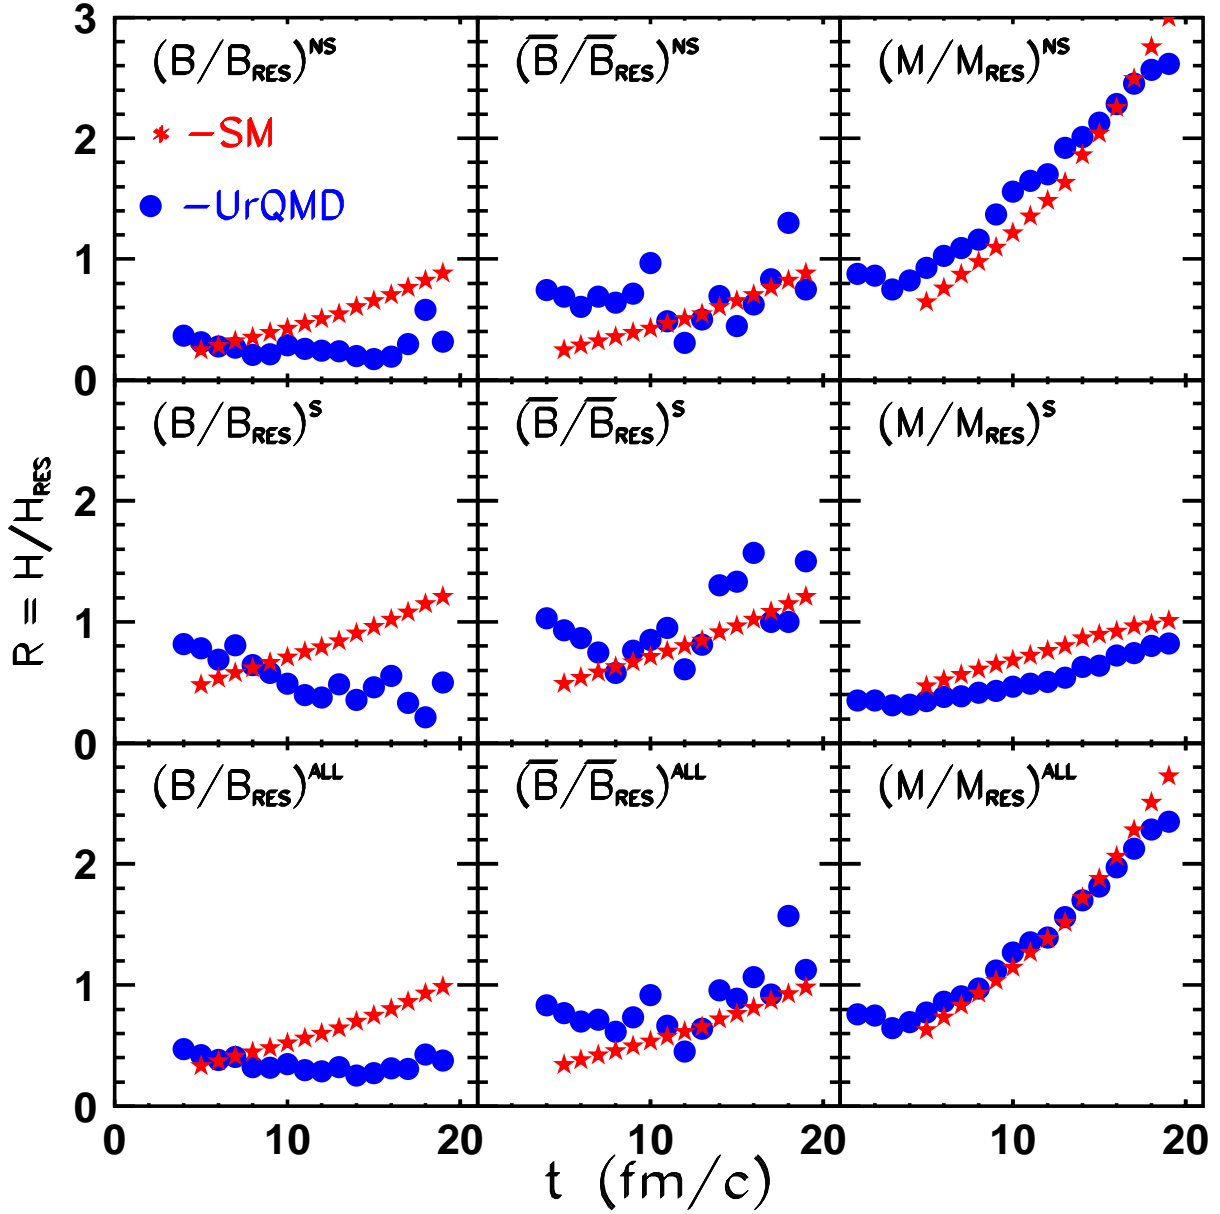

FIG. 6. Time evolution of the hadron to resonance ratio $R = H/H_{res}$ in the central cell of Au+Au collisions at RHIC shown separately for baryons (left panels), antibaryons (middle panels), and mesons (right panels), as well as for non-strange hadrons (upper row), strange hadrons (middle row), and total hadron yields (bottom row). Circles denote the UrQMD predictions, stars correspond to the SM results.

FIG. 7. The rapidity distributions of baryon resonances in Pb+Pb collisions at $E_{lab} = 160A$ GeV (left panel) and in Au+Au collisions at $\sqrt{s} = 200A$ GeV (right panel). Collisions are calculated in the UrQMD with the impact parameter $b = 3$ fm.

TABLES

TABLE I. The time evolution of the thermodynamic characteristics of hadronic matter in the central cell of volume $V = 125 \text{ fm}^3$ in central Au+Au collisions at RHIC ($\sqrt{s} = 200A \text{ GeV}$) energy. The temperature T , baryon chemical potential μ_B , strange chemical potential μ_S , pressure P , entropy density s , and entropy density per baryon density s/ρ_B , are extracted from the statistical model of an ideal hadron gas, using the microscopically evaluated energy density $\varepsilon^{\text{cell}}$, baryonic density ρ_B^{cell} , and strangeness density ρ_S^{cell} as input.

time fm/c	$\varepsilon^{\text{cell}}$ MeV/fm ³	ρ_B^{cell} fm ⁻³	ρ_S^{cell} fm ⁻³	T MeV	μ_B MeV	μ_S MeV	P MeV/fm ³	s fm ⁻³	s/ρ_B^{cell}
