## A B S T R A C T

Particle-resolved direct numerical simulations of a 3-D liquid–solid fluidized bed experimentally investigated by Aguilar-Corona (2008) have been performed at different fluidization velocities (corresponding to a range of bed solid volume fraction between 0.1 and 0.4), using Implicit Tensorial Penalty Method. Particle Reynolds number and Stokes number are  $O(100)$  and  $O(10)$ , respectively. In this paper, we compare the statistical quantities computed from numerical results with the experimental data obtained with 3-D trajectory and High Frequency PIV. Fluidization law predicted by the numerical simulations is in very good agreement with the experimental curve and the main features of trajectories and Lagrangian velocity signal of the particles are well reproduced by the simulations. The evolution of particle and flow velocity variances as a function of bed solid volume fraction is also well captured by the simulations. In particular, the numerical simulations predict the right level of anisotropy of the dispersed phase fluctuations and its independence of bed solid volume fraction. They also confirm the high value of the ratio between the fluid and the particle phase fluctuating kinetic energy. A quick analysis suggests that the fluid velocity fluctuations are mainly driven by fluid–particle wake interactions (pseudo-turbulence) whereas the particle velocity fluctuations derive essentially from the large scale flow motion (recirculation). Lagrangian autocorrelation function of particle fluctuating velocity exhibits large-scale oscillations, which are not observed in the corresponding experimental curves, a difference probably due to a statistical averaging effect. Evolution as a function of the bed solid volume fraction and the collision frequency based upon transverse component of particle kinetic energy correctly matches the experimental trend and is well fitted by a theoretical expression derived from Kinetic Theory of Granular Flows.

## 1. Introduction

Liquid fluidization is used in various industrial application involving biochemical, catalytic reactions and crystallization processes. The flow in a liquid fluidized bed lies within an intermediate regime between the settling of particles controlled by the hydrodynamic interactions and the rapid granular flow controlled by the collisions between particles, where the particle Reynolds number is in a range of  $O(100)$  and the particle Stokes number is in a range of  $O(10)$ , both based on particle settling velocity. In this sense, liquid fluidization is a challenging problem for two-phase

modeling. For practical applications, two-phase continuum models are generally used to carry out numerical simulations, based upon two-fluid or statistical models (Gevrin et al., 2008; Zhang et al., 2013). However, modeling of liquid–solid fluidization is still an open research topic and multi-scale modeling developments are still needed to correctly predict inter-particle and particle–fluid interactions. One major issue is to predict the right level of particulate and carrying flow phase fluctuations as a function of bed solid phase fraction (or fluidization velocity).

Resolved particle direct numerical simulations of particulate flows have been developing last two decades (see the review of Tenetti and Subramanian, 2014). These simulations can provide the particulate phase fluctuation characteristics in order to develop appropriate two-phase continuum models. Many of particle resolved simulations have been carried out on fixed structured grids to take

advantage of parallelization and avoid the complexity of mesh reconstruction.

Pan et al. (2002) carried out resolved simulations of fluidization of 1204 finite size spheres in a 2-D bed using the method of distributed Lagrange multipliers and as simulation results, the fluidization velocity versus fluid fraction was found to be a power law which exponent well compared with that predicted by the correlation of Richardson and Zaki (1954). Zhang et al. (2006) performed a 3-D fully resolved simulation of 1024 particles settling under gravity in a periodic domain accounting for elastic collisions of particles. Their method is based on a linearization of Navier-Stokes equations in the vicinity of particle interface (Zhang and Prosperetti, 2005). In their study, Particle Reynolds number was  $O(10 - 50)$  and the solid volume fraction equal to 10%. They have shown that the settling velocity was matching (Richardson and Zaki, 1954) correlation and evidenced the relation between the velocity fluctuations and particles micro-structuration. Bagchi and Balachandar (2003), Burton and Eaton (2005) and then Vreman (2016) used body-fitted methods to study turbulent homogeneous isotropic turbulence (steady or decaying in time) in the presence of fixed spheres of finite size compared to the smallest turbulent length scale.

Using a Lattice Boltzmann Method to solve the interstitial flow and an equation of motion accounting for lubrication and collisions between particles, Derksen and Sundaresan (2007) have simulated in limited size domains the propagation of concentration waves in liquid-solid fluidized beds with large bed solid fraction (close to maximum packing) and particle Reynolds number of order of  $O(10)$ . Their results were in qualitative agreement with an experimental study of Duru and Guazzelli (2002). Based on the same method, Derksen (2014) performed the simulation of the mixing of a passive scalar in a fluidized bed with periodical boundaries in a wide range of bed solid volume fraction (0.2–0.5) and particle Reynolds numbers of order 10. Derksen's results first show a good agreement with Richardson and Zaki (1954) exponent dependence with Reynolds number. Interestingly, Derksen (2014) showed that the diffusion of the passive scalar in the bed is similar to the auto-diffusion of particles, scaling of which is close to what was experimentally observed in sedimentation by Nicolai et al. (1995).

Uhlmann (2005) developed an Immersed Boundary Method to simulate the sedimentation of 1000 spherical finite particles at high Reynolds number (400) and highly dilute limit, but no quantitative comparison with existing data was provided. More recently, Uhlmann and Dušek (2014) evaluated the accuracy of their method as a function of the spatial resolution (number of meshes per particle diameter) for the case of a single sphere settling in an infinite stagnant fluid, in a wide range of Reynolds and Archimedes (or Galileo) numbers. The higher the latter number, the higher spatial resolution is required, up to 48 mesh points per particle diameter at high Galileo number. Then Chouippe and Uhlmann (2015) and Fornari et al. (2016) used this method to study particle settling in turbulent flow conditions.

Corre et al. (2010) used a fictitious domain approach to perform particle-resolved simulations of the liquid-fluidized bed experimentally studied by Aguilar-Corona (2008). Instantaneous and averaged flow characteristics of the fluidized bed were qualitatively in good agreement with experimental trends. Since then, this method was improved and has been applied in the present study with a higher level of accuracy (Vincent et al., 2014). The numerical technique is a four-way coupling method, based on a one-fluid formulation of the incompressible Navier-Stokes equations solved on a structured Cartesian grid. The resolved-scale particles are modeled by an Implicit Tensorial Penalty Fictitious Domain Method (ITPM). They are tracked by using a hybrid Eulerian-Lagrangian Volume of Fluid approach, which accounts for collisions and lubrication effects.

**Table 1**  
Phase properties and fluidization parameters.

Liquid phase	$\rho_f$	1400 kg/m <sup>3</sup>
	$\mu_f$	$3.8 \times 10^{-3}$ Pa s
Fluidization velocity	$U_F$	0.17/0.15/0.12/0.09/0.073 m/s
Particles	$\rho_p$	2230 kg/m <sup>3</sup>
	$d_p$	$6 \times 10^{-3}$ m
	$V_t$	0.24 m/s
	$Re_t$	530
	$St_t$	5.3
Fluidization law	$U_{F0}(1 - \phi_b)^n$	$n = 2.41, U_{F0} = 0.226$ m/s

This study has two scopes. The first one is to evaluate the effective ability of ITPM to predict two-phase flow behavior by performing particle resolved simulations of a liquid-solid fluidized bed involving finite size particles, with large particle Reynolds and moderate Stokes numbers. The second one is to analyze velocity fluctuations of both phases in this regime. The bed geometry, particle size and number and flow parameters used in these simulations are the same as in Aguilar's experiments, allowing a direct quantitative comparison between experiments and numerical data.

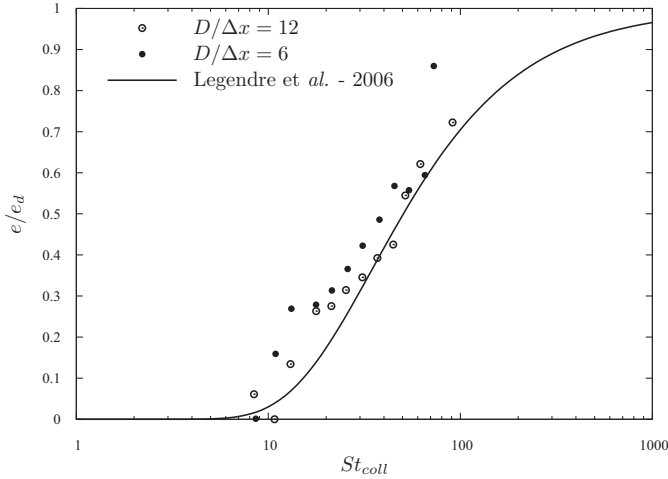

The paper is structured as follows: flow parameters and numerical model (detailed in other references) are briefly presented in Sections 2 and 3, respectively. Statistical quantities (as defined in Appendix A) computed from the numerical results are compared with experimental data obtained by Aguilar Corona with same flow parameters and geometry. Fluidization law and particle velocity fluctuations predicted by the simulations are also compared in Section 4.

## 2. Flow parameters

Flow parameters chosen for the simulation of the fluidized bed are taken from the experimental study of Aguilar-Corona (2008) in a cylindrical column of 8 cm inner diameter. Phase material properties and fluidization parameters are reported in Table 1. Monodisperse spherical beads of Pyrex ( $d_p = 6$  mm,  $\rho_p = 2230$  kg/m<sup>3</sup>) have been fluidized in a concentrated aqueous solution (65% w/w) of potassium thiocyanate (KSCN) of density  $\rho_f = 1400$  kg/m<sup>3</sup> and viscosity  $\mu_f = 3.8 \times 10^{-3}$  Pa s at  $T = 20^\circ\text{C}$ . At this temperature, refractive indices of both phases are matched, allowing the implementation of optical techniques such as high-speed video for the 3-D Lagrangian tracking of colored particles or high frequency Particle Image Velocimetry for the measurement of the velocity field in the liquid phase (Aguilar-Corona, 2008). Particle terminal velocity,  $V_t$ , is 0.24 m/s and Reynolds number based on  $V_t$  is  $Re_t = 530$ . Inertia of the particles is characterized by a Stokes number here defined as  $St_t = \frac{8\rho_p}{3\rho_f C_{Dt}} = 5.3$  ( $C_{Dt}$  is the drag coefficient of a single particle at  $V_t$ , here equal to 0.8). Fluidization law and fluctuating motion of both phases have been measured by Aguilar-Corona (2008) in a range of fluidization velocities ranging between 0.17 and 0.05 m/s, corresponding respectively to be solid volume fraction ranging between 0.1 and 0.5. Details of the measurement techniques can be found in Aguilar-Corona (2008).

## 3. Numerical model

Details of numerical approach and validation test cases are given in Vincent et al. (2014). The DNS approach is based on a one-fluid formalism of the incompressible Navier-Stokes equations with an algebraic adaptive augmented Lagrangian method used for pressure-velocity coupling (Implicit Tensorial Penalty Method, ITPM). The particles are considered as a fluid with specific rheological properties whose evolutions are modeled by the Navier-Stokes equations. This method enforces the solid behavior of the parti-

**Fig. 1.** Normal restitution coefficient of collisions with respect to collisional Stokes number  $St_{coll} = \frac{2}{9} \frac{R u_{coll} \rho_e}{\mu_f}$ : influence of the spatial resolution.  $D$  in this figure is the particle diameter.  $e$  is the restitution coefficient calculated from the ratio of the normal particle relative velocity before collision (at the position where lubrication force is activated) and the normal velocity after collision (where lubrication is turned off) and  $e_d$  is the reference value corresponding to collision of two glass particles.

cles in the framework of Eulerian fixed grid. A Lagrangian Volume of Fluid (VoF-Lag) method enables particle tracking while avoiding particle shape deformation and ensuring volume conservation of the solid phase. The convergence of the method was demonstrated for 2D and 3D reference test problems in Vincent et al. (2014), with a second order convergence in space.

In dense flows such as in fluidized beds, wall-particle and inter-particle collisions must be accounted for as well as lubrication. Fully resolved fluid motion due to solvent mediated hydrodynamic and lubrication interactions requires a highly refined Eulerian grid at the scale of the particle (about 150 grid points per particle). However, such a refinement level is not affordable for the simulation of the present liquid-solid fluidized bed. Therefore sub-grid lubrication force model proposed by Brändle de Motta et al. (2013) has been added to close particles in a pairwise manner (in the normal direction). Lubrication is activated at a dimensionless separation distance of  $2\Delta x/d_p$  and the lubrication force is kept constant if the distance (scaled by the particle radius) is less or equal than  $10^{-3}$ . When particles overlap, due to filtering effect at the subgrid scale, an inter-particle repulsive force is activated (a linear spring-dashpot (Hookean) model). The values of lubrication and collision models parameters have been optimized in Brändle de Motta et al. (2013).

Using the parameters of the studied fluidized bed and 12 grid points per particle diameter, this model predicts a normal restitution coefficient (normalized by the reference value in vacuum, close to 1) that matches reasonably well the scaling law proposed by Legendre et al. (2006), as illustrated by Fig. 1. The collision and lubrication force models for multiple particle-particle and particle-wall interactions are implemented in the Navier-Stokes equations as volume force terms, and their semi-implicit treatment avoids particle overlapping during the solving step of the flow field.

Fig. 2 shows the computational domain. It has the same dimensions as the experimental fluidization column. It is composed of a parallelepipedic box of dimensions  $0.08 \times 0.08 \times 0.64$  m. The solid wall boundary of the cylindrical column is simulated using a Darcy penalty method (Khadra et al., 2000), consisting in adding a Darcy term in the momentum equations with a very small permeability ascribed to the cells located outside the cylindrical envelope. This method ensures a no-slip condition at the cylinder wall. A uniform

**Fig. 2.** Geometry and dimensions of the computational domain.

distribution of fluid velocity is imposed at the bottom of the bed and a free outlet boundary condition is defined at the top of the bed. The domain is discretized with a uniform grid composed of 32 million cells ( $160 \times 160 \times 1280$ ). The grid is kept constant at all fluidization velocities and it corresponds to a resolution of 12 cells per particle. The choice of the grid resolution was the best compromise (as was observed in Vincent et al., 2014, JCP) between accuracy of solution and calculation time. Concerning the sensitivity of results to the grid resolution using the ITPM, it was observed in Vincent et al. (2014) that correct results were obtained when comparing particle flows with reference solutions for particle settling in a tank (Fig. 13 of that paper) or particle rotating in a Stokes flow (Fig. 17). In each case 8–12 points were enough to get a satisfactory solution.

At the beginning of the simulation, the particles were uniformly distributed in the domain with an equivalent solid concentration of 0.1 (the corresponding bed height is 0.47 m).

Both fluid and particles are at rest at the beginning of the first simulation, corresponding to a fluidization velocity  $U_F = 0.17$  m/s. After 10 s of physical time simulation, particles reached a steady fluidization regime. In order to save computation time, for other test cases at lower fluidization velocities, the initial conditions were taken from the steady fluidized regime at  $U_F = 0.17$  m/s.

Simulations were carried out during a physical time of 20 s with a time step of  $\Delta t = 5 \times 10^{-4}$  s for each fluidization velocity studied and using 128 Intel Quad-Core in French supercomputing centers. This is a convenient number of cores to have an optimal speed of the parallel computations without saturating the parallel message exchanges. The cost is high because the numerical method used to satisfy the incompressible and solid constraints (based on an augmented Lagrangian formulation) in both fluid and solid parts is coupling all velocity unknowns in an implicit way. This leads to reduced physical and modeling errors, but huge non symmetric and not well conditioned linear systems to solve. The restitution time for each case is about 50 days in order to simulate 20 s real time of bed flow.

Fig. 3 shows 3-D snapshots of particle distribution in the bed and illustrates the transient stage of the calculation after 5, 10 and 20 s ( $U_F = 0.12$  m/s). The bed settles down after 5 s and particle packing takes place within a steady volume. Another 5 s delay of simulation time is considered before performing statistics. Statistical averages presented in next section were therefore calculated

Fig. 3. 3-D views of the simulated particles inside the bed (from left to right:  $t = 0, 5, 10$  and  $20$  s).

Fig. 4. Time-evolution of maximum axial particle position at different fluidization velocities:  $U_F = 0.17, 0.15, 0.12, 0.09, 0.073$  m/s (resp.  $\phi_b = 0.11, 0.14, 0.22, 0.31, 0.39$ ).

over a 10s period of simulation, 10s after the beginning of each simulation (see Fig. 4).

#### 4. Results and discussions

Numerical results are compared to experimental data taken from Aguilar-Corona (2008). In experiments, averaged bed height

was determined from video camera in slightly unmatched refractive index conditions. Measurement of this quantity at different fluidization velocities gives the fluidization law. Fluctuating motion of the particles was analyzed from the recording of 12 trajectories of marked particles during 3 min at a sampling frequency of 60 Hz. Fluctuating motion of the liquid phase was characterized from the acquisition of the velocity field in a median plane of the column, using high speed PIV (between 250 and 500 Hz) and a spatial resolution of  $d_p/5$ .

##### 4.1. Fluidization law

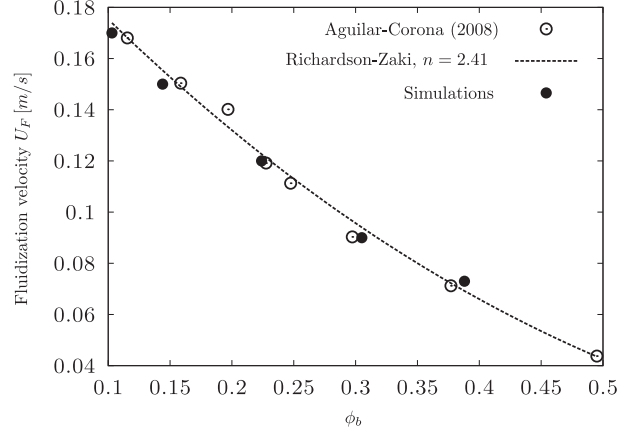

The fluidization law (relationship between the fluidization velocity and bed solid fraction) is the first step of validation of the numerical model, reflecting the macroscopic balance between buoyancy and drag forces. In order to calculate the bed solid concentration  $\phi_b$ , the bed height  $h_b$  was computed using two different methods, which led to the same result.

First, the bed height was set equal to the time averaged maximum particle position in the axial direction. Fig. 4 displays the time-evolution of this parameter at different fluidization velocities. After a transient period, it oscillates around a steady value for all cases investigated due to particle agitation. The intensity of fluctuations is a decreasing function of the fluidization velocity, with a maximum of the order of 5% for the lowest fluidization velocity.

Second, the bed height was also determined by averaging in time (during 10s) and space (over the bed volume) a particle phase indicator function  $\chi_p(\mathbf{x}, t)$ . This function is defined on each

**Fig. 5.** Axial profile of time-section average of particle phase fraction  $\chi_p$ .

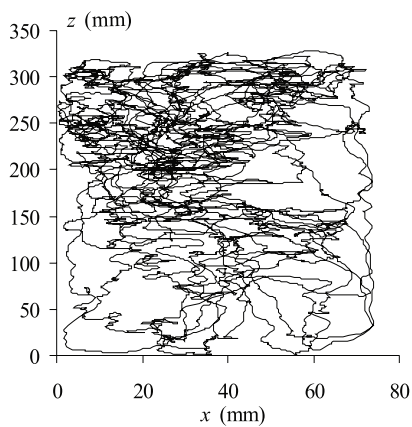

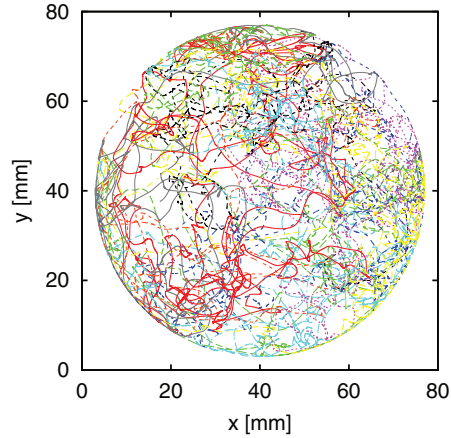

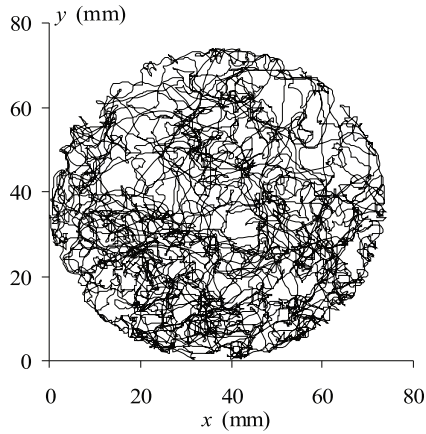

**Fig. 6.** Fluidization velocity with respect to the bed solid concentration.  $\odot$ : Aguilar-Corona (2008), ---: Richardson and Zaki (1954)'s correlation with  $n = 2.41$  and  $\bullet$ : present simulations.

Eulerian mesh cell, equal to 1 if the node is inside the particle and 0 if not. A vertical profile of the time-section average of the particle phase indicator function (or phase fraction)  $\{\chi_p\}_{layer}$  as defined in Eq. (A.3), is shown by Fig. 5 at different fluidization velocities. This quantity represents the solid volume fraction averaged in cylinders of diameter  $D$  and height  $\Delta z$ . So the integral of  $\{\chi_p\}_{layer}$  along  $z$  is equal to  $\phi_b h_b$ .

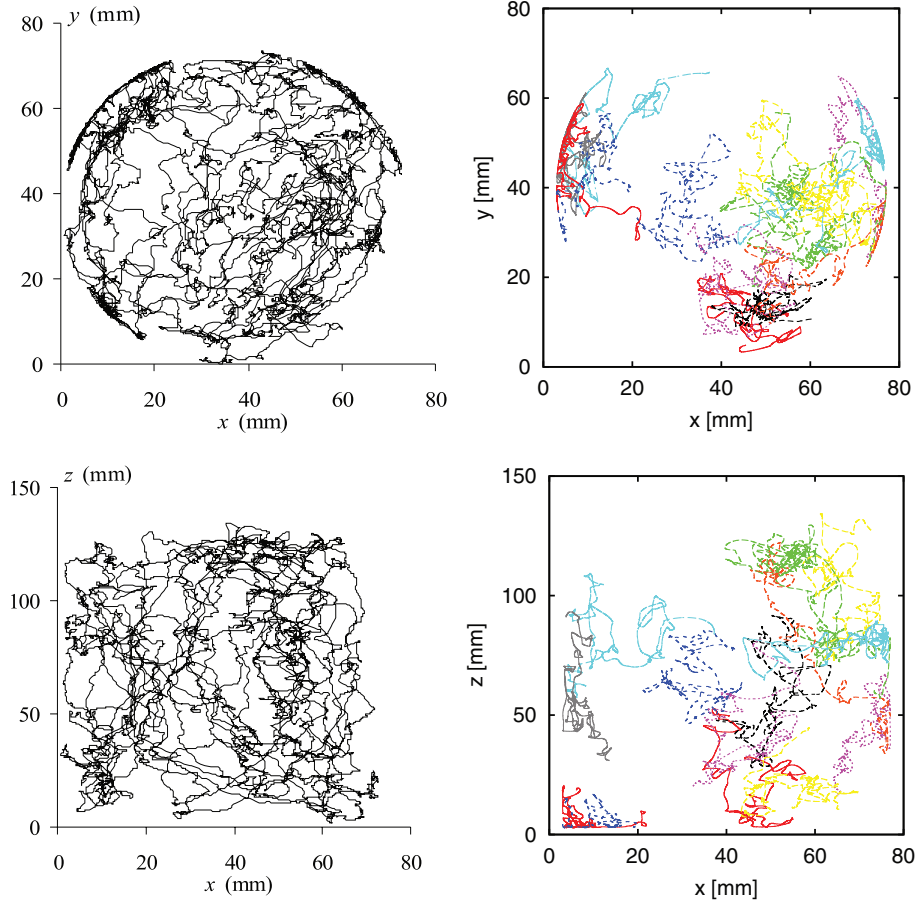

Fig. 5 shows that the phase fraction is rather homogeneous along the bed height but in the freeboard region a gradient of the

solid volume fraction develops, becoming stiffer as the fluidization velocity is decreased. The bed height is then computed by applying a linear regression with a high order polynomial interpolation on the volume fraction profile at the interface between the bed and the freeboard region, and the  $z$  value of the inflection point of that function is defined as the bed height  $h_b$ .

Both estimations lead to close values of  $h_b$  for all velocities with a difference of a few percent. The bed solid fraction  $\phi_b$  is then

**Fig. 7.** Projections of particle trajectories in  $x$ - $y$  plane (top) and  $x$ - $z$  plane (bottom). Left: experimental data by Aguilar-Corona (2008) ( $U_F = 0.15$  m/s,  $\phi_b = 0.14$ ), right: simulations.

**Fig. 8.** Projections of particle trajectories in  $x$ - $y$  plane (top) and  $x$ - $z$  plane (bottom). Left: experimental data by [Aguilar-Corona \(2008\)](#) ( $U_f = 0.073$  m/s,  $\phi_b = 0.38$ ), right: simulations.

calculated according to:

$$\phi_b = \frac{2 n_p d_p^3}{3 h_b D^2} \quad (1)$$

Plotting the fluidization velocity as a function of the bed solid concentration  $\phi_b$  gives the fluidization law. [Fig. 6](#) shows the bed solid concentration measured in DNS together with the experimental data of [Aguilar-Corona \(2008\)](#) and the correlation of [Richardson and Zaki \(1954\)](#):

$$U_f = U_{F0} (1 - \phi_b)^n \quad (2)$$

where  $n$  is a function of  $Re_t$ ,  $U_f$  is the fluidization velocity and  $U_{F0}$  is the fluidization velocity leading to particles entrainment. The exponent value best fitting experimental data is  $n = 2.41$  ( $Re_t = 530$ ), and is in quite good agreement with the value predicted by Richardson-Zaki correlation at that particle Reynolds number ( $n = 2.39$  for  $Re_t > 500$ ). Experimental value of  $U_{F0}$  is found equal to 0.226 m/s, and the measured terminal velocity of the particles is  $V_t = 0.24$  m/s. The ratio of  $U_{F0}/V_t$  is equal to 0.94, which corresponds to the upper limit of the range of values of this parameter in liquid fluidization. Note also that it is not related to the ratio  $d_p/D$  ([Di Felice and Kehlenbeck, 2000](#)). The agreement between experiments and numerical simulations is quite good, and to the best of our knowledge, this result is the first validation of particle resolved simulation of fluidization law in a full 3-D fluidized bed in that range of particle Reynolds number.

#### 4.2. Particle trajectories and Lagrangian velocity signal

[Figs. 7 and 8](#) exhibit projections of 16 particle trajectories in the radial and vertical planes of the bed, for two different fluidization velocities (0.15 and 0.073 m/s). It can be observed that particle trajectories are quite sensitive to this parameter. At high fluidization velocity (low concentration), trajectories occupy all the bed space, with an apparent slight deficit of particles in the bed bottom zone (close to the flow inlet). For the same simulation time (10 s), the space travelled by the same number of particle trajectories tends to reduce at higher concentration (lower fluidization velocity). This confinement effect can be clearly observed on the trajectory envelopes projected in the cross section ( $x$ - $y$  plane), with the development of dark spots near the bed wall, the signature of particle trapping over long-time periods. Additionally, the shape of the paths becomes more and more angular as the bed is compacted, in response to the increase of inter-particle collisions. Overall, the multi-scale diffusive-like motion of the particles in the bed as calculated by the numerical simulations exhibits remarkable similarities with the experimental signals (12 particle trajectories recorded during more than 3 min), suggesting that the physics of the fluid-particle and particle-particle interactions are qualitatively well captured by the numerical model, in both dilute and dense regimes.

[Fig. 9](#) exhibits the instantaneous axial and radial particle velocity components following one particle trajectory for the case  $\phi_b = 0.31$  ( $U_f = 0.09$  m/s). Numerical and experimental signals present qualitatively similar features, being composed of large scale, low frequency and small scale, higher frequency fluctuations. The am-

**Fig. 9.** Experimental data by Aguilar-Corona (2008) (left) and simulation results of a particle Lagrangian velocity signal ( $\phi_b = 0.31$ ;  $U_F = 0.09$  m/s). Top: transverse and bottom: axial components.

plitude of fluctuations is more pronounced on the axial component  $U_{p,z}$  than on the transverse one,  $U_{p,x}$ . The frequency of the high amplitude velocity fluctuations is smaller on  $U_{p,z}$  than on  $U_{p,x}$  signals.

Modes of high frequency can be observed in the numerical signal, which is not the case of the experimental signal. Their occurrence could be inferred to the collisional model (used in the numerical simulations) that generates abrupt modification of the velocity upon collisions, whereas their absence in the experimental signal could be due to a filtering effect (velocity sampling frequency in the experiments: 30 Hz).

#### 4.3. Recirculation

The low frequency, large amplitude fluctuations suggest the presence of large-scale coherent structures. Fig. 10 shows time and azimuthal average of the particle velocity field defined as  $\langle u_p \rangle_{ann\Delta z}$ . It represents the average of particle velocity in a hollow cylinder of inner radius  $r$  and outer radius  $r + \Delta r$  and of thickness  $\Delta z$  (cf. see the appendix). Fields of  $\langle u_p \rangle_{ann}$  reveal the presence of a localized large-scale recirculation in the lower section of the bed, size of which compares with the bed diameter. For both concentrations  $\phi_b = 0.31$  ( $U_F = 0.09$  m/s) and  $\phi_b = 0.39$  ( $U_F = 0.073$  m/s), particles preferentially rise up near the bed axis and flow downward near the wall. The upward velocity is larger than the downward velocity owing to mass conservation. The shape of particle path-lines indicates that the recirculation is stronger in the bottom of the bed, confirming the existence of a large-scale toroidal motion above the flow inlet detected in the trajectography experiments (cf. Fig. 7). Fig. 11 displays radial profiles of the axial component of particle velocity averaged in time and over the bed height  $\langle u_{p,z} \rangle_{ann}$  ( $\langle \cdot \rangle_{ann}$  denotes the average of  $\langle \cdot \rangle_{ann\Delta z}$

over bed height). As a general trend particle motion in the bed is upward in the middle of the bed and downward in the near wall region (between 0.2 and 0.6 column radius from the wall). When particles are very close to the wall they tend to rise along the wall. Note that the magnitude of this mean motion is an order of magnitude smaller than the particle r.m.s. velocity presented in the next section.

As regards the statistical sampling, a longer sampling time would allow obtaining smoother profiles (the simulation time was constrained by the available computer resources). The jagged nature of the profiles results from the spatial discretization. For example the number of events used to establish averaged radial profiles depends drastically on the radius. This corresponds to a range of events from  $3.10^5$  to  $7.10^6$  when  $r$  varies from 0 to  $R$ . However the profiles become smoothen without being significantly changed when the size of the sample is increased in the radial or axial direction.

#### 4.4. Particle and fluid velocity variance

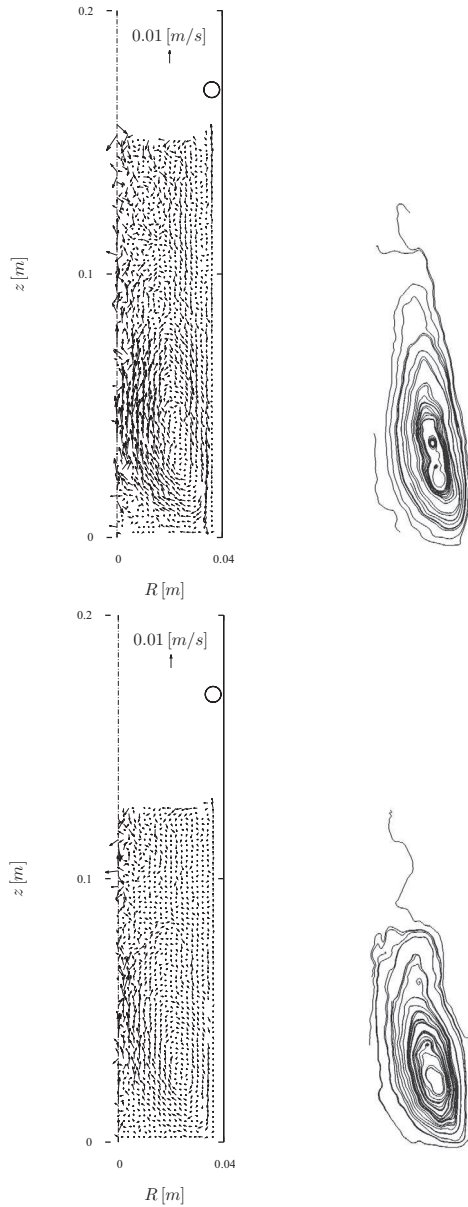

The average of the velocity variance of particles in the whole bed is computed as follows:

$$\langle u_{p,i}^2 \rangle = \langle (u_{p,i} - \langle u_{p,i} \rangle_{ins})^2 \rangle \quad (3)$$

$\langle \cdot \rangle$  denotes the time-space average defined in the appendix,  $u_{p,i}$  is the  $i$  component of the instantaneous Lagrangian particle velocity, and the symbol  $\langle \cdot \rangle_{ins}$  refers to the instantaneous Lagrangian average operator (defined in the same way as  $\langle \cdot \rangle$  in the appendix at a given instant).

The variance of radial particle velocity as a function of vertical position in the bed, calculated in horizontal layers of thickness  $\Delta z$  and diameter  $D$ , is noted  $\langle u_{p,x}^2 + u_{p,y}^2 \rangle_{layer}$  (see the appendix for the

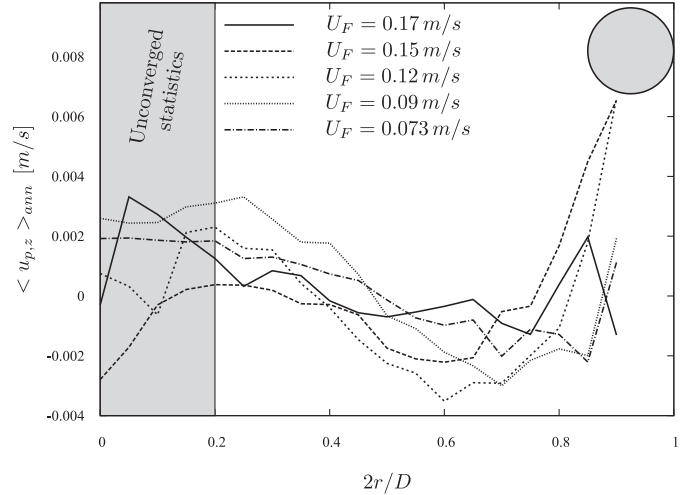

**Fig. 10.** Averaged particle velocity field and streamlines for the case  $U_f = 0.09$  m/s (top) and  $U_f = 0.073$  m/s (bottom).

definition of averages). The axial profile of this quantity normalized by the radial velocity variance in the whole bed is reported in Fig. 12 (top) at different fluidization velocities. Profiles collapse on a single curve, and exhibit a rather homogeneous distribution of radial velocity variance in a large portion of the bed, slightly increasing from 0.9 to 1.1 between  $z/h_b = 0.2$  and  $z/h_b = 0.9$ . In the bottom part of the bed,  $0 < z/h_b < 0.2$ , the variance is smaller and is growing from 0.5 to 0.9. In the top part of the bed ( $z/h_b > 0.9$ ), the occurrence of peaks of large amplitude in the near-freeboard region results from the transition of fluid velocity between a concentrated medium and a free-particle domain, getting sharper as the bed solid fraction increases (or as the fluidization velocity decreases).

The variance of axial particle velocity component as a function of radial position in the bed is calculated in vertical hollow cylinder of thickness  $\Delta r$  and is noted  $\langle u_{p,z}^2 \rangle_{ann}$  (see the appendix).

**Fig. 11.** Radial profile of axial velocity averaged over the bed height.

The radial profiles of normalized variance  $\frac{\langle u_{p,z}^2 \rangle_{ann}}{\langle u_{p,z}^2 \rangle}$  are shown in Fig. 12 (bottom) for various fluidization velocities. The axial velocity variance is minimum in the core of the bed and maximum near the wall, due to the transition between negative velocities in the recirculation loop to positive values very near the wall (see Fig. 11). However, the shape of the profiles depends on the fluidization velocity. At highest fluidization velocity (minimum bed solid fraction), the profile shows a marked gradient along bed radius (from 0.55 to 1.25), which tends to flatten as the fluidization velocity decreases. At largest bed concentration (smallest fluidization velocity) the shape of the profile is rather homogeneous varying from 0.9 in the core of the bed to 1.1 near the wall.

Fig. 13 shows the variance of particle velocity components in the whole bed (Eq. (3)) as a function of bed solid volume fraction and compared to experimental data. The numerical data are reasonably in good agreement with experiments, showing a strong decrease of the agitation with the concentration. However at the largest fluidization velocity (lowest concentration), the simulation overpredicts the experimental value by a factor of two. At larger concentrations the trend is reversed, numerical results underpredict experimental values. The same behavior is observed for both components (axial and transverse).

The particle agitation in the fluidized bed is not isotropic: the variance of the axial component of velocity is stronger than that of the transverse component (isotropy of the fluctuations in the transverse plane was checked). This behavior is already well known in gravity driven gas–solid suspensions, like in sedimentation. The anisotropy coefficient  $k_{anis}$  is defined as the ratio of the particle velocity variance in flow direction ( $z$ ) to that in the transverse plane ( $x, y$ ):

$$k_{anis} = \sqrt{\frac{\langle u_{p,z}^2 \rangle}{\frac{1}{2}(\langle u_{p,x}^2 \rangle + \langle u_{p,y}^2 \rangle)}}. \quad (4)$$

Its evolution as a function of bed solid fraction is shown in Fig. 14. Numerical predictions (1.5 in average) are close to the experimental values (1.6) and nearly constant in the range of bed solid fraction investigated, unlike sedimentation case at low Reynolds number where anisotropy is decreasing as particle concentration increases (Nicolai et al., 1995). This result emphasizes the leading role of large-scale motion in the agitation of particles fluidized by a liquid at high  $Re_p$ . Note that despite the differences observed between numerical and experimental data at lowest and

highest solid fraction, the correct prediction of anisotropy coefficient over all the concentration range investigated suggests that the structure of the large scale motion is well captured by the numerical model.

The dependence of total fluid and particle fluctuating kinetic energy ( $E_f$  and  $E_p$ ) on the bed solid volume fraction is displayed

in Fig. 15. For the particle phase it is computed as:

$$E_p = \frac{1}{2} (2\langle u_{p,x}^2 \rangle + \langle u_{p,z}^2 \rangle) \quad (5)$$

and for the fluid phase:

$$E_f = \frac{1}{2} (2[u_{f,x}^2]_{plane} + [u_{f,z}^2]_{plane}) \quad (6)$$

where  $[\cdot]_{plane}$  denotes the Eulerian average in a vertical median plane (see definition in the appendix). The choice of this average is driven by the correspondence with experimental data obtained with High Frequency PIV in a vertical median plane of the bed (Aguilar-Corona, 2008).

Fig. 15 shows that the fluid fluctuating kinetic energy with respect to the solid volume fraction does also fit well experimental data obtained from HF PIV measurements, except at low phase fraction where it underestimates experimental data. Interestingly, the fluctuation level of the liquid phase is always significantly larger than that of the solid phase in all the range of solid phase fraction investigated. The ratio  $E_f/E_p$  is a growing function of  $\phi_b$ .

The particle and fluid agitation are shown here at moderate concentration range, while one can expect two limiting behaviors at small and high volume fractions.

In the very dilute regime ( $\phi_b \rightarrow 0$ ), particle agitation is expected to be close to that observed in a dilute turbulent pipe flow. This regime corresponds to a fluidization velocity equal to the particle terminal velocity (particle entrainment). In the present case, particle terminal velocity is  $V_t = 0.24$  m/s, and flow Reynolds number is  $Re_f = \frac{\rho_f V_t D}{\mu_f} \sim 7 \times 10^3$ , with a wall friction velocity derived from Blasius law equal to 0.016 m/s. The corresponding fluctuating kinetic energy is about  $3 \times 10^{-4}$  m<sup>2</sup>/s<sup>2</sup>, which is nearly two orders of magnitude smaller than  $E_f$  measured (in the experiments and simulations) at  $\phi_b = 0.1$ . Neglecting the fluid turbulent modulation by the particles in the very dilute limit, an estimation of particle fluctuating kinetic energy can be scaled as that of the continuous phase weighted by a function of particle Stokes number (Deutsch and Simonin, 1991; Tchen, 1947), here defined as the ratio of particle response time to the fluid turbulent time macro-scale. For the present system, such an estimate gives in very dilute regime the same order of magnitude for  $E_p|_{\phi_b \rightarrow 0}$  as  $E_f|_{\phi_b \rightarrow 0}$  (taken equal to that of a steady turbulent pipe flow), and therefore is one order of magnitude smaller than the particle fluctuating kinetic energy measured at the lowest volume fraction  $E_p|_{\phi_b=0.1}$ . Therefore, both particle and fluid agitation should increase at very low concentration, without however being captured by the present measurements. From these estimations, we conclude that the fluctuating energy for both phases at  $\phi_b = 0.1$  is far larger than the very dilute limit, which means that the fluctuations are dominated by strong particle–fluid flow coupling. Consequently, if we decompose the fluid fluctuating energy in two components, one of them induced by large scale collective motion and the other one due to small scale fluid–particle wake turbulence (also referred to in the literature as pseudo-turbulent kinetic energy),  $E_f = \tilde{E}_f + \delta E_f$ , the second component would be far greater than the first one. Note that a rigorous formulation of the energy decomposition is reviewed in Fox (2014). The strong coupling seems to be intrinsic to liquid fluidization whereas the opposite is true in gas fluidization, which is essentially related to difference in particle inertia.

When the concentration increases, the particle fluctuating energy decreases. At large volume fraction ( $\phi_b \rightarrow \phi_{max}$ ), the particle phase approaches a porous media.  $E_p$  vanishes whereas  $E_f$  remains finite, meaning that velocity fluctuations of both phases become uncorrelated. In this limit, large scale motion disappears and flow fluctuations derive from the so-called pseudo-turbulence ( $E_f = \delta E_f$ , or equivalently  $\tilde{E}_f \approx 0$ ). Interestingly, the decrease of fluid fluctuating energy with concentration  $E_f|_{\phi_b=0.1} - E_f|_{\phi_b \rightarrow \phi_{max}}$  is close to  $E_p|_{\phi_b=0.1}$ , suggesting that the particle fluctuating energy at low concentration is mainly driven by the flow large scale fluctuating motion  $\tilde{E}_f$ .

Note that in Fig. 15, the decay with bed solid fraction of particle agitation is stiffer in numerical than in experimental curves, whereas the reverse trend is observed with fluid agitation. The origin of the differences observed between numerical and exper-

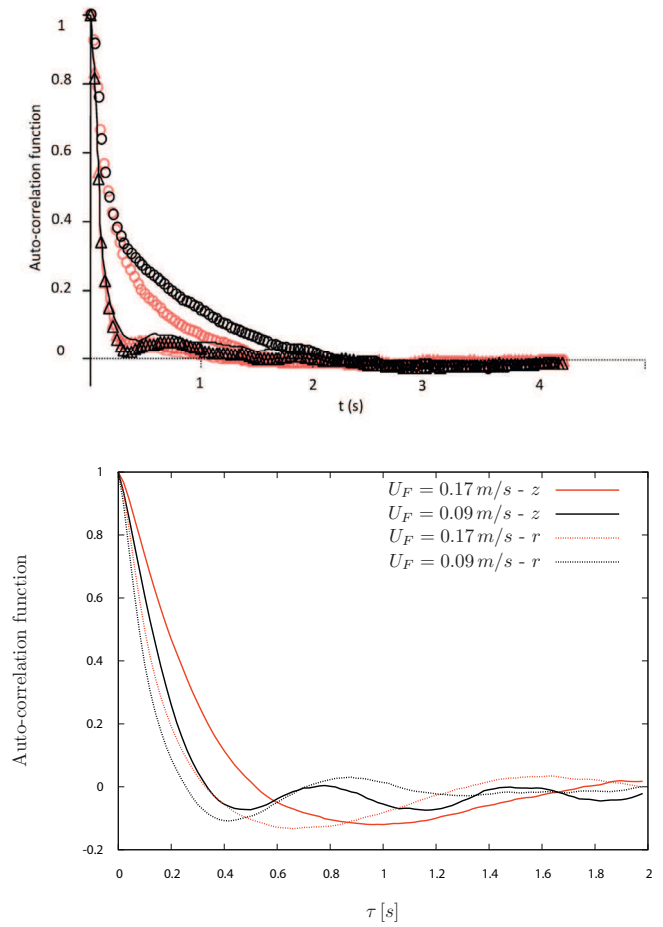

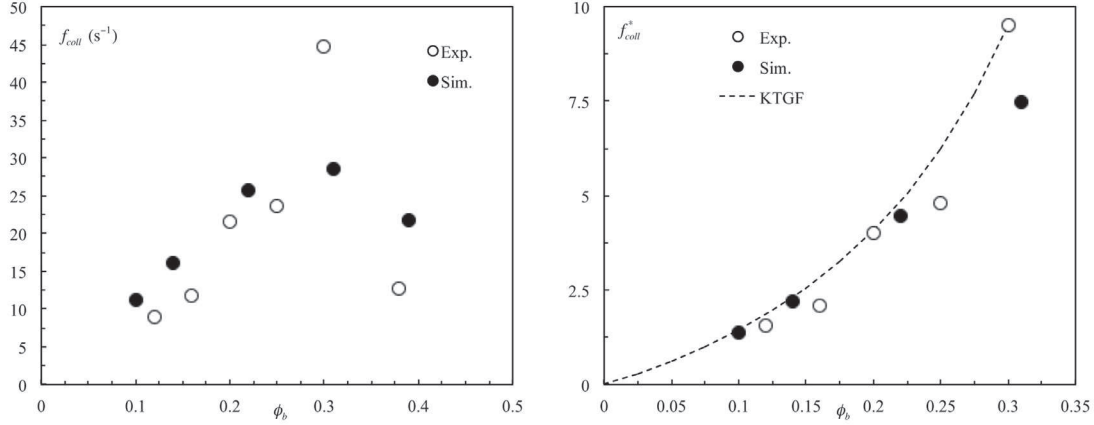

Fig. 16. Particle velocity autocorrelation functions measured in top: experiments (circles: axial component. Triangles: radial component. Black :  $\phi_b = 0.3$ . Red= $\phi_b = 0.12$ ) and bottom: numerical simulation results.

imental data is difficult to identify. First, statistics on the particle phase are not derived in the same way (2133 particles during 10 s for the numerical data, 12 trajectories during 3 min for the experimental data). Second, in this range of particle Reynolds number ( $Re_t = 530$ ), the flow is probably under-resolved with 12 cells per particle diameter and the small-scale structures of the flow are probably partially filtered (Uhlmann and Dušek, 2014). The resulting particle relative velocity prior to collisions, and therefore the numerical treatment of collisions can be affected. All these issues require to be addressed separately in order to quantify their contribution to the calculation of both phases agitation.

#### 4.5. Particle fluctuation time scales

The time-scale (macro-scale) characteristic of particle agitation can be derived from the computation of autocorrelation function of axial and radial velocity components (given in the appendix). The autocorrelation function is shown in Fig. 16 for two bed solid volume fractions (0.12 and 0.3, respectively corresponding to 0.17 and 0.09 m/s). After the initial step of continuous decay, both components exhibit a large oscillating behavior at long times. Origin of these oscillations is likely due to the contribution of the localized recirculation zones in the bed bottom section (see Fig. 10), which seems to be supported by the observation that period of oscillations decreases as the fluidization velocity is decreasing, i.e. when the bed height is decreasing. Comparison of numerical and experimental curve shapes exhibits some discrepancies. At short times

**Fig. 17.** Collision frequency with respect to the bed solid volume fraction (left), non-dimensional collision frequency (right)  $f_{coll}^* = f_{coll} \frac{d_p}{\sqrt{\frac{3}{4} (u_{p,x}^2 + u_{p,y}^2)}}$  compared to theoretical expression derived from KTGF  $f_{coll}^* = 24 \sqrt{\frac{2}{3\pi}} \phi_b g_0$  with  $g_0 = \left(1 - \frac{\phi_b}{\phi_m}\right)^{-2.5\phi_m}$  and  $\phi_m = 0.585$ .

(< 0.4 s) curves behave the same with a stronger decay of the transverse component compared to the axial velocity component. At longer times, experimental curves decay much more slowly than calculated curves, which oscillate around the abscissa axis. This is particularly noticeable for the autocorrelation function of the particle axial velocity component. Regarding the radial motion, the decorrelation time of velocity fluctuations, that is to say the time at which the curves reach the horizontal axis is nearly constant for both bed solid fractions and compares well with experimental data, close to 0.3 s. The decorrelation time of axial fluctuations as predicted by the numerical data is significantly smaller compared to the experimental data and its evolution with the bed solid fraction is reversed. When the bed solid volume fraction increases from 0.12 to 0.3, it decreases from 0.5 s to 0.3 s whereas experimental data shows an increase from 1.8 s to 2.1 s. It is believed that the absence of the oscillatory behavior on the experimental curves is mainly due to a subsampling of the recirculation zones by the tracked marked particles, which statistical weight in the numerical signal must be strengthened by the localized and steady nature of such structures. As these structures are anti-diffusive, they hinder the long time diffusive behavior observed in the experimental trajectories. This result emphasizes the limits of the comparison between ensemble average short-time autocorrelation function over all the particles (which corresponds to the numerical data processing) and the calculation of same quantity over long-time trajectories (experimental data processing).

Interparticle collision frequency has been also computed using the collision detection model, which is activated if particles overlap during the lubrication step (see Section 3). The frequency of collisions is then defined as the inverse of the averaged time between two consecutive collisions for each particle and averaged over all the particles in the bed and over time. Consequently, only the average detection of elastic collisions can be achieved based on such a method, i.e. when the restitution coefficient is non-zero. As shown by Fig. 1, such a condition is valid when the collision Stokes number ( $St_{coll} = \frac{1}{9} \frac{\rho_p d_p u_{coll}}{\mu_f}$ ) is roughly larger than 10. The average collision frequency  $f_{coll}$  is shown in Fig. 17 as a function of global bed solid volume fraction  $\phi_b$  and compared to the experimental data of Aguilar-Corona et al. (2011) based on a threshold value of particle acceleration. A fairly good agreement between numerical and experimental data is observed in a range of bed solid volume fraction up to 25%. At 30%, the agreement is less good and for higher bed solid volume fraction, the collision frequency is decreasing and tends towards zero when  $\phi_b$  approaches the maximum packing.

The same trend is observed with both experimental and numerical data, illustrating the transition between damped elastic to fully damped collisions (normal restitution coefficient equal to zero). Collisional Stokes number is continuously decreasing as the solid volume fraction increases due to the decrease of particle agitation. Above  $\phi_b = 0.3 - 0.4$ , the collision Stokes number based on the transverse fluctuating velocity becomes smaller than 10 and the restitution coefficient becomes smaller than 0.05 (see Fig. 1), which makes the collisions difficult to detect from either numerical or experimental signals.

Below 0.3, the dimensionless collision frequency is well predicted by the numerical model. It remarkably fits the theoretical expression derived from the kinetic theory (noted KTGF in Fig. 17). From the scaling of the collision time,  $d_p / \sqrt{\frac{3}{4} (u_{p,x}^2 + u_{p,y}^2)}$  that can be identified to  $d_p / \sqrt{\frac{3}{2} \theta_p}$  in KTGF, one can conclude that the transverse fluctuating motion of particles is the correct characteristic velocity scale to be considered for the collisions in the fluidized bed. This is consistent with Février et al. (2005) and Fox (2014) who suggested that the total particle velocity fluctuations can be decomposed in large and small scale fluctuations  $E_p = \tilde{E}_p + \delta E_p$ . The first part contains particle large scale motion represented by the streamlines of Fig. 10. It is approximately equal to the particle velocity variance in the axial direction and is fully coupled to the flow large scale motion via the buoyancy force and the non-uniform two-phase mixture density field ( $\tilde{E}_p \approx \tilde{E}_f$ ). The second part accounts for random uncorrelated motion (transverse fluctuations), similar to Brownian motion resulting from collisions, usually referred to as granular temperature  $\frac{3}{2} \theta_p$  in gas-solid flows. Note that the measured and calculated particle velocity variances (Fig. 13) suggest that  $\tilde{E}_p / \delta E_p > 1$  in liquid fluidization but this ratio is expected to decrease with particle inertia (Février et al., 2005).

## 5. Conclusions

Particle resolved simulations of a liquid-solid fluidized bed were performed using a one-fluid formulation of the incompressible Navier-Stokes equations, where the pressure-velocity coupling is provided by an algebraic augmented Lagrangian method and particles presence is modeled with an implicit penalty fictitious domain method, sub-grid scale lubrication force and soft-sphere collision models. We carried out simulations in a fully 3-D fluidized bed experimentally investigated by Aguilar-Corona (2008) on a structured uniform Eulerian grid at various fluidization velocities.

Simulation results show the ability of the numerical approach to reach a steady regime of fluidization, and perfectly reproduce the experimental fluidization law. The instantaneous flow field exhibits small and large-scale motion in both phases. This behavior is observed in all range of fluidization velocity investigated, from dilute ( $\phi_b = 0.11$ ) to dense regimes ( $\phi_b = 0.39$ ). As the bed solid concentration is increased, the agitation of both phases is decreased, and the experimental trend is well reproduced except in the case of the lowest global concentration (highest fluidization velocity). However, the anisotropy of the agitation of particles is well predicted and is shown to be independent of the bed global concentration, reproducing the experimental trend. Fluid velocity variance in the bed is larger than that of the particle phase up to an order of magnitude at high concentration, in agreement with the experimental data. The results obtained at different fluidization velocities (or particle Reynolds numbers) suggest the following image. The fluid velocity fluctuations in the liquid fluidized bed result mainly from pseudo-turbulence generated by particle wakes, the particle velocity fluctuations in the axial direction follow the large scale flow motion whereas they are mainly driven by collisions in the transverse plane.

Overall, comparison between numerical and experimental instantaneous fields and averaged quantities tend to demonstrate that the physics of particle–fluid and interparticle interactions are well captured by the present numerical approach. The numerical database generated by this work will serve as a basis for a future support of statistical models for liquid fluidization. One can take advantage of the numerical data to provide quantities that can hardly be obtained in experiments, like pair distribution function, two-point correlations and inter-correlation of fluctuating quantities (particle velocity concentration, pressure gradient-concentration, fluid–particle velocities).

## Appendix A. Definition of the statistical operators

The average operators of a quantity  $\phi$  are defined in an Eulerian or Lagrangian way, whether  $\phi$  describes the behavior of the continuous or discrete phase. The different average operators are explicitly defined in this section.

*Lagrangian averages:*

- Arithmetic average on the ensemble of particles

$$\langle \phi \rangle = \frac{1}{\Delta T} \int \frac{1}{N_p} \sum_{n=1}^{N_p} \phi_n(t) dt \quad (\text{A.1})$$

where  $\phi_n$  is a variable associated to the  $n$ th particle.  $N_p$  is the total number of particles, and  $\Delta T$  is the total simulation time. The time step for statistical calculations of the Eulerian phase is 50 times the simulation time step.

- Average over cylindrical shells of height  $h_b$  and thickness  $\Delta r$  such that  $\mathcal{H}(\mathbf{x}, r, \Delta r) = \{1 \text{ if } r < \|\mathbf{x} - \mathbf{x} \cdot \mathbf{e}_z\| < r + \Delta r \text{ else } 0\}$ ,

$$\langle \phi \rangle_{ann} = \frac{\int \sum_{n=1}^{N_p} \phi_n(t) \mathcal{H}(\mathbf{x}_n(t), r, \Delta r) dt}{\int \sum_{n=1}^{N_p} \mathcal{H}(\mathbf{x}_n(t), r, \Delta r) dt} \quad (\text{A.2})$$

- Average over a disk of diameter  $D$  and thickness  $\Delta z$ , such that  $\mathcal{H}(\mathbf{x}, z, \Delta z) = \{1 \text{ if } z < \|\mathbf{x} \cdot \mathbf{e}_z\| < z + \Delta z \text{ else } 0\}$ ,

$$\langle \phi \rangle_{layer} = \frac{\int \sum_{n=1}^{N_p} \phi_n(t) \mathcal{H}(\mathbf{x}_n(t), z, \Delta z) dt}{\int \sum_{n=1}^{N_p} \mathcal{H}(\mathbf{x}_n(t), z, \Delta z) dt} \quad (\text{A.3})$$

Note that the  $\Delta_z$  and  $\Delta_r$  considered for the radial and axial profiles are equal to the diameter of the column divided by 40. This leads to somehow fluctuating profiles at the highest fluidization velocity. Increasing the size of  $\Delta_z$  and  $\Delta_r$  gives smoother profiles without changing dependence on  $r$  or  $z$ .

*Eulerian averages:*

- Average over the Eulerian grid with  $N_{cells}$  the number of cells defined only in the part of the fluidized bed laden with particles.

$$\langle \phi \rangle = \frac{1}{\Delta T} \int \frac{\sum_{i=1}^{N_{cells}} \phi_i}{N_{cells}} dt \quad (\text{A.4})$$

where  $\phi_i$  is the value of the variable  $\phi$  of the continuous phase defined on the  $i$ th cell.

- Average over a disk of diameter  $D$  and thickness  $\Delta z$ ,

$$\langle \phi \rangle_{layer} = \frac{\int \sum_{i=1}^{N_{cells}} \phi_i \mathcal{H}(\mathbf{x}_i, z, \Delta z) dt}{\int \sum_{i=1}^{N_{cells}} \mathcal{H}(\mathbf{x}_i, z, \Delta z) dt} \quad (\text{A.5})$$

where  $\mathbf{x}_i$  is the position of the  $i$ th cell.

- Phase average over the Eulerian grid

$$\langle \phi \rangle = \frac{\int \sum_{i=1}^{N_{cells}} \phi_i (1 - \chi_i) dt}{\int \sum_{i=1}^{N_{cells}} (1 - \chi_i) dt} \quad (\text{A.6})$$

where  $\chi_i$  is the solid volume fraction of the  $i$ th cell.

- Phase average on a plan  $\mathcal{P} = \{\mathbf{x}, \mathbf{x} \cdot \mathbf{e}_y = 0\}$ .

$$\langle \phi \rangle_{plan} = \frac{\int \sum_{i=1}^{N_{cells}} \phi_i (1 - \chi_i) \delta_{i \in \mathcal{P}} dt}{\int \sum_{i=1}^{N_{cells}} (1 - \chi_i) \delta_{i \in \mathcal{P}} dt} \quad (\text{A.7})$$
