New insights into the genetic diversity of *Schistosoma mansoni* and *S. haematobium* in Yemen

Hany Sady^{1,2}, Hesham M. Al-Mekhlafi^{1,3,4*}, Bonnie L. Webster^{5*}, Romano Ngui¹, Wahib M. Atroosh¹, Ahmed K. Al-Delaimy¹, Nabil A. Nasr¹, Kek Heng Chua⁶, Yvonne A. L. Lim¹ and Johari Surin¹

Abstract

Background: Human schistosomiasis is a neglected tropical disease of great importance that remains highly prevalent in Yemen, especially amongst rural communities. In order to investigate the genetic diversity of human *Schistosoma* species, a DNA barcoding study was conducted on *S. mansoni* and *S. haematobium* in Yemen.

Methods: A cross-sectional study was conducted to collect urine and faecal samples from 400 children from five provinces in Yemen. The samples were examined for the presence of *Schistosoma* eggs. A partial fragment of the schistosome *cox1* mitochondrial gene was analysed from each individual sample to evaluate the genetic diversity of the *S. mansoni* and *S. haematobium* infections. The data was also analysed together with previous published *cox1* data for *S. mansoni* and *S. haematobium* from Africa and the Indian Ocean Islands.

Results: Overall, 31.8 % of participants were found to be excreting schistosome eggs in either the urine or faeces (8.0 % *S. mansoni* and 22.5 % *S. haematobium*). Nineteen unique haplotypes of *S. mansoni* were detected and split into four lineages. Furthermore, nine unique haplotypes of *S. haematobium* were identified that could be split into two distinct groups.

Conclusion: This study provides novel and interesting insights into the population diversity and structure of *S. mansoni* and *S. haematobium* in Yemen. The data adds to our understanding of the evolutionary history and phylogeography of these devastating parasites whilst the genetic information could support the control and monitoring of urogenital and intestinal schistosomiasis in these endemic areas.

Keywords: *Schistosoma mansoni*, *Schistosoma haematobium*, Neglected tropical diseases, Molecular epidemiology, DNA barcoding, Genetic diversity, Evolution, Yemen

Background

Schistosomiasis is one of the most prevalent neglected tropical diseases (NTDs) in the tropics and subtropics, where it is endemic in 76 countries. It is estimated that 240 million people are infected, 85 % of which reside in Africa, with nearly 700 million people estimated to be at risk of infection [1–3]. Three *Schistosoma* species, namely *Schistosoma mansoni*, *S. haematobium* and *S. japonicum* are considered medically important to humans because of

their high prevalence rates, pathogenicity and vast distribution [2, 4]. Praziquantel (PZQ) continues to be the drug of choice in terms of controlling the disease in areas with high schistosomiasis morbidity [3, 5]. However, the parasites response to the drug requires suitable monitoring as part of current mass drug administration (MDA) programmes [6].

Pathogen genetic diversity can be affected by many factors, including environmental influence, host immunity and the large-scale administration of treatment [7–14]. High genetic diversity in a parasite population may contribute to the development of drug resistant species and thus cause the emergence of unsusceptible genotypes, although such a correlation is still considered to be

somehow controversial [15]. Several studies have investigated the systematics, genetic diversity and structure of *Schistosoma* species by analysis of the mitochondrial (mt) cytochrome oxidase subunit I (*cox1*) gene [15–20].

Globally, partial *cox1* analysis of *S. mansoni* isolates has shown a geographical separation into five main groups or lineages, with the most extensive genetic diversity being found in the old world, particularly in East Africa [15, 21]. In contrast partial *cox1* molecular data of *S. haematobium* showed extremely low levels of genetic diversity within and between *S. haematobium* populations and divided them into two distinct groups; Group 1 was centred around a highly common, persistent and widespread mainland African haplotype (H1) and Group 2 was more diverse and unique to the Indian Ocean Islands [19, 22].

Yemen has been reported to have the highest prevalence of *S. mansoni* and *S. haematobium* in Middle Eastern regions [23]. Despite sustained efforts to control the disease, recent studies have shown a high rate of infection among children in rural areas, whilst also identifying previously unknown transmission foci [24–28]. Despite numerous epidemiological studies on schistosomes in Yemen, molecular analysis of the *S. haematobium* and *S. mansoni* populations has not yet been done. This study was conducted in order to investigate the *mtcox1* variation of human *Schistosoma* species in Yemen, enabling a better understanding of the genetic diversity and molecular epidemiology of human schistosome in Yemen and the relationship with other geographical populations.

Methods

Ethical statement

This study was conducted in Yemen between January and July 2012, after receiving approval from the Medical Ethics Committee of the University of Malaya Medical Centre (Ref. no: 968.4). The study protocol was also approved by the Yemen National Schistosomiasis Control Program (NSCP), the Ministry of Health and Population, as well as Hodeidah University, Yemen.

The parents or guardians and their children were met in their villages where they were invited to participate in this study. A clear explanation of the study's objectives and methods were given prior to data collection, with written signed or thumb-printed (for those who are illiterate) consent having been obtained from the parents on behalf of their children, and these procedures were approved by the Medical Ethics Committee of the University of Malaya Medical Centre. The children and their parents were informed that they could withdraw from the study at any stage without any consequences and without citing reasons for doing so.

Each participant who confirmed to be infected with schistosomiasis was treated with a single dose of 40 mg/kg body weight of PZQ under observation of the

researcher and participating medical officer (Direct Observed Therapy).

Study design, area and population

An exploratory, cross sectional study was carried out among a cohort of children aged ≤ 15 years, all of whom were living in rural communities in Yemen. Data were collected in a period of 7 months from January to July 2012. Overall, 250 households were randomly selected from 20 villages in Taiz, Ibb, Dhamar, Sana'a and Hodiedah provinces. In each province, two rural districts were randomly selected from the available district list and then two villages within the selected districts were considered in collaboration with the Schistosomiasis Control Project office in each province (Fig. 1). The districts were Mosa and Almafer (Taiz), Alsabrah and Alodien (Ibb), Otmah and Gabal al sharq (Dhamar), Alhemah and Manakhah (Sana'a), and Gabal Ras and Bora (Hodiedah). The five provinces are well known as being endemically plagued with both urinary and intestinal schistosomiasis based on information gathered by the Yemen National Schistosomiasis Control Program (NSCP). Of the 632 children who agreed to participate in this study, 400 children successfully submitted the required stool and urine specimens, gave their signed consent and completed the questionnaire (77 from Sana'a, 76 from Taiz, 69 from Ibb, 85 from Hodiedah and 93 from Dhamar).

A description of the study area and population details have been published previously [28].

Parasitological surveys

Faecal and urine samples were collected separately into individual clearly labelled 100 ml clean containers with wide mouths and screw-cap lids. The samples were collected between 10 am and 2 pm as this is the maximum egg excretion period that was reported by Gray et al. [29]. The containers were placed into zipped plastic bags before being transported (within 6 h of collection) in suitable cool boxes with a temperature of 4–6 °C for subsequent examination at the nearest health centre laboratory. The samples were further subjected to microscopic examination to identify the presence and intensity of schistosome eggs. For *S. mansoni* 1 g of each faecal sample was examined using formalin ether sedimentation and Kato-Katz techniques [30, 31]. *S. haematobium* urine samples were examined for haematuria using a dipstick test (Chuncheon, Korea), and then 10 mls of the urine samples were filtered using nucleopore membranes and the filtrate was examined for schistosome eggs [32]. For molecular analysis about 1 g of each stool sample was preserved in 70 % ethanol (DNA-friendly) before being refrigerated [33] and about 1 ml of sediment from each urine sample was preserved in 70 % ethanol before being refrigerated [34]. The preserved

gel stained with SYBR[®] Safe DNA (Invitrogen, Auckland, New Zealand).

DNA sequencing and *cox1* data analysis

PCR products were purified using the QIAquick Gel Extraction Kit (catalog. no. 28104; QIAGEN, Hilden, Germany) and sequenced in both directions using a dilution of the universal forward primer and the specific reverse primer that corresponded to the species specific amplicon size (375 bp for *S. mansoni*, 543 bp for *S. haematobium*). Amplicon sequences were run on an Applied Biosystems 3730XL DNA Analyzer (Applied Biosystems, USA) according to the manufacturer's instructions.

Purified PCR products from samples that showed mixed chromatograms within sequence data were cloned in the pGEM[®]-T Vector (Promega, USA) and amplified in *Escherichia coli* JM109 competent cells. Recombinant clones were selected from each specimen and screened by PCR. Minipreparations of plasmid DNA were done using the QIAprep Spin Miniprep kit (QIAGEN, USA). Three or four clones containing inserts of approximately the expected size were randomly selected for each sample and sequenced according to the method mentioned above.

Sequence Scanner v1.0 (<http://www.appliedbiosystems.com>) and BioEdit Sequence Alignment Editor Software

7.2.0 (<http://www.mbio.ncsu.edu>) were used to manually view, edit and remove any sequence ambiguities. Consensus sequences were aligned and any polymorphism between sequences was checked by visualisation of the original sequence chromatograms.

Using the Basic Local Alignment Search Tool (NCBI-BLAST), the consensus sequences were compared and queried to sequence information on the Genbank database to confirm the identity of the species (<http://blast.ncbi.nlm.nih.gov>). *S. mansoni* and *S. haematobium* sequences were grouped separately and aligned using Clustal W [37]. Any identical sequences were identified and grouped to form individual haplotypes. Individual haplotype sequences were then deposited in the Genbank (Genbank ID: 1783061) (accession numbers: KP294279-KP294306; Tables 1 and 2).

Population genetic analysis

Haplotype sequences of *S. mansoni* and *S. haematobium* were analysed using MEGA 5 (www.megasoftware.net). Neighbour-joining (NJ), maximum parsimony and minimum evolution algorithms using pair-wise distances calculated by the Kimura-2parameter (K2P) method [38], with a 1000 bootstrap value were used to investigate the relationships between the haplotypes [39]. Furthermore, a Maximum Likelihood (ML) analysis with 500 replicates was used to investigate the topology of the trees, prior

to a best model (HKY + G) being selected based on the ML in jModeltest 0.1.1 [40].

Haplotype analysis

Nucleotide divergence was calculated for the *S. mansoni* and *S. haematobium* haplotypes using the Juke-Cantor correction model in DnaSP V5.10 [41]. Reference sequences from Webster et al. [15, 19, 22] were also included in the analysis. This was done by alignment of the unique haplotypes consensus sequences of the present study with the indicated published reference sequences using BioEdit Sequence Alignment Editor Software, and then refined manually to fit with our sequences size (375 bp for *S. mansoni*, 543 bp for *S. haematobium*). A minimum spanning network was also generated in order to estimate genealogical relationships among haplotypes using TCS (<http://darwin.uvigo.es/software/tcs.html>) software.

Tests of selection

Selection and neutrality tests were conducted in DnaSP V5.10 to investigate any selection in our mitochondrial *cox1* data without deviating from natural selection using the McDonald-Kreitman and Tajima's tests.

Results

Prevalence of human schistosomiasis

Of the 400 participants, 127 (31.8 %) were egg-positive for schistosomiasis. Overall, 90 participants (22.5 %) had urogenital schistosomiasis, 32 (8.0 %) had intestinal schistosomiasis and 5 (1.3 %) were co-infected with both *S. haematobium* and *S. mansoni* (Table 3). The highest prevalence of schistosomiasis was reported in Hodiedah (37.6 %), followed by Taiz (36.8 %), whereas Dhamar had the lowest rate of prevalence (19.4 %). With regards to schistosome species, Hodiedah had the highest prevalence (36.5 %) of *S. haematobium* infection followed by Sana'a (33.8 %) while Ibb had the highest prevalence of *S. mansoni* infection (31.9 %). Data on the prevalence, distribution and risk factors of schistosomiasis among the participants has been published [28].

Of the 127 egg-positive samples, schistosome *cox1* amplicons and sequences were obtained from 31 stool and 78 urine samples (Table 3). Only *S. haematobium* specific (543 bp) amplicons were obtained from the urine samples and *S. mansoni* specific (375 bp) amplicons were obtained from the stool samples. On the other hand, 3 % of stools and 13 % of urines egg-positive

samples were PCR-negative. These were retested several times, but *cox1* amplification remained unsuccessful. Moreover, *Schistosoma* egg-negative samples were also PCR negative.

***Schistosoma mansoni* population genetics**

As the schistosome DNA was extracted and amplified from whole faecal samples the DNA sequences represented the genetic profile from a pooled *S. mansoni* population infecting each individual host. Mixed sequence chromatograms were observed at the polymorphic sites within the *mtcox1* region amplified, with the chromatograms giving the highest peak being recorded as the haplotype data. These haplotypes will therefore represent the most common haplotype found within the pooled population but observations of the mixed chromatograms within sequence data show that there are many more haplotypes that could not be clearly identified. Moreover, our selection was confirmed by cloning and sequencing of samples that showed mixed sequence chromatograms (5 *S. mansoni* and 2 *S. haematobium*). Among the five localities in Yemen, 19 unique *S. mansoni cox1* haplotypes were detected from 31 samples. Haplotype distribution varied by location and the highest diversity was observed in Ibb and Taiz (Table 4).

Figure 2 shows the minimum spanning TCS haplotype network for *S. mansoni*. The network consisted of four linked groups but these were not divided by location, therefore there was no population structure observed between different areas. At a geographical level, the minimum spanning TCS network of *S. mansoni* is shown in Fig. 3. The *S. mansoni* haplotypes from the Yemen provinces connected closely to 3 of the 6 geographical groups found by Webster et al. [15]. These haplotypes connected groups 4 (Coastal Kenya and Zambia), 5 (Zambia ZA2), and 2 (Nigeria, Niger and Central Africa) which were connected to Group 1 (Far West Africa, Egypt, Saudi Arabia and Oman). On the other hand, none of the Yemeni haplotypes occurred among Group 3 (East Africa) and Group 6 (Zambia ZA1). Haplotypes found within Ibb province had the highest diversity and were found in 3 of the groups and the Taiz province haplotype (Y7TSM) also provided another link with Group 1.

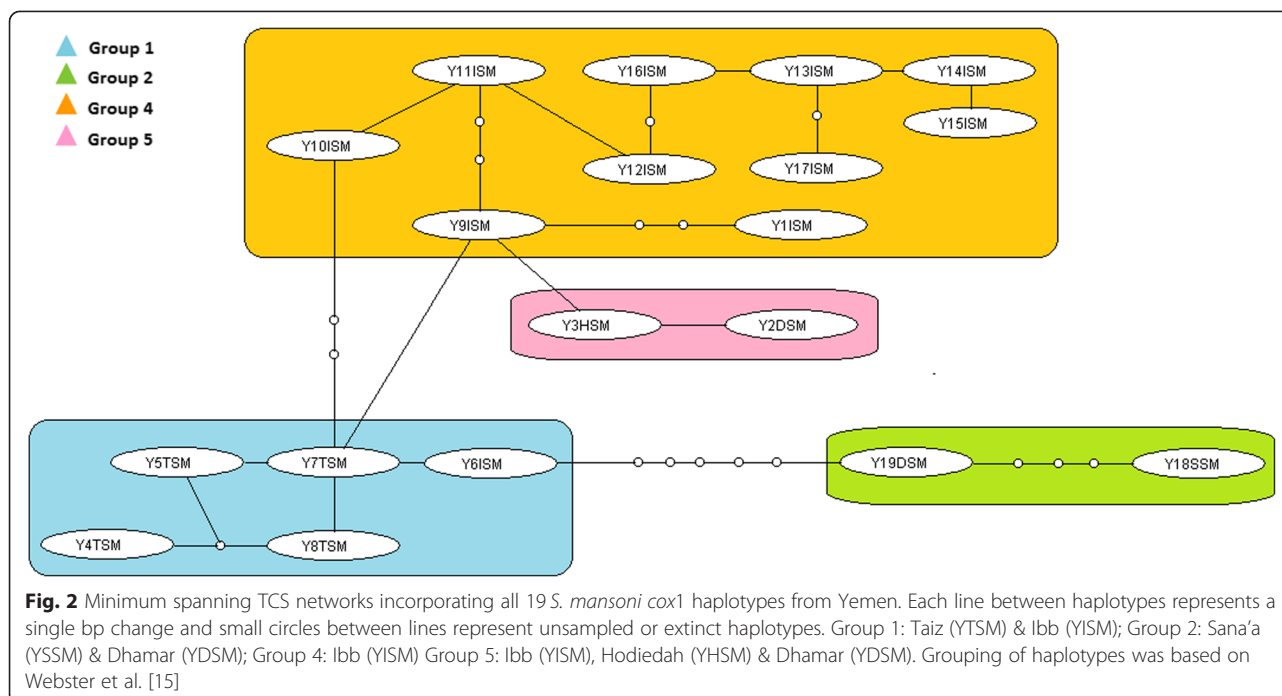

***Schistosoma mansoni* phylogenetic structuring**

The *S. mansoni* haplotypes clustered into four groups that correlated to the haplotype network groups, with a clear separation of group 2 from the rest of the haplotypes (Fig. 4). This was also highlighted in the net nucleotide divergence between the groups showing a

Table 4 *S. mansoni cox1* diversity

n = number of samples with that haplotype

relatively low genetic separation of the Ibb, Taiz and Hodiedah lineages (groups 1, 4 and 5) compared to the larger divergence found in the Sana'a and Dhamar lineages (Group 2) (Table 5).

Schistosoma haematobium population genetics

As the schistosome DNA was extracted and amplified from whole urine samples the DNA sequences represented the genetic profile from a pooled *S. haematobium* population infecting each individual host. Mixed sequence chromatograms were observed in only 2 of the sequences indicating that the haplotypes give a good representation of the diversity found within the *S. haematobium* populations. From the five provinces, 9 unique *S. haematobium cox1* haplotypes were detected within the 78 amplified samples. Diversity was low within and between localities and there was one dominant haplotype (Y2TDISH), which was detected in three out of the 5 provinces, namely Taiz, Dhamar and Ibb (Y2TSH, Y2DSH and Y2ISH), representing 29.5 % of the total haplotypes observed (Table 6). The rest of the haplotypes were unique for their location, with higher diversity being observed in Dhamar and Hodiedah.

Figure 5 shows the minimum spanning TCS network representing putative genealogy of the haplotypes at a locality level. The haplotypes divided into two groups. The first group (Group 1) was made up of 3 haplotypes all from Hodiedah while the second group (Group 2) was made up of 6 haplotypes from Taiz, Sana'a, Dhamar and Ibb. Both groups were linked via a long branch with several steps connecting the 2 haplotype groups. When

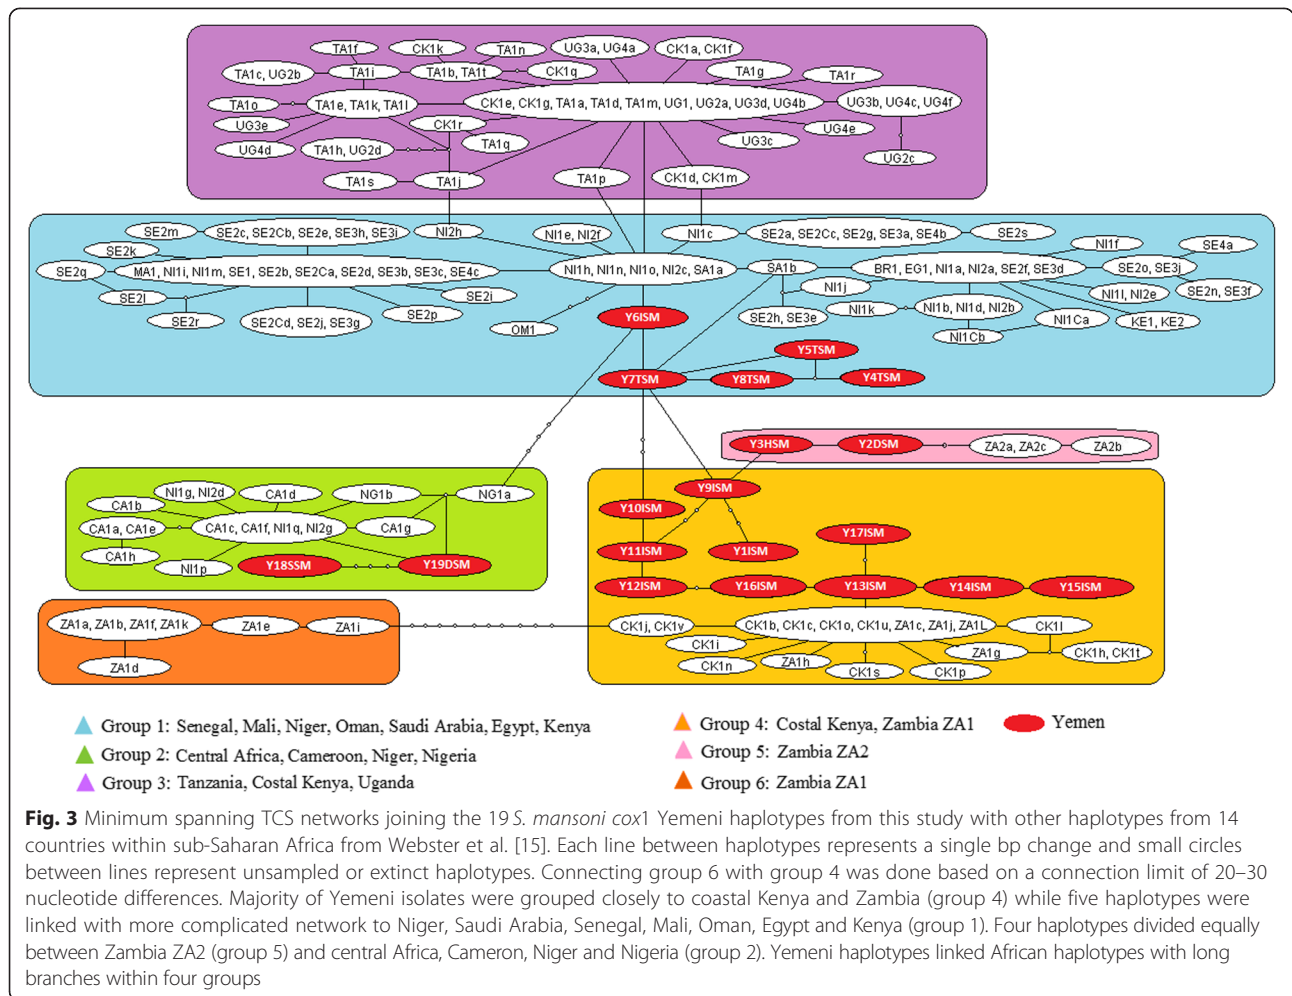

the Yemen haplotypes were analysed together with the *S. haematobium cox1* haplotype data from Webster et al. [22] the haplotypes were integrated into the 2 groups (Fig. 6). The most common haplotype found in Yemen grouped with the haplotypes found in Madagascar, Mauritius, Zanzibar and Coastal Kenya whilst 1 haplotype from Hodiedah matched the dominant mainland African haplotype H1. Five of the haplotypes from Yemen were also novel haplotypes which were not reported previously, 2 of which (Y1DSH and Y4HSH) actually formed a connection between the 2 groups.

Schistosoma haematobium phylogenetic structuring

The tree topology supported the clustering of the 9 Yemen haplotypes into the two *S. haematobium* groups with the predominant haplotype (Y2TDISH) clustering within Group 2 together with haplotypes from Taiz, Ibb, Dhamar and Sana'a provinces, whereas the haplotypes from Hodiedah clustered with the Group 1 (Fig. 7). The net nucleotide divergence 0.01621 ± 0.00500 between the two *S. haematobium* groups was low compared to that between *S. haematobium* and its sister taxa *S. bovis*. (Group 1: 0.13252 ± 0.04940 ; Group 2: 0.12605 ± 0.05946).

Neutrality and selection test

In this study a test for selection reinforced neutrality within the *cox1* mitochondrial data. Tajima's D test and McDonald-Kreitman test results showed that strong selection was not occurring in either *S. mansoni* (Tajima's $D = 0.702$; $P > 0.10$; Fisher's exact test $P = 0.978$) or *S.*

haematobium (Tajima's $D = 0.747$; $P > 0.10$; Fisher's exact test $P = 0.490$).

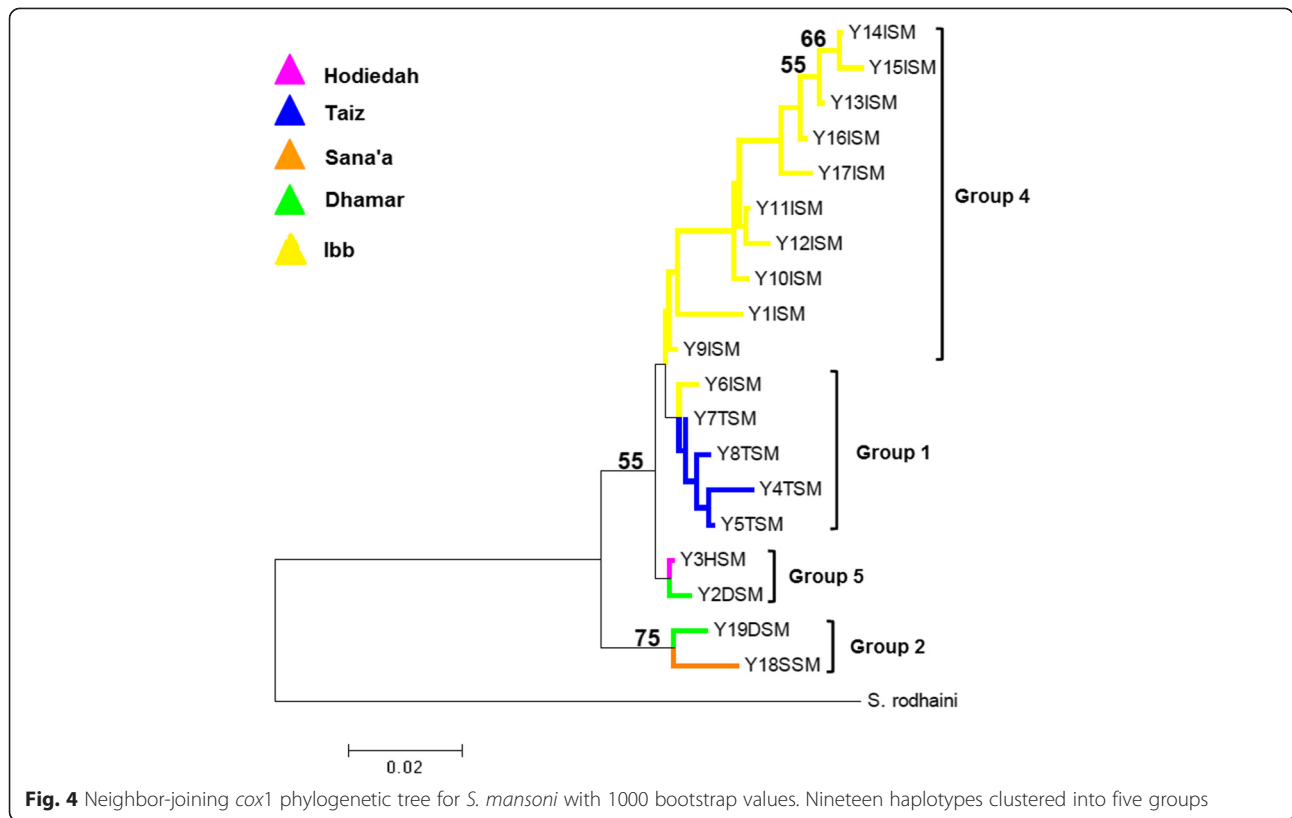

Discussion

Here we present the first genetic data on human *Schistosoma* species in Yemen. Schistosomiasis is still highly prevalent among children in rural Yemen [28] and 31.8 % of our cohort were infected with *Schistosoma* species. Out of these infected children, 122 (96.1 %) were found to be infected by either *S. mansoni* or *S. haematobium* while 5 (3.9 %) children were co-infected with both species. The overall prevalence was 23.8 % for *S. haematobium* and 9.3 % for *S. mansoni*. The highest overall prevalence of schistosomiasis was reported in Hodiedah province, followed by Taiz, while Dhamar had the lowest prevalence. Hodiedah had the highest prevalence of *S. haematobium*, while Ibb had the highest prevalence of *S. mansoni*.

We used conventional PCR to amplify the partial mt *cox1* DNA region of *S. haematobium* and *S. mansoni* DNA extracted from stool and urine samples. The

success rate using the PCR method to amplify *Schistosoma* DNA was 82.6 %, with some false negative reactions being attributed to errors in removing inhibitors from the samples. Moreover, additional processing required for the stool kit may also contribute to the low sensitivity of PCR when compared to microscopy. In the case of *S. haematobium*, this success rate was significantly associated with the number of eggs in the samples while no such association was found with *S. mansoni*.

From 31 *S. mansoni* PCR positive samples from 5 provinces, we obtained 19 unique and diverse haplotypes that divided into 4 lineages. These haplotypes give a good representation of *S. mansoni* diversity in Yemen however due to them being obtained from pooled samples there is more diversity yet to characterise. These 19 haplotypes integrated into groups 1, 2, 4 and 5 based on studies by Webster et al. [15] and Morgan et al. [21]. Of note, phylogenetic support was lower in some groups (1 and 4) when compared with previous reports. This may be due to the high number of haplotypes reported in this present study,

and because of the use of a smaller *cox1* DNA region (375 bp) being analysed in this study which decreases the number of parsimony informative positions. The larger the mt region used, the more haplotypes would be detected, but the geographic topologies of the data would remain the same [15]. Previous *cox1* analyses of *S. mansoni* samples from across Africa have detected a high degree of genetic diversity within and between hosts and localities. Morgan et al. [21] discovered 85 unique haplotypes split into five lineages within 53 geographically widespread localities and Webster et al. [15] discovered 120 unique haplotypes split into five distinct lineages from 54 countries across South America, Africa and the Arabian Peninsula. Although lower numbers of *S. mansoni* samples were analysed from Yemen, the genetic diversity among *S. mansoni* haplotypes remained high

strongly supporting the finding by Webster et al. [15] and Morgan et al. [21].

The TCS network and phylogenetic analysis show the high diversity of haplotypes that divided into 4 groups / lineages. The long connections between the main group (Group 1) and other groups were separated by nodes in the TCS network and were not represented by a detected genotype. This suggests that there are still more unsampled haplotypes within and between the provinces. TCS analysis showed that central nodes were connected with other haplotypes, creating star like assemblages to form ancestral haplotypes, which were extensively abundant and widely distributed as suggested by Webster et al. [15]. In the current study, the ancestral haplotypes were found in Taiz and Ibb provinces in which, perhaps, the parasites spread to other provinces. Moreover, the

n = number of samples that had the same haplotype. Y2TDISH is the common haplotype found between regions

highest genetic diversity was found among Ibb haplotypes, which were mostly distributed in Group 4, though Y6ISM was present in Group 1.

On the other hand, the genetic diversity of *S. mansoni* was found to be very low in Sana'a, Dhamar and Hodiedah probably attributed to the low prevalence of the *S.*

mansoni in these provinces. The only haplotype of Hodiedah, found within Group 5, was linked with Dhamar haplotypes. Likewise, Ibb haplotypes linked the main ancestral haplotypes from Taiz within Group 1 with haplotypes of other provinces that showed lower genetic diversity. This is probably due to Ibb province being geographically connected with Taiz, Hodiedah and Dhamar provinces. It is important to mention that among the Yemeni population, Taiz and Ibb populations have the highest migration rate of people moving either to other Yemen provinces or other countries. These would suggest that Taiz and Ibb provinces are likely to be the origin of *S. mansoni* in Yemen due to the high genetic diversity found within those areas.

The net divergence between the lineages revealed a relatively short time span between the genetic separation of the Taiz, Ibb and Hodiedah (1, 4 and 5) lineages when compared to the larger divergence of lineage 2 consisting of Sana'a and Dhamar isolates. Moreover, the phylogenetic analysis showed a strong bootstrap for lineage 4, which involved Sana'a and Dhamar haplotypes, via a long branch from lineage 1. That said, there has been a long time between the separation of the haplotypes of Sana'a and Dhamar from the rest of the *S. mansoni* population, with successive splitting of populations within Ibb haplotypes in lineage 5. This may be attributed to population, movement, which carried those haplotypes between provinces, starting from Taiz to Ibb, then to Dhamar and ending with Sana'a province.

The results of the present study were incorporated with the results of the previous large-scale studies conducted on isolates from across Africa and also from the Arabian Peninsula and the Neotropic ecozone [15, 19]. Interestingly, for *S. mansoni*, our findings show that Yemen has a higher genetic diversity than Tanzania,

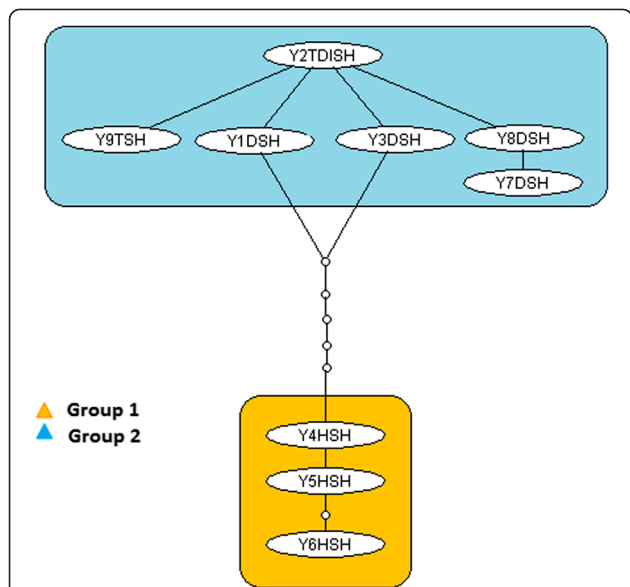

Fig. 5 Minimum spanning TCS networks incorporating all 9 *S. haematobium* *cox1* haplotypes from Yemen. Each line between haplotypes represents a single bp change and small circles between lines represent unsampled or extinct haplotypes. The network forms 2 groups of haplotypes linked together. Group 1 forms one branch containing only samples from Hodiedah (YHSH). Group 2 forms simple network containing Taiz (YTSH), Dhamar (YDSH), Sana'a (YSSH) and Ibb (YISH). The majority of the samples are closely clustered around the main haplotype (Y2TDISH) with separate single links representing a single polymorphic mutation

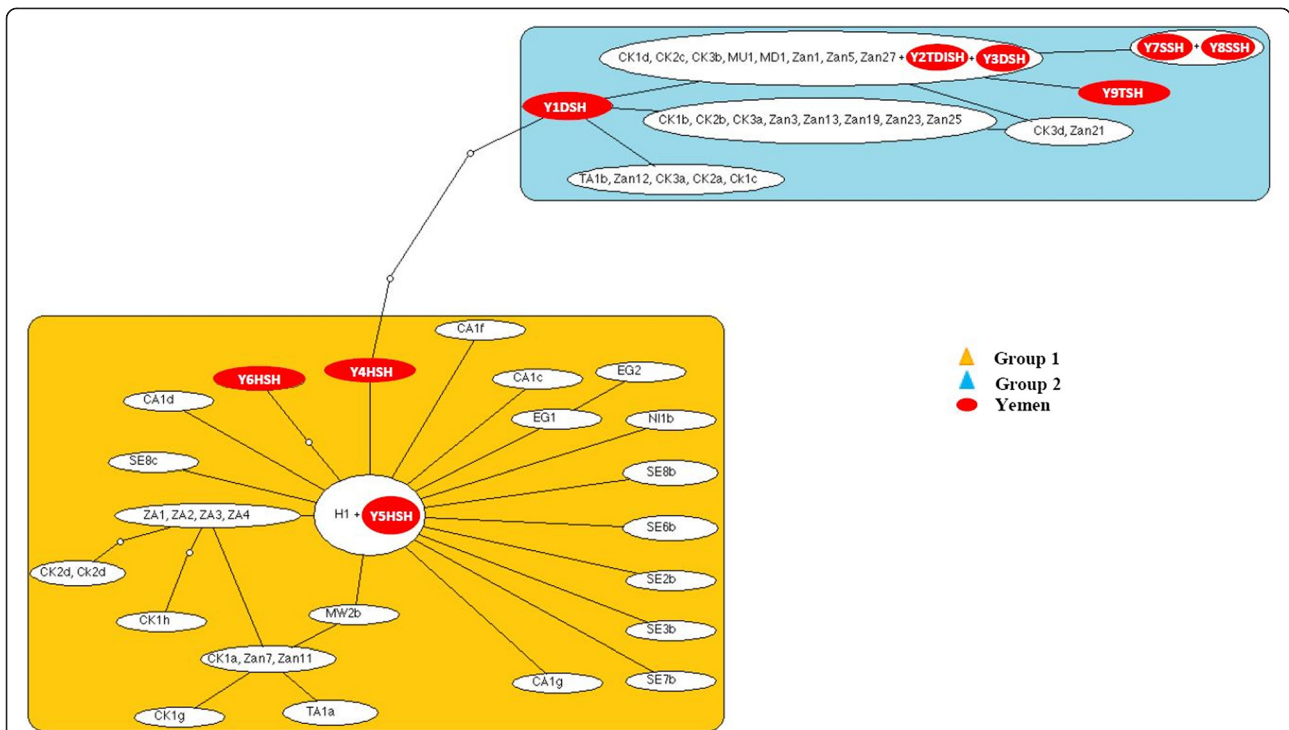

Fig. 6 Minimum spanning TCS networks joining the 9 *S. haematobium* cox1 Yemeni haplotypes by this study and 18 countries across Africa and the Indian Ocean Islands from by Webster et al. [15, 22]. Each line between haplotypes represents a single bp change and small circles between lines represent unsampled or extinct haplotypes. H1 involved haplotypes from SE1, SE2a, SE3a, SE4, SE5, SE6a, SE7a, SE8a, SE9, MA2, NI1a, NI2, LB1, GB1, NG1, CA1, CA1a, CA2, CA3, CA4, CA5, SU1, KE2, TA1a, MW1, MW2a, MW3 & Zan4. Hodiedah haplotypes were exclusively linked with group 1 and Y5HSH was found similar to H1. The rest of Yemeni haplotypes were grouped with coastal Kenya, Zanzibar, Tanzania, Mauritius & Madagascar. Y2TDISH include Y2DSH, Y2TSH & Y2ISH haplotypes (group 2). Yemeni haplotypes linked the two groups of African haplotypes with small branches

Zambia and Coastal Kenya, which suggests that *S. mansoni* was first introduced in East Africa before spreading to Central and West Africa with subsequent splitting of populations. This is in accordance with a previous postulation that African *S. mansoni* evolutionary origin was in East Africa [21]. However, these speculations need further investigation as historical human migrations

between Africa and Arabian Peninsula may have occurred continuously and reciprocally.

The regional TCS network for *S. mansoni* (Fig. 3) shows the isolates from Yemen may well bridge the gap between the African lineages. On the basis of this TCS network, one may speculate that Ibb haplotypes were probably introduced to Zambia and coastal Kenya (Group 4). On the

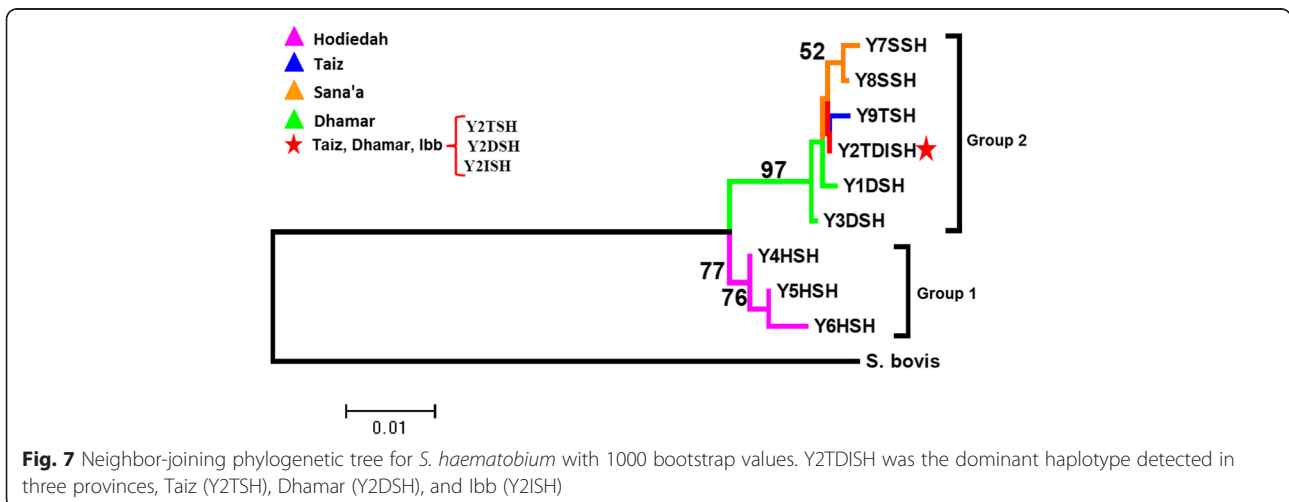

Fig. 7 Neighbor-joining phylogenetic tree for *S. haematobium* with 1000 bootstrap values. Y2TDISH was the dominant haplotype detected in three provinces, Taiz (Y2TSH), Dhamar (Y2DSH), and Ibb (Y2ISH)

other hand, other Ibb haplotypes (Group 1) were most probably moved to either Nigeria through a long branch to Central West Africa (Group 2), or Niger by a link to far West Africa (Group 1). In addition, Taiz haplotypes with a high genetic diversity were most properly moved to Saudi Arabia, which then links to both Brazil and Egypt.

With regard to *S. haematobium*, the present study shows that the genetic diversity of *S. haematobium* was low across Yemen, supporting the findings by Webster et al. [19] who revealed low levels of genetic diversity among 61 unique haplotypes from across Africa. In the 78 positive urine samples, we found only 9 unique haplotypes, which were divided into two groups. Group 2 involved 4 provinces, namely Sana'a, Taiz, Ibb and Dhamar, with Y2TDISH being the predominant haplotype. Whilst Group 1 exclusively involved haplotypes from Hodiedah. The net divergence between the two groups was similar to that previously reported in Webster et al. [19].

The TCS network shows that the predominant haplotype (Y2TDISH) was linked by a single bp change with other haplotypes from Taiz, Sana'a and two haplotypes from Dhamar, which connected Group 1 with Group 2. The majority of those haplotypes branched off from Y2TDISH by single mutations, although their clear links with other haplotypes suggest that they persist within the populations and disseminate from one area to another due to population movement. The network discovered around the predominant haplotype reflected the geographical links between the 4 provinces in Group 2, as well as the extensive movement of populations between those provinces. This TCS network suggests that Dhamar may be the origin of *S. haematobium* in Yemen, as this had the highest genetic diversity of all the provinces studied. However, this may need further investigation using more isolates including other provinces which were not included in the current study.

The divergence of the *S. haematobium* populations between the 2 groups might be affected by the compatibility with their intermediate snail hosts (*Bulinus spp.*), which are specific and varied according to geographical location [42, 43]. However, there have been no studies on the intermediate host of *S. haematobium* in Yemen, necessitating future research to elucidate the role of *Bulinus* species in the transmission of *S. haematobium* in Yemen.

The genetic diversity of *S. haematobium* in Yemen was considered high when compared with the low diversity across Africa, but not higher than the Indian Islands, and coastal Kenya regions [19]. The low genetic diversity reported across Africa was possibly attributed to a re-invasion by a small population of *S. haematobium* that originated as part of a larger population group from Asia across the Arabian Peninsula, with fast distribution and growth from East to West through Africa [19, 44]. Due to parasitic inbreeding, the worms are incompatible with

the new genetic flow across Africa. While the TCS network created by Webster et al. [19] formed two distinct groups of *S. haematobium* haplotypes that cannot be linked, the TCS network generated by the present study shows Yemen haplotypes bridging the gap and connecting both groups, namely Group 1 (mainland Africa with few haplotypes from Zanzibar) and Group 2 (the Indian Ocean islands and the neighbouring African coastal regions of coastal Kenya and Tanzania) (Fig. 6). However, this will be a direct affect of the smaller DNA region used in the analysis which reduces the polymorphisms between the groups bringing them genetically closer.

This highly associated haplotype network between Yemen and Africa may be explained by the numerous commercial Yemeni traders trips that took place when sailors were using the monsoon winds to sail across the Indian Ocean, at which time they landed at the sheltered harbour located on the site of present-day Zanzibar Town in Tanzania. Although the islands had few resources of interest to the traders, they offered a good location from which to make contact and trade with towns of the East African coast. Nowadays, population movement between Yemen and East Africa including Kenya, Tanzania and Ethiopia is still very active. Another factor could be the annual Islamic pilgrimage that involved the travelling of people from all over the world to the Arabian Peninsula, specifically to Mecca. Although Mecca has an arid climate, which does not favour the transmission of schistosomiasis, the pilgrims would often cross through Yemen and other northern parts of the peninsula where schistosomiasis was endemic.

This conjecture is supported by the discovery of the oldest ever urogenital *Schistosoma* egg in 6200-year-old human skeletal remains at a prehistoric town (Tell Zeidan) by the Euphrates river valley in northern Syria [45]. Moreover, modern genetic analysis suggests that the genus *Schistosoma* originally evolved in Asia and then spread to Africa [44]. There are a few theories on the origin of *Schistosoma*, with primary arguments being for both an African and Asian origin [46–48]. Davis [46] proposed that the genus *Schistosoma* arose before the separation of the super continent Gondwanaland more than 150 million years ago, with the earliest known archaeological examples coming from ancient Egyptian mummies and Syrian graves dated 5200 and 6500 years old respectively [45, 49].

In 2008, Yemen launched its first campaign to eliminate schistosomiasis as a national public health problem, with the aim of controlling schistosomiasis nationwide and eliminating its morbidity. This campaign was waged through repeated periodic (often yearly) distribution of PZQ to targeted population in schools and communities, together with the dissemination of health education messages on schistosomiasis [25]. Although PZQ has been used effectively for about three decades, the

reliance of schistosomiasis control programmes on PZQ only makes the control of this disease highly vulnerable to the emergence and spread of drug resistant strains [9]. This might be anticipated due to drug pressure leading to intensive and prolonged new selection pressures on the parasites, which may in turn affect the genotypic and phenotypic structure of a parasite population in a controlled setting resulting in a decline in diversity over time to a few persistent genotypes [50, 51]. Non-susceptible survival genotypes with reduction of diversity were reported in a laboratory population [51, 52] and also among travellers in Egypt, Senegal and Mali [8, 53–55]. Furthermore, previous experience with oxamniquinone, which was in wide use prior to the development and use of PZQ, revealed the ability of schistosome parasites to develop drug resistance under field conditions [56, 57]. Hence, evolutionary theory must play a role both in the monitoring, evaluation, and importantly in predicting the sustained impact of these control programmes.

Conclusion

The findings of the present study have brought new insight into the population genetics of human *Schistosoma* species across Yemen. In particular, the genetic diversity of *S. mansoni* was found to be high while *S. haematobium* showed low diversity. This data was obtained from pooled schistosome DNA from whole urine and stool samples. Therefore, by adapting the methods used by Webster et al. [19] which described obtaining the haplotype data from individual miracidia, the true extent of the diversity within and between *Schistosoma* populations can be fully assessed in future studies. Data compiled in order to identify genetic diversity as reported by this study, and in comparison with previous studies, may have a value in monitoring changes in schistosome populations over time, in response to control pressure and due to environmental changes or migration of hosts. The genetic analysis of more individual schistosome larval stages, together with investigations into intermediate host snails from different endemic areas in Yemen and other countries in the Arabian Peninsula, using other mitochondrial genes and microsatellite markers is still required in order to interpret the true genetic diversity, population movement and dynamics of transmission for *S. mansoni* and *S. haematobium* populations on a large scale.

The authors declare that they have no competing interests.

Authors' contributions

HMA, KHC and JS designed and supervised the study. HS conducted the sampling and field survey. HMA, BLW and HS analyzed and interpreted the data, and wrote the paper. WMA, RN, AKA and NAN were involved in the laboratory examination of samples. KHC, JS and YALL revised the manuscript. All authors approved the final version of the manuscript.

Acknowledgements

The authors would like to acknowledge the Yemen National Schistosomiasis Control Program offices (Taiz, Ibb, Dhahar, Sana'a and Hodeidah), Ministry of Health and Population, Yemen for their generous cooperation during this study. Thanks also are indebted to the parents and their children for their participation in this study. We also would like to thank Mr. Tom Pennance from the Natural History Museum, London for English editing. The work presented in this paper was funded by the University of Malaya High Impact Research Grant UM-MOHE UM.C/625/1/HIR/MOHE/MED/18 from the Ministry of Higher Education Malaysia, and also by the University of Malaya Research Grants; RG331-15AFR.
