Abstract

A new modelling framework, called μic , has been developed to enable simulations of complex particulate growths, in particular the microstructural evolution of hydrating cement paste. μic has been developed using the vector approach, which preserves the multi-scale nature of the cement microstructure. Support libraries built into the framework enable fast simulation of systems containing millions of particles, allowing every single particle in a system to be modelled and all the interactions to be calculated. The modelling framework has been developed using object oriented programming and its extensible and flexible architecture, due to this microstructural development mechanisms and algorithms can be easily added. The framework facilitates the otherwise complex task of modelling new systems and phenomena. The microstructures generated by μic can be used to obtain important information that can in the future be used to model the evolution of mechanical properties and durability-related phenomena. The model can also be used to study the mechanisms of microstructural development of cement.

Various models of cement hydration kinetics and the reaction mechanism were tested using μic . It was observed that while the traditional approach to the nucleation and growth mechanism could be used to explain the acceleration of reaction-rates during the early hydration of cement pastes, the subsequent deceleration could not be reproduced. If a diffusion controlled mechanism is used to explain the deceleration, changes larger than an order of magnitude in the transport properties of C-S-H have to be assumed. Furthermore, the rate of change of reaction rates shows a continuous linear evolution through the reaction peak and the thickness around different particle sizes would be very different at the onset of the supposed diffusion regime. It was found that it is possible to explain

the hydration kinetics during the first 24 hours using a nucleation and growth mechanism when a loosely packed C-S-H with a lower bulk density is assumed to form. It is proposed that this loosely packed C-S-H fills a large fraction of the microstructure within a few hours of hydration and that its density continues to increase due to an internal growth process within the bulk of the product. It was found that an initial density of C-S-H between 0.1 g/cc and 0.2 g/cc was required in order to fit the observed experimental behaviour. While this density is much lower than the generally accepted range of 1.7 g/cc to 2.1 g/cc, this low packing density can explain the absence of water in large capillary pores observed in NMR measurements that study cement hydration on wet samples, and the fibrous or ribbon-like nanostructure of C-S-H observed in high-resolution TEM images.

The current study demonstrates the versatility of μic and how the possibility of modelling different phenomena on a multi-scale three-dimensional model can prove to be an important tool to achieve better understanding of cement hydration. It was also shown that the use of mechanistic, rather than empirical, rules can improve the predictive power of the models.

Key Words: Microstructure, Modelling, Modelling platform, Vector approach, Cement, Alite, Hydration, Kinetics, Mechanism, Calcium silicate hydrate, Densification

Résumé

Une nouvelle architecture dédiée à la modélisation ayant pour nom μic a été développée pour permettre la simulation de phénomènes de croissance particulaire complexes, en particulier l'évolution micro-structurale de la pâte de ciment au cours de son hydratation. μic a été développé avec une approche vectorielle, apte à préserver la nature multi-échelle de la microstructure du ciment. Les bibliothèques de support fournies avec μic rendent possible la simulation rapide de systèmes comprenant des millions de particules, chaque particule étant modélisée individuellement et toutes les interactions traitées explicitement. Cet environnement de simulation a été écrit en utilisant une approche orientée objet et son architecture permet une grande flexibilité dans l'ajout de mécanismes de développement et d'algorithmes spécifiques. Cette architecture facilite la tâche complexe de construction de modèles pour de nouveaux systèmes ou phénomènes. Les microstructures générées par μic peuvent être utilisées pour obtenir des informations importantes, utilisables dans le futur pour la modélisation de l'évolution des propriétés mécaniques ainsi que les phénomènes liés aux problèmes de durabilité. Ce modèle peut aussi être utilisé pour l'étude des mécanismes d'hydratation eux-mêmes.

Différents modèles de cinétique d'hydratation du ciment et de mécanismes de réaction ont été testés avec μic . Il a été observé que quoique l'approche traditionnelle de nucléation et croissance pût expliquer l'accélération du taux de réaction lors de l'hydratation initiale, la décélération qui s'en suit ne pouvait être reproduite. Si un mécanisme contrôlé par un phénomène de diffusion est supposé pour expliquer la décélération, des changements de plus d'un ordre de grandeur des propriétés de transport du C-S-H doivent être admis. De plus, la variation du taux de la réaction évolue linéairement lors du passage du pic de chaleur et l'épaisseur

du C-S-H autour de particules de tailles différentes serait très variable au moment du changement de régime. Il est possible d'expliquer la cinétique d'hydratation durant les premières 24 heures en utilisant un mécanisme de nucléation et croissance si l'on suppose la formation d'un C-S-H peu dense. Il est proposé que ce C-S-H peu dense remplisse une importante part de la microstructure lors des premières heures de l'hydratation, puis que sa densité augmente par le moyen d'un processus de croissance interne. Il a été trouvé que la densité initiale devait être entre 0.1 g/cc et 0.2 g/cc pour reproduire le comportement expérimental observé. Quoique cette densité soit très inférieure aux bornes généralement acceptées, comprises entre 1.7 g/cc et 2.1 g/cc, elle peut expliquer l'absence d'eau dans les grands pores capillaires observée lors d'études utilisant la RMN sur des échantillons en condition humide, ainsi que la nanostructure fibreuse en rubans du C-S-H observée sur des images MET à haute résolution.

Cette étude démontre la versatilité de μic et le potentiel offert par la possibilité de modéliser différents phénomènes au sein d'un même modèle multi-échelle tri-dimensionnel, comme outil permettant une meilleure compréhension de l'hydratation du ciment. Il est également montré que l'usage de règles de nature mécaniste plutôt qu'empirique améliore le pouvoir prédictif des modèles.

Mots Clés: Microstructure, Modélisation, Architecture de modélisation, Approche vectorielle, Ciment, Alite, Hydratation, Cinétique, Mécanisme, Silicate de calcium hydraté, Densification

Acknowledgement

I would like to express my gratitude to all the people who helped me over the last three and a half years in the work leading to this dissertation. Firstly I would like to thank my supervisor Prof. Karen Scrivener for giving me the opportunity to work with her, for the regular (at times heated) discussions, for being a constant source of motivation (and at times annoyance) and most of all for being a great boss and an even greater sport from the first to the last day of this work. I thank EPFL for accepting me as a student and supporting me with a scholarship for the first year of the Ph.D. I thank the Swiss National Science Foundation for providing financial support for this research.

Thanks to all my colleagues at LMC for the all the great work and fun. Special thanks to my office mates Mohsen and Julien for all the great times (and stupid pranks), to Cyrille, the encyclopaedia of all useful (and lots more pointless) information, for all the stimulating discussions, to Kyle for bringing the much needed practical perspective (and prudishness). Thanks to Dr. Navi and Dr. Pignat for letting me work on their model and explaining its details. Thanks to Mercedes for letting me steal her experimental results and alite, and to Emmanuel for philosophising about these results. Thanks to Amor for the discussions. To all LMC colleagues for their invaluable help and support. Also thanks to all the different people who were willing to discuss my work during workshops, seminars and weekdays.

My love and thanks to my loving, caring and patient (and at times pestering) wife Ruchi for getting me through all the rough and the smooth, for always being there and supporting me no matter what, for being my best friend. Thanks to my parents for giving me the motivation to work and the freedom and support to be myself.

Chapter 1: Introduction

This study presents a new modelling platform called μic (pronounced Mike). This platform uses the vector approach in three-dimensions to model the microstructural development of hydrating cement pastes. μic uses the vector approach to represent the geometry of the microstructure. The efficiency of the vector approach was improved in order to enable simulations of millions of particles with the calculation of all interactions in the system. Due to its flexible design, the users of the platform can define custom materials, particles and reactions, and control the development of the microstructure by defining laws that define the mechanisms of the reactions. The versatility of μic allows users to model many different particulate growth systems not limited to cement hydration.

In this study the modelling platform has been used to model various possible hydration mechanisms and the applicability of these mechanisms has been tested by comparison with experimental results. The hydration kinetics of alite samples with different particle size distributions were simulated. The calculated results were compared against heat-evolution from hydrating alite samples measured using isothermal calorimetry. The results provide important information regarding cement hydration and highlight the gaps in our understanding of the underlying mechanisms.

One of the major problems in studying cement is the large number of interactions at work during hydration. This interaction happens between different materials and different particles at the same time. As most of these processes occur

at the micro-scale, they cannot be directly observed and indirect experimental techniques are used to study them. For example, while calorimetry is widely used to study the rate of hydration of cement, since only the total heat-evolved from samples is measured, the individual reaction rates of individual phases are not available. Similarly, while electron microscopy is widely used to study the evolution of cement microstructures, since most of the high-resolution techniques require a drying of the sample, the progress of hydration on the same sample cannot be observed.

Since most of our understanding of the mechanism of cement hydration depends on various indirect experimental techniques, the results are often open to interpretation. While most experimental techniques provide bulk-values of the properties, the underlying mechanisms occur at the micrometre or nanometre scale, interpretation of the link between mechanisms and properties requires simplifications regarding interactions which are difficult to test. However, with the continuous development of computational techniques, it has now become possible to numerically simulate these processes and to observe their macroscopic effects, which can be compared with experimental results.

Numerical models use combinations of fundamental processes to simulate systems and processes. The processes underlying these models generally define the behaviour of smaller discrete sub-systems and the interactions between these sub-systems. Since smaller and simpler elements of the system are considered, the behavioural laws are much simpler to formulate analytically and the task of integration of the behaviour of the entire system is left to the computer. Numerical models can, therefore, be used as an important technique, which works in a way complimentary to the experiments, in order to further our understanding of cement hydration.

Still, most of the currently available numerical models on cement remain empirical and highly dependent on experimental results. While this is not

surprising, given the wide range of parameters on which the properties of cements depend, these models can only serve a limited purpose in the advancement of our understanding of the processes underlying cement hydration. Empirical models are mathematical expressions that are designed to follow the experimental results and do not necessarily represent the mechanisms that control these properties. Even if used only for predicting properties for different conditions, empirical models are only applicable over a limited range of conditions and are hard to extend beyond this range.

For these reasons, the need for a numerical microstructural model which can incorporate customised mechanisms in simulations was felt. μic provides a modelling platform on which different theories concerning cement hydration could be explicitly modelled and studied. At the same time, μic provides an effective means to reconstruct numerical microstructures resulting from complex processes that occur at the level of individual particles. These microstructures can be analysed for the calculation of different properties, such as mechanical and transport properties in the case of cement.

The following chapters discuss the importance of numerical modelling in cement science, the development of μic and its features, and numerical studies of cementitious systems using μic . Chapter 2 discusses our current understanding of cement hydration and different approaches used thus far to understand and model hydration and microstructural development. Various microstructural models and their advantages and drawbacks are also presented in this chapter.

Chapter 3 presents the concepts behind the development of μic and its architecture. The typical procedure for defining a problem in μic has also been presented.

Chapter 4 demonstrates that while μic can be used to simulate hydrating cement microstructures using the traditionally applied laws on customary set-ups, it can also be used to model other, completely different, systems. It has also been

shown that microstructural models can be used to obtain both, the localised effects of bulk properties and the macroscopic effects of microscopic mechanisms.

In chapter 5, μic has been used to investigate hydration kinetics of alite. Rates of hydration measured from alite powders with different particle size distributions have been compared with computed results obtained from the simulation of different hydration mechanisms. It has been shown that some of the widely accepted mechanisms cannot explain the hydration kinetics of alite and new explanations of the observed behaviour are needed.

Chapter 6 presents the conclusions of the study and the perspectives for future numerical and experimental studies on cement hydration.

Chapter 2: Cement Hydration: Chemistry and Numerics

In this chapter, our current state of knowledge of cement hydration and the approaches used to understand it further and to model it are presented. In the discussion, some of the important aspects of hydration that are still not well understood are identified. It is seen that, while cement science has evolved considerably over the last century, many important aspects of hydration are still not well understood. While many advances have been made in modelling cement hydration, most of the existing models rely heavily on empirical results, often limiting the applicability of the models. Since the current work deals with alite hydration, the hydration of alite will be focussed upon in the following discussion.

2.1 Production, Composition and Hydration of Cement

Portland cement is produced by burning lime, clay and other naturally available minerals mixed in a kiln in large amounts at around 1450°C^1 . The materials partially fuse to form clinker nodules upon cooling. Clinker is chiefly composed of phases containing calcium oxide, silicon dioxide, aluminium oxide and ferric oxide, present with other minority components such as magnesium, potassium and sodium oxides. The nodular clinker is then mixed with a small quantity (typically around 5%) of calcium sulphate and is finely ground to produce cement.

For the sake of convenience, the names of most of the constituents of cement are abbreviated, as listed in table 2.1. The oxides in the clinker combine to form phases that constitute cement. For example, calcium oxide and silicon dioxide combine to form a modified form of tricalcium silicate, which is also known as alite and is the most important phase in cement. The other major phases present in cement are belite, aluminate and ferrite (table 2.2). The phases are not present in their pure form and contain ionic substitutions in their crystalline structures. Calcium sulphate is added to the clinker before grinding. Although typically referred to as gypsum, other forms of calcium sulphate may also be used.

Table 2.1: Abbreviations in cement science

Formula	Abbreviation	Formula	Abbreviation
CaO	C	SiO ₂	S
Al ₂ O ₃	A	Fe ₂ O ₃	F
MgO	M	K ₂ O	K
SO ₃	\bar{S}	H ₂ O	H

Table 2.2: Contents of Portland cement

Compound	Phase Names	Abbreviated Name	Typical amount
Tricalcium Silicate	Alite	C ₃ S	50-70%
Dicalcium Silicate	Belite	C ₂ S	15-30%
Tricalcium Aluminate	Aluminate	C ₃ A	5-10%
Tetracalcium Aluminoferrite	Ferrite	C ₄ AF	5-15%

Cement reacts with water in a process called hydration. With hydration, the solid volume in cement paste increases, converting cement into a stiff solid. The reaction products, called hydrates, give cement its binding properties and are responsible for strength development. In the following sections, the hydration of cement, and particularly alite, the development of its microstructure and its reaction kinetics are discussed in more detail.

2.2 Hydration of Alite

Alite reacts with water producing calcium silicate hydrate (C-S-H) and calcium hydroxide (CH or portlandite), as shown in equation 2.1.

This equation is not always exact as the composition of C-S-H is known to vary^{2,3,4}. Still, $\text{C}_{1.7}\text{SH}_4$ is currently assumed to be an acceptable approximation for the product¹. Portlandite is crystalline in nature and has a well-defined composition. It is known to grow either as massive crystals or as hexagonal platelets, depending on the pore-solution and cement composition^{5,6,7}. In Portland cement, belite also hydrates in a manner similar to alite, producing similar products, as shown in equation 2.2. Belite reacts only to a small extent in the early ages, and acts as a reserve for hydration at later ages⁸.

Within a few hours of mixing with water, cement paste starts to gain in stiffness and strength, going from a viscous fluid to a plastic solid to a stiff solid⁹. This change happens because the hydration products have a lower density than the anhydrous phases and occupy more space, filling most of the space created by the consumption of water and increasing the solid volume. C-S-H is the most important hydration product as it fills the largest amount of space in a hydrated cement and holds the microstructure together. A large number of studies on the development of cement microstructure, therefore, focus on the properties of C-S-H.

2.2.1 Models of C-S-H

The C-S-H in cement is often classified into inner and outer product. The C-S-H that occupies the space created by the dissolution of alite is usually referred to as the inner product and the C-S-H that grows in the space between the particles is called the outer product⁹. The values of the bulk density of C-S-H in the

Figure 2.1: The Feldman-Sereda model of C-S-H¹⁷, the circles show adsorbed water and crosses show inter-layer water

literature vary, mostly between 1.85 g/cc and 2.1 g/cc^{10,11,12,13}. While values of porosity of C-S-H found in the literature vary between 28% and 49%^{9,14}, it is generally accepted that inner C-S-H has a lower porosity than the outer C-S-H. The solid density of C-S-H has been reported to be between 2.5 g/cc and 2.8 g/cc^{14,15,16}.

There is general agreement on the development of a porous, gel-like, higher-density inner and a lower-density outer product, although the structure of C-S-H is still not clear and several models of C-S-H exist. Feldman and Sereda^{17,18} postulated a layered structure of C-S-H with water bonded between the layers of C-S-H and also adsorbed on the surface of the layers (figure 2.1). This model was based on nitrogen sorption and the observed length and modulus changes in samples at different moisture conditions. Daimon et al.¹⁹ made similar conclusions based on nitrogen and water-vapour absorption and made minor modifications to the model.

Based on surface-area and shrinkage measurements using different techniques, Jennings presented a colloidal structure for C-S-H^{20,21}, which is similar to the Powers model in many aspects⁹. According to this model, C-S-H exists as a fractal assembly of spherical globules, that are arranged in different configurations that control its density and the presence of two types of C-S-H was suggested²⁰ (figure 2.2). The variable density of C-S-H has been proposed in many earlier studies as well^{9,10}. In a later modification, the spherical globules were replaced by layered

Figure 2.2: Schematics of low-density (left) and high-density (middle) C-S-H according to Jennings model²⁰, and the modified globular unit²²

bricks, although they are still referred to as globules, in order to explain large irreversible changes resulting from shrinkage and creep²².

Although the exact chemical structure of C-S-H is not known, it is often compared to that of jennite and tobermorite^{3,25}. The molecular structure of C-S-H is beyond the scope of the current study, but it is noteworthy that C-S-H has generally been attributed with a layered chain structure with short-range crystallinity^{3,25,27}. This structure also manifests at the sub-micron-scale as in microscopic studies C-S-H has been described as a platy or fibrous^{3,6,23,28,27}. A

Figure 2.3: SEM micrograph of C_3S hydrating in paste (from de Jong et al.²³) (Left), and TEM micrograph showing low-density fibrillar outer and inner C-S-H in a mature cement paste (from Richardson²⁷) (Right)

Figure 2.4: Transmission electron micrograph of low-density product inside the shell (from Mathur²⁴). Pores are in black and materials in lighter tones in this dark-field image.

fibrillar C-S-H can be seen in many published micrographs (figures 2.3 and 2.4) and images resembling suspensions of fibrillar or foil-like C-S-H can also be found.

The fibrous structure of C-S-H has often been used to explain the development of mechanical properties in cement^{6,23,28,27}. It has been argued that the fibrous structures grow outwards from cement particles and get tangled, or join with the fibres from the other particles giving cement its mechanical properties^{6,18,28}.

The microstructure of C-S-H is still not well understood. All models of C-S-H suffer from different weaknesses and none of them can explain all observed

Figure 2.5: TEM image of inner product in a hardened cement paste resembling a colloidal suspension of fibres (from Richardson²⁶)

properties. But until the formation of C-S-H cannot be directly observed as it occurs, our understanding of its structure can only be limited to extrapolative interpretations of indirect experimental measurements.

2.2.2 Distribution of Hydrates

The main problem in understanding the development of cement microstructure lies in the fact that all the important processes in hydration happen on the microscopic scale and cannot be observed directly. A combination of various techniques have traditionally been used to study the hydration of Portland cement and many different theories regarding the mechanism of hydration and the structure of hydrates have been presented.

In their pioneering work on the development of cement microstructure in 1940s, Powers and Brownyard²⁹ presented a systematic study of cement hydration and the development of properties of cement paste. Although their experiments were largely limited to observed macroscopic phenomena, the theories postulated extended into the nano-scale. The authors carried out wide ranging experiments measuring properties such as compressive strength, bleeding rate, length-changes and weight loss due to drying and presented an extensive set of theories on the development of properties of concrete and cement. Some of the ideas presented in their work are still used practically^{30,31,32}.

In their study, cement microstructure was presented as a collection of spherical gel hydrate particles collecting around cement particles, leaving empty spaces which were called the capillary pores. A denser inner product, which constitutes around 45% of the total product, forms inside the original boundaries of the grains and a lower density outer product fills the space outside, binding the grains together. The inner product grows inwards and the outer product outwards from the original grain boundaries.

Figure 2.6: Drawing of cement microstructure for 0.3 w/c having a capillary porosity of 7%³³. Spaces marked 'C' represent capillary pores.

The gel was suggested to contain a water-filled porosity in the vicinity of 28 percent by volume and the water in these pores was referred to as the non-evaporable water. The spherical particles of gel were later replaced by ribbon-like fibres in line with microscopic observations. A drawing of the modified model is shown in figure 2.6. Powers also used this model to explain the mechanical and frost-resistance properties of concrete^{9,34,35}.

The Powers' model of cement microstructure was originally developed before high resolution electron micrographs of cement were available, but later microscopic observations reinforced and improved many of the ideas presented. For example, the spherical gel particles in the Powers model were replaced by ribbon-like fibres⁹ in line with electron micrographs presented by Grudemo^{36,37}, who was one of the first to study the microstructure of cement paste using electron microscopy. While there were some discrepancies between the early observations, most studies agreed with the growth of an outer product away from the grain and an inner product towards the hydrating particles^{6,38,39,40}. It was noted that no clear boundary between the inner and outer products was apparent⁴⁰.

While the microstructure can be affected due to sample processing before microscopic observations, the micrographs still provide important information about the development of the microstructure. Hadley⁴¹ observed the presence of shells of hydrates around cement grains, at a small distance, in SEM images of

fracture surfaces. The shells were observed to remain unfilled even after 28 days of curing. He also observed the growth of needle-like crystals, thought to be ettringite, inside the shells. In many cases the shells were found to be completely hollow, without cement grains inside them and these features were later named “Hadley Grains”. The presence of these hollow shells was later confirmed in other studies and the growth of products, both inwards and outwards, from this shell with hydration became the accepted mechanism of microstructural development^{42,43,44,45}. This also led to the conclusion that hydration takes place by the dissolution of anhydrous phases and their later deposition relatively far-away. Recent studies have shown that the shells are in fact not completely hollow and contain a fibrous low density product, which can only be observed at very high magnifications²⁴ (figure 2.4).

Using a combination of different electron microscopy techniques, Scrivener⁴⁴ presented the evolution of hydration (figure 2.7) as the formation of AFt (Alumino-Ferro-tri) needles around cement grains at the onset of hydration and the later deposition of outer C-S-H on these needles at a distance from the reacting particles, explaining the formation of hollow shells. Although at first it was suggested that these hollow shells are limited only to cements and are not observed in pure alite⁴⁶, recent studies have indicated the presence of shells and Hadley grains in the hydration of pure C_3S , where the only known hydrates are C-S-H and portlandite⁴⁷.

Figure 2.7: Evolution of a hydrating cement grain (after Scrivener⁴⁴)

It must be noted here that most samples for electron microscopy go through extensive preparation, usually involving drying, fracturing or polishing and impregnation in resin, which could alter the microstructure. Still electron microscopy is a powerful means to study processes that may otherwise not be visible.

2.3 Hydration Kinetics of Cement

Different phases of cement react at different and time-varying rates. As cement hydration is exothermic in nature, heat evolution measured by calorimetry is an effective method of following the overall progress of hydration. Figure 2.8 shows the typical heat evolution curve recorded using an isothermal calorimeter during approximately the first day of hydration of ordinary Portland cement. The curve is broadly divided into five stages.

The first stage gives a rapid evolution of heat for several minutes. This is generally attributed to the initial rapid dissolution of cement particles and a rapid hydration of the aluminate phase⁴⁸. A continuous low evolution of heat is observed in the second stage of the process. This stage is referred to as the induction period or the dormant period and, although the mechanism behind this period is disputed,

Figure 2.8: Typical heat evolution curve of Portland cement

it is apparent that there is some barrier to reaction before it picks up again in the next stage. In stage three, the reaction accelerates for a few hours before a peak is reached. The heat evolution subsides in the following hours in stage four and settles to a more constant value in stage five^{38,49,50}.

At any stage of hydration, the observed heat evolution might be the result of a combined reaction of more than one cement phase and it is difficult to isolate the contribution of individual phases. Although these phases might behave in a different way in isolation than in the presence of other phases in cement, studies on pure cement phases have provided valuable information about the reaction mechanism and kinetics of each phase in cement. Since alite, the primary phase in cement, is focussed upon in this study, the hydration of alite is discussed in more detail in the following discussion.

2.4 Stages of Alite Hydration

Figure 2.9 shows the typical heat evolution curve from the hydration of alite. As shown in the figure, the curve can be divided into five main stages, the commonly used names of which are listed below:

- Stage 1: Dissolution period,

Figure 2.9: Typical heat evolution curve of the alite phase

- Stage 2: Induction period,
- Stage 3: Acceleration period,
- Stage 4: Deceleration period, and
- Stage 5: Slow reaction.

2.4.1 Stages 1 & 2: Dissolution and Induction Periods

A large evolution of heat, generally attributed to the rapid dissolution of C_3S , which rapidly subsides within a few minutes, is observed in the first stage of the curve³⁸. It has been shown that the rate of dissolution in this stage depends on the particle size, crystalline structure and defects of C_3S ^{51,52}. Leading into the second stage, the rate of reaction slows-down considerably before a saturation with respect to the anhydrous phases is reached⁴⁸ and it has been proposed that the dissolution slows down due to saturation with respect to C-S-H⁵³. It has also been suggested that the reaction slows down due to the formation of a meta-stable layer of hydrates around the reacting particles^{38,54}.

The second stage witnesses a much lower heat evolution that can last for over an hour. Despite this stage being often referred to as the dormant period, a continuous heat-evolution is observed in this stage. This indicates that the reaction continues at a slow rate during this period.

The mechanism behind the second stage has long been a subject of debate. Possibly due to the shape of the evolution during the first two stages, which looks similar to the dissolution of salts nearing saturation, the induction period was at first attributed to saturation with respect to the anhydrous phases⁵⁵, but this was quickly rejected as evidence indicated much lower concentrations in the solution⁴⁸. The formation of an inhibiting or protective layer of early hydrates around the reacting particles, which is later breached, was suggested to slow down the reaction during the induction period^{54,56,57,58}.

Kondo and Ueda³⁸, and later Pommersheim and Clifton⁴⁹, presented the mechanism of early hydration of cement using mathematical models, where the induction period was explained by the formation of a protective layer on the surface of the particles and the subsequent acceleration was explained by the gradual erosion of this layer. These models are discussed in more detail in section 2.5.1. It was also suggested that calcium ions tend to dissolve faster than the silicate ions upon the initial hydrolysis of C_3S immediately after mixing with water and the adsorption of these calcium ions on the silica-rich surface layer could lead to a slow-down in the dissolution of C_3S ⁵⁹. Still, no conclusive evidence of the presence of any inhibiting layer has been reported and most arguments in its favour are speculative.

The poisoning of CH crystals by SiO_2 has also been suggested to cause the induction period^{59,60}. It has however been shown using dilute solutions of alite that the nucleation of portlandite can be repressed until the accelerating part of the reaction, indicating that CH crystals do not play a role in the induction period⁶¹.

It is now widely accepted that once the pore-solution is saturated, which generally happens during mixing, the nucleation and growth of C-S-H starts^{53,62}. According to this viewpoint, the induction period is not a separate chemical or physical process, and is observed because the rate of reaction, albeit accelerating, is too low to be measurable. This inference is also supported by the fact that induction period is found to be shorter for finer powders where the reaction in the third stage is faster^{56,63}.

2.4.2 Stage 3: Accelerating Reaction Rates

In the third stage the hydration accelerates until a peak is reached. As this feature is consistently observed in all studies and is, in all certainty, directly linked to the mechanism of the reaction, the reason for this acceleration has been, and continues to be, the subject of an extensive debate. The reaction rate and the

position of the peak is known to depend on the temperature and the particle sizes of C_3S ⁶⁴. The rate of reaction is also known to depend on the crystal structure and surface defects in C_3S ^{51,52}.

In most of the early work on hydration kinetics, the first four stages of hydration were explained using separate processes^{38,49,65}. As discussed earlier, Kondo and Ueda³⁸, and Pommersheim and Clifton⁴⁹, explained the acceleration in the reaction rate by the gradual deconsumption of a protective layer that forms early in the reaction⁵⁴. While many recent studies still propose similar mechanisms, no conclusive evidence to the presence of a protective layer is reported.

In 1970 Tenoutasse and DeDonder⁵⁰ suggested that a single mechanism of nucleation and growth could be used to explain the behaviour observed in stages 2 to 4. One of the reasons for this conclusion was that the Johnson-Mehl-Avrami-Kolmogorov equation^{66,67,68,69}, which models the nucleation and growth of solid nuclei in a homogeneous fluid medium, can be used to fit the observed rate of hydration for cement. Later studies verifying that this equation can be used to fit the rate of hydration in pure-alite^{56,64,70} and for Portland cement⁷¹ lent further credence to the possibility of cement hydration being controlled by a nucleation and growth mechanism.

The nucleation and growth mechanism is a demand based process and the rate of the reaction is not limited by the availability of reactants. In this process, germs of the product form and start to grow at a rate that is proportional to the surface area available on these germs. Since these germs can redissolve, they have to reach a minimum critical size over which growth is preferred to dissolution. The nuclei continue to grow at a rate proportional to their free surface area leading first to an acceleration in the process, and then a subsequent deceleration due to reduction in the available surface area resulting from impingement of neighbouring nuclei^{66,67,68,69}. This process results in an S-shaped evolution of the reaction similar to that observed in cement.

Based on the nucleation and growth mechanism, it was suggested that a slow nucleation of C-S-H occurs on the surface of alite particles during the so-called induction period. Once the nuclei reach a critical size the reaction accelerates, entering the third stage^{63,72,73}. While most authors have suggested the formation of a continuous layer of C-S-H forming over the surface of C₃S particles⁶³, it was recognised that increase in the surface area of the particles due to growth of particles could not account for the increased reaction rate. Studies have suggested the possibility of discontinuous growth of nuclei on the surface of the particles well into the third stage of the reaction^{53,74}.

Apart from slight variations, it is now generally accepted that the nucleation and growth mechanism is responsible for the observed acceleration in stage three. The reaction kinetics of alite during the nucleation and growth period are discussed in more detail in chapter 5.

2.4.3 Stages 4 & 5: Reducing Reaction Rates

In stage 4, the reaction rates slow down to almost half their value quickly followed by a slower reduction in stage 5 until most of the C₃S or water has been consumed⁷⁰. In most early studies, it was postulated that thickness of hydrates depositing over the cement particles increases with hydration and the rate of reaction is controlled by the diffusion of ions through this layer of hydrates. According to this theory, stage 4 occurs when a shift towards a diffusion controlled mechanism starts and in stage 5 the reaction is controlled entirely by diffusion and the availability of materials^{38,75}.

Some recent studies have indicated that the nucleation and growth mechanism can also be used to explain the observed behaviours until a few hours after the peak^{74,62}. In these studies, the reduction in the reaction rate is explained by the reduction in the available surface area for growth due to impingement between neighbouring nuclei, either from the same particle, or from the

surrounding particles. It has also been suggested that as the nucleation and growth process continues, the surface of the particles gets progressively covered by hydrates, leading to a diffusion controlled regime when the entire surface of the particles gets covered⁶¹. However, no conclusive evidence of this was found.

Only a limited number of studies focussing on these stages of hydration have been found and the reaction mechanism in these stages is still not clear. If a diffusion controlled regime is assumed, the point of transition from the nucleation and growth mechanism to diffusion controlled kinetics is also not clear.

2.5 Analytical and Numerical Models of Hydration Kinetics

2.5.1 Concentric Growth Models

Kondo and Ueda³⁸, and later Pommersheim and Clifton^{49,75}, explained the hydration kinetics of alite using mathematical models of suggested mechanisms acting due to concentric layered growth of hydrates over reacting spherical cement particles (figure 2.10). In both these models, an initial layer of meta-stable hydrates forms upon the first contact of cement with water. This “barrier-layer” of early hydrates slows down the reaction, leading to the so-called “induction period”. This layer dissolves or becomes more permeable with time leading to an acceleration in the reaction rate.

Figure 2.10: Schematic representation of hydrating C_3S grain in concentric growth models by Kondo and Ueda³⁸ (left) and Pommersheim and Clifton⁴⁹ (right)

With hydration the reacting core of the particle reduces and is replaced by an inner hydration product, which grows inwards from the original “barrier-layer”. Outside this layer an outer hydration product grows outwards into the capillary pore-space. Once the cover of hydrates around the particles reaches a certain thickness, the resistance offered to the reacting ions becomes sufficiently high to control the rate of the reaction, and the reaction shifts to a diffusion controlled regime. The relations used by the authors of these models can be found in the original works referred to above. Since each mechanism uses a different equation, the relation that predicts the slowest reaction rate any any instant in time is chosen as the governing mechanism.

Although these and other similar models were used to explain the hydration kinetics of alite for many years, experimental observations did not show the presence of a protective “barrier-layer” during the induction period or afterwards. Since the presence of this layer is crucial to the validity of these models, the validity of these models is often questioned. However, the idea of spherical cement particles with concentric growth of hydrates is still widely used to model various phenomena.

Various other simple mathematical relations have been developed to model chemical processes using the assumption of a spherical reaction front. While most of these models were developed for systems other than cement, they have been widely used to model cement hydration. For example, one such sigmoid relation, which was developed by Jander⁷⁶ for solid state reactions, has been used in various forms to fit the early evolution of hydration^{38,64}. One of the frequently used forms of this equation is shown in equation 2.3.

$$\alpha(r) = 1 - \left(1 - \left(\frac{kt}{r} \right) \right)^3 \quad (2.3)$$

In this equation α is the degree of hydration, t the time, k is the rate constant and r the radius of the particle. This equation models the formation of a thickening diffusion barrier on the reaction surfaces that slows down the reactions. Ginstling and Brounshtein⁷⁷ derived another expression to account for the reduction in the interfacial area between the reactants and the products (eq. 2.4).

$$1 - \frac{2}{3}\alpha - (1 - \alpha)^{\frac{2}{3}} = \frac{kt}{r^2} \quad (2.4)$$

A problem with using these relations with cement is that while most of these relations are derived for a single particle or for a powder with particles of the same size, cement is composed of particles of a wide range of sizes and these relations may therefore not be applicable to cement^{65,78}. In the models that choose between multiple mechanisms, such as the Pommersheim and Clifton model discussed above, the switch between different regimes could take place at different moments for different particles, which cannot be accounted for in single particle models. These relations could still be applied to polydisperse powders by adding the effect of individual particle sizes and it was also shown that the fit parameters in this case are not the same as in the case when the fits are made assuming a single averaged particle size⁶⁴.

Relations modelling similar mechanisms to explicitly consider the effect of different particle sizes have also been developed specially for cement^{79,80,81,82}. While these relations provided insight about hydration, since each equation is dedicated to a single hypothesised mechanism for which it is derived, the derivation, and even the use, of these relations may be cumbersome. Moreover, while these relations can be useful in studying systems where the reaction mechanism is understood, a good fit of experimental data with these equations does not necessarily mean that the mechanisms being studied are similar to those assumed for the derivation of the equation. In fact most sigmoid equations with sufficient number of parameters can be fit to cement hydration.

2.5.2 The Johnson-Mehl-Avrami-Kolmogorov Equation

The Johnson-Mehl-Avrami-Kolmogorov equation^{66,67,68}, more commonly referred to as the Avrami equation, was originally empirically derived by Austin and Rickett to model the decomposition of austenite⁶⁹. The later derivations of the equation modelled the rate of phase change in solidifying metal melts. Although this equation could also be considered a concentric growth model, it is being considered separately here because of its frequent use in cement. This equation models the nucleation and growth process, where small nuclei of the product form at random locations in the pore-space and grow to overlap and form a solid skeleton, at constant rates on all available surfaces. In the derivation, spherical isotropic growth of the nuclei is assumed, and the reduction in the surface area due to overlaps between neighbouring nuclei is accounted for statistically.

The most commonly used form of this equation is shown in equation 2.5, where α is the degree of phase change, t the time, and k and n are parameters that depend on the rate of reaction and the mechanism of growth of crystals respectively.

$$-\ln(1-\alpha)=kt^n \quad (2.5)$$

Figure 2.11: Schematics of overlapping spherical grains from Avrami⁶⁷

While this equation has often been erroneously used for systems with varying temperature, it is only applicable to isothermal systems. To study the rates of reactions, the equation can be differentiated to the form in equation 2.6.

$$\frac{d\alpha}{dt} = kn t^{n-1} e^{-kt^n} \quad (2.6)$$

Although in the original theory, n was defined to be an integer between 1 and 4, it was found that the value of n may be non-integral^{83,84}. Later, the parameter n was further defined in terms of three other parameters, P , S and Q as shown in equation 2.7.

$$n = \left(\frac{P}{S} \right) + Q \quad (2.7)$$

In this equation P is a dimensionality constant for the growth of products, being 1 for a one-dimensional growth, 2 for a two-dimensional growth and 3 for a three-dimensional growth. S is related to the rate-limiting mechanism, being 1 for interface controlled growth, where the creation of new surface controls the rate, and 2 for cases where the diffusion of ions to the growth sites controls the rate. Q depends on the nucleation rate, being 1 for a constant nucleation rate and 0 for cases where only an initial nucleation event occurs⁵⁶. This means that as long as the mechanism of a reaction remains the same, the value of n should stay constant for a reaction.

Tenoutasse and DeDonder⁵⁰ reported the first use of this equation to model cement hydration. Many researchers have since reported good fits of the equation with experimental results^{56,64,70,71} and the Avrami equation has become the most widely accepted relation used to model the early-age hydration kinetics of cement.

In the Avrami equation, the parameter k is a combined rate constant that can depend on many factors such as the rate of nucleation and the rate of growth, the diffusion in solution and the temperature of the system. In the case of cement,

this factor can depend on the temperature, the state of the pore-solution and the specific surface, and hence by extension the particle size distribution, of the cement, amongst other factors. Although some studies assumed a negligible effect of particle size distribution on hydration⁸⁵, it is generally accepted that the fit value of k in the Avrami equation is found to be higher for finer cements^{64,78}, which directly follows from the fact that finer cements exhibit higher reaction rates. However, a relation linking the variation of k to the particle size distribution or the specific surface area of cement can not be found in the literature.

Although the value of n in the Avrami equation should depend only on the reaction mechanism, wide discrepancies in reported values for cement and alite hydration can be found in the literature. While in the original application of the equation by Tenoutasse and DeDonder⁵⁰, 3 was found to be an acceptable value for n , later studies found n to vary between 2 and 3^{56,70,86}. Earlier, Bezjak and Jelenik⁶⁴ had suggested that the lower observed values of n could be due to misinterpretation of the Avrami parameters for poly-sized cement specimens. They pointed out that, in a poly-sized cement specimen, particles of different sizes react together and are at different stages of the reaction at any moment in time. This results in an overall behaviour that is a mixture of the overlapping of hydration mechanisms, making the interpretation of the Avrami parameters difficult. Consequently, the observed value of n could also result from a combination of different mechanisms acting together.

The use of the Avrami equation in cement has often been criticised. One of the important criticisms arising from the above discussion is that the use of this equation usually becomes only a fitting exercise, and the relationship between the fit-parameters and the material properties or the reaction mechanism is not clear. It has also been shown that the fits are not sensitive to the value of n and that with a variation in n , the data can still be fit by varying k ⁷⁰. The fits do not

provide any additional information than what can be obtained just by plotting the experimental results.

Another serious criticism to the Avrami equation is that while this equation was derived for systems where nucleation occurs at homogeneously distributed random locations in the system, in the case of cement it is known that the nucleation occurs heterogeneously, only on the surface of the particles^{50,70,74}. It was recently shown that a relation derived for cases where the nucleation is assumed to occur on a boundary⁸⁷ gives better fits to heat-evolution curves from cement hydration⁶².

Despite serious reasons for the Avrami equation not being applicable to cement, it is currently the most widely used equation to fit hydration-rates. This is probably owing to the simple form of the equation and that it only has two fit parameters. While these two parameters may not be sufficient to capture all the factors at play during cement hydration, they provide a simple means to compare different systems. Still, good fits with these equations do not necessarily imply that the actual mechanism in cement is similar to that modelled in the equation.

2.5.3 The Dijon Numerical Model for Boundary Nucleation

In order to better reproduce the conditions in real cements, Garrault and Nonat⁵³ developed a numerical model to simulate the growth of C-S-H nuclei on the surface of C_3S particles. In this model, nuclei of C-S-H form on a two-dimensional surface with periodic-boundary conditions to simulate closed continuous surfaces. At each step in the simulation, the nuclei grow both parallel and perpendicular to the surface. It was observed that good fits with experimental results can be obtained if the perpendicular growth rate is assumed to be higher than the parallel growth rate. The growth is simulated by generation of new C-S-H elements on the boundaries of the C-S-H elements already present on the surface.

Figure 2.12: Schematics of the nucleation and growth implemented in the Dijon model

The vertical growth is obtained by duplicating the C-S-H layers in the vertical direction.

The physics of this model have been based on AFM images that show an aggregation of nanometric thin C-S-H particles of similar sizes on the surface of C_3S particles^{53,88}. In order to obtain the values of the perpendicular and the parallel growth rates under different conditions, the model has been calibrated with experimental results obtained from hydration of alite particles in dilute lime solutions of different concentrations, where the rate of hydration and the concentration of the solutions was measured.

In this model, the induction period is modelled as the time taken for the formation of the nuclei, and the following acceleration results from the continuous increase in the surface available for growth. As the nuclei on the surface continue to grow they start to impinge on each other, reducing the surface for growth and hence the rate of hydration. This model predicts that in the early hours of the hydration, the surface of cement particles is only partially covered by hydrates and gets fully covered by hydrates after the peak of hydration.

It can be shown that if the Avrami equation is used to model the fraction of the surface covered at any moment in time, which is an example of homogeneous

nucleation in two-dimensions, the volume of product (V) on the surface can be written as equation 2.8 where A is the surface area of the particle, k_{par} the parallel growth rate constant, k_{perp} the perpendicular growth rate and t the time.

$$V = A \cdot \left(1 - \exp(-k_{par} \cdot t^2)\right) \cdot k_{perp} \cdot t \quad (2.8)$$

One of the critical drawbacks of this approach is that while the growth of nuclei is considered explicitly, the effect of inter-particle interaction is not considered. Since the setting of cement can mechanically occur only when the hydrates start to bind the particles together, the interaction between the hydration products from different particles starts before the set. In this model, although the reaction rate is modelled until times well beyond the observed setting times of normal cement, the interaction between different particles cannot be considered in the numerical system used in this model. Still, this model provides important information about cement hydration as the parameters obtained from this model are able to predict reaction rates in systems that are significantly different from those used for calibration.

2.6 Summary of Cement Hydration and Outstanding Questions

It can be seen from the above discussion that while tremendous progress in understanding cement has been made, many outstanding questions remain. In this section, the aspects of our knowledge relevant to this study and the pertaining questions are discussed. Since the current study focusses on alite, the discussion is limited to the points relevant to alite.

Although most of the reactant and product phases in alite hydration are known, discrepancies in the chemical composition of C-S-H exist. While the properties exhibited by cement indicate complexity in its structure, an accurate model of C-S-H structure is not available and descriptions of the product vary from colloidal to fibrillar. Fibres or suspension of fibres of C-S-H can be often

observed in micrographs, but the observations are at times inconsistent. As samples are dried before observation, the microstructure of the samples could be altered and the morphology of C-S-H is still not well understood. The density of C-S-H has been shown to vary and the exact range of this variation is not known. The fibres observed in micrographs could indicate the variation of the density over a wide range.

Even though the presence of empty hollow shells around cement particles has been widely accepted, recent results show that the shells are not empty and are filled with a low density product. This observation is contrary to the belief that the inner product is always “high-density”.

Compared to C-S-H, CH displays more consistent properties, but it hasn't been as extensively studied as C-S-H. The shape and size of CH crystals is known to vary, but their relationship with various controlling factors is not well understood. An early idea that portlandite might play an important role in reaction kinetics was later rejected.

While the hydration mechanism during the induction period is still not clear, it is generally agreed that the nucleation and growth of C-S-H controls the hydration kinetics. Nucleation and growth is a physical process depending on the shape and dispersion of a phase and proper understanding of the kinetics would require a better knowledge of the morphology of C-S-H.

The hydration mechanism after the peak of hydration and the point of shift from the nucleation and growth regime to a diffusion controlled regime is also not clear. Data concerning the post-peak hydration is limited and it is generally assumed that hydration peaks due to a shift to a diffusion controlled mechanism. However, the disperse nature of C-S-H observed in micrographs suggests high permeability for fluids and ions. Studies have also shown the possibility of the nucleation and growth mechanism explaining the post-peak behaviour.

Understanding hydration is critical to the progress of cement science and it is hoped that answers to some of the questions above are brought out in the current study.

2.7 Modelling Cement Hydration

The tremendous advances in computing technology in the last few decades have provided a great impetus to computer based scientific research. Increased speeds and availability of computers have made possible extensive numerical modelling of various extremely complex materials and processes. Computer based numerical models, at the same time, provide a methodology to study the anomalies and characteristic peculiarities of a material by allowing comparison of model derived values against those experimentally observed. The use of numerical modelling is arguably best justified for complex composite materials like cement, where simplified equation based models would entail over-simplification of the problem and would overlook some of the smaller features that could significantly affect the final result.

In the hundred odd year history of cement research, a number of studies have focussed on developing prediction models of cement behaviour. The compressive strength of cement has been the focal point of most of these studies and is still a critical parameter in determining the quality of a cement.

The mechanical properties of concrete vary over time, directly dependent on hydration and the development of cement microstructure. Mechanical strength of materials is known to reduce with increasing porosity and several relations linking the two have been proposed for different materials^{89,90,91}. On the basis of a wide experimental programme, Powers proposed an empirical relationship linking the gel-space ratio to mechanical strength of mortars⁹ (figure 2.13). The gel-space ratio is defined as the ratio of the volume of hydrates, to the volume that the hydrates can occupy and is therefore directly related to porosity.

Figure 2.13: Relationship of compressive strength with gel-space ratio (after Powers 1958⁹¹)

While this relationship might hold for one particular type of mix, it would be a gross generalisation to assume that the changes in arrangement and structure of porosity and the microstructure do not have a role to play. Figure 2.14, which compares the variation of compressive strength with porosity against Balshin's⁸⁹ model for different systems⁹², clearly shows that a mortar mix can have twice as

Figure 2.14: Experimental scatter of compressive strengths of different systems against Balshin's model⁹²

much mechanical strength for the same porosity, clearly demonstrating the importance of accounting for microstructure and not just the total porosity in the calculation of mechanical properties.

In recent years an increasing emphasis is being laid on durability based design. With the demands on concrete structures increasing rapidly, problems like corrosion, ion transport and other long term effects have gained focus in many studies and porosity and pore-connectivity have been found to be important parameters controlling deterioration. Since most of these effects are long term, only accelerated tests, whose accuracy is frequently questioned, are possible in laboratories. Furthermore, these phenomena are microscopic in nature and depend on three-dimensionally connected pores that are hard to study using the test methods currently today. Microstructural models can hence play a vital role in providing information that would be vital to understanding cement.

Given our current understanding of cementitious materials, no computer model can claim to accurately model cement paste. However, it is still possible to compute properties at various stages based on certain assumptions that, despite simplifications, maintain the essence of processes that lead to the formation of the material. These computed values can then be used both to predict the properties and to understand the processes underlying cement hydration, satisfying both engineers and scientists.

All models are by definition a simplified representation of the reality and are valid only in the range of assumptions and simplifications made during the development of the model. However, this does not in any way reduce the value of the models as long as the simplifications are made keeping the objective of the model in mind and the limitations are understood by the user. In fact every different assumption or simplification of a problem can be considered to be a different approach to the problem. Many different models and approaches to modelling cement have therefore emerged over the years and several of them are

still being developed. Some of these approaches are discussed in the following sections in chronological order. Since the current study presents a new microstructural model, mainly the currently available microstructural models are focussed on.

2.7.1 Numerical Models for Cement Microstructure

2.7.1.1 Numerical Concrete

Numerical concrete was one of the first attempts to model the mechanical properties of concrete as a composite^{94,95,93}. In this model two-dimensional sections of concrete with aggregates having spherical, polygonal or other arbitrary shapes were generated from statistical representation of three-dimensional specimens and

Figure 2.15: A meshed section from Numerical Concrete (after Sadouki and Wittmann⁹³)

meshed (figure 2.15). The finite element method was then used to calculate the mechanical properties of the samples. Although this model does not simulate cement hydration, the approach of analysing the properties of concrete as a composite material is note-worthy and numerically generated cement microstructures can be similarly analysed for mechanical or other phase-related properties.

2.7.1.2 Jennings and Johnson Model

Around the same time as numerical concrete, a three-dimensional model simulating the hydration of C_3S was developed by Jennings and Johnson^{96,97} working at the National Bureau of Standards (now known as the National Institute of Standards and Technology or NIST), USA. In this model the cement particles were represented as spheres placed inside a cubic specimen. Hydration was simulated as the reduction in the radii of the anhydrous phases and the concentric growth of C-S-H layers on the surface of these particles. CH particles grew as new nuclei formed in the pore-space. The overlaps between particles increased with hydration and were accounted for by redistribution of products in space (figure 2.16). It was noted that spheres have a significant advantage over other shapes in simulations due to computational factors. In the Jennings and Johnson model, all spheres were represented by the coordinates of their centres and radii. This approach of representing shapes using properties that are not limited by a resolution was later referred to as the continuum approach. This term, however, does not accurately represent the approach and can be confused with other disciplines such as continuum mechanics. For this reason this approach has now been renamed the “vector approach”. Due to limited computational power at the time of development, this model was not widely used and could not be developed further.

Figure 2.16: Microstructure (left) and adjusting for overlaps (right) in the Jennings and Johnson model⁹⁶

2.7.1.3 CEMHYD3D

Another model using a significantly different approach, known as the discrete or pixel approach, was later developed at NIST^{98,99}. In this model, called CEMHYD3D, the microstructure is stored as a grid of discrete three-dimensional cubic elements, called volume-pixels or voxels. Each voxel is marked as an anhydrous or hydrate phase or pore. The model uses the cellular-automata (CA) approach, which was developed in the 1950s by John von Neumann, with the help of his co-worker Stanislaw Ulam, to study biological self-replication¹⁰⁰. In the CA approach, at any step in the simulation, every cell (or voxel) in a system can have one of a finite number of pre-defined states and is allowed to update its state to another of the pre-defined states based on its neighbourhood.

In CEMHYD3D, the CA approach has been used to simulate the diffusion of species through the pore-water leading to reactions and precipitations as in figure 2.17. In the figure, the first set of pixels in dissolution and diffusion/reaction indicate the initial states of the pixels and the following three sets of pixels indicate the states after a movement of the pixel in the centre in the direction indicated by the arrow. In short, in this set-up, when a solid pixel attempts to move into water it dissolves, and when a diffusing specie moves towards a solid boundary it reacts.

Figure 2.17: Cellular automata as applied in CEMHYD3D for dissolution (top) and diffusion or reaction (bottom), black squares show solid phases, grey squares show diffusing phases and white boxes show water

For the development of this model, an extensive set of cement specimens was analysed using microscopy and other techniques. Properties such as particle shapes, distribution of phases and reactions were represented statistically for different types of cements. As the resolution of these analyses was limited to $1\ \mu\text{m}$, this is also the smallest possible size of a voxel in this model. The cellular-automata was then set up with the probabilities of events being derived from the statistical analysis. Spherical particles of sizes dependent on the mesh size are packed in a cubic computational volume and are assigned phases based on the input characteristics of the cement. The cellular-automata system is then started and species are allowed to undergo phase transitions according to the chart shown in figure 2.18.

CEMHYD3D is still one of the most widely used and well known models in cement today. The discrete approach is well suited for easy spatial distribution of different phases and representation of different shapes and faster calculations. Also, as the model is already in the form of discrete elements, this approach can be easily integrated with finite element methods for calculation of mechanical properties. Another advantage of this approach is that due to the regular nature of the mesh, most operations on the system are fast. Support of randomly shaped cement particles, reconstructed from X-Ray tomography results, has been also included in the recent versions of the model^{102,103}. The functionality of the model

Figure 2.18: State transition diagram for CEMHYD3D¹⁰¹

has been extended to calculate mechanical properties, early age properties and durability of different cement systems, largely based on empirical relations. However, the validity of using the rather coarse mesh, as in this model, for calculation of all these properties can be questioned.

Despite the computational advantages, the discrete approach suffers from several shortcomings when applied to cement. One of the most important problems in this approach arises from the fact the size of the smallest feature that can be represented in the computations is limited by the size of the voxel and features with sizes close to that of the voxel are represented less accurately. This shortcoming has important implications in cement as while the size of the voxels in this model is limited to 1 μm , real cement contains particles that are only a fraction of a micrometre in size. Given the large range of particle sizes in cement, if the size of the voxels were to be reduced to accommodate all sizes of cement particles present, the total number of elements in the system would be prohibitively large to analyse. Furthermore, as the size of capillary pores in cement goes down to 10 nm, a large part of the pore-features cannot be represented even with this large number of elements.

One of the major criticisms of CEMHYD3D is that because of the cellular-automata used in the model, very early into the hydration, cement particles disintegrate into single voxels and “diffuse” in the microstructure. Due to this no clear boundaries of cement particles remain and the system can be compared to a soup of voxels, whereas distinct boundaries of cement particles can be clearly seen in micrographs (figure 2.19). Being a microstructural model, the relative arrangement of phases in the microstructure is a property that should be preserved in the model. Another criticism of the model is that the cellular-automata scheme used prevents direct conversion of the simulation steps to time, necessitating empirical calibration with experiments. Also, while this model attempts to simulate

Figure 2.19: Comparison of an SEM image (left) to a slice from CEMHYD3D (right) at the same resolution

the diffusion of species in the microstructure, the correct representation of ionic movements is not possible at 1 μm scale.

When conceived CEMHYD3D was an important development, but its use has been extended beyond its capabilities, pointing towards the need for a new microstructural model that can take the recently acquired knowledge into account and to make proper use of the currently available computational power. The wide use of this model also shows the lack of simple user-friendly models in the field of cement.

2.7.1.4 DuCOM

A multi-scale model, called DuCOM, to model concrete has been developed at the University of Tokyo^{104,105}. This model has been developed as a finite-element package aimed at predicting the durability of structures based on semi-empirical relations connecting a large number of process parameters to the final properties of the structure. This model simulates the pore-sizes in cement based on the hydration of representative unit cells. Although this model is not a microstructural model, its development has been backed by a comprehensive experimental and analytical program presenting interesting co-relations between process parameters and concrete properties. This model also highlights the complexity of processes

underlying concrete construction and the importance of durability based design in structures.

However, this model depends almost entirely on empirical relations that have been calibrated to experimental results. Furthermore, the hydration is simulated using a single particle of cement. The median size of the particle size distribution of the cement is used as the size for this particle.

2.7.1.5 HYMOSTRUC

Using a vector approach similar to that used by Jennings and Johnson earlier, a microstructural model simulating the cement hydration was developed by van Breugel^{106,107}. In this model, the hydration of equally spaced cement particles is followed based on the assumption that reaction rate of a particle depends only on the particle size and not on its neighbourhood. As the particles react concentric layers of hydrates form around cement grains causing particles to grow and come in contact with each other (figure 2.20). In this model, the pore-size distribution is modelled assuming a logarithmic variation shown in equation 2.9.

$$V_{por} = a \cdot \ln\left(\frac{\phi}{\phi_0}\right) \quad (2.9)$$

In this equation V_{por} is the pore-volume, ϕ the size of the pore, ϕ_0 the size of the smallest pore fixed at $0.002 \mu\text{m}$, representing the boundary between gel-pores

Figure 2.20: Schematics of hydration in HYMOSTRUC¹⁰⁶; the hydration is simulated as the concentric growth of particles

and capillary pores, and a is the pore-structure constant that depends on the microstructure and was obtained experimentally.

The model was later modified to account for random parking of particles replacing the original assumption of equal spacing between the particles¹⁰⁸. In this extended version of the model, the pore-structure constant was determined by analysis of two-dimensional slices from the simulations. At the same time, the model was extended for calculating autogenous shrinkage based on the pore-structure using a combination of various empirical equations using pore-parameters calculated from the model. The specifics of how these parameters were extracted from the model are not clear. Another pixel-based method to analyse pores was later added to the model¹⁰⁹.

The authors of this model noted that if the hydration of every individual particle in the model were to be followed the computation would become too large and time-consuming to be carried out. So, only a statistical approach to reaction rates is used assuming that the reaction rates of the particles depend only on size. Since this model does not do any calculation of interactions or overlaps between particles, the microstructural information is not utilised in the simulations and the state at any step in the calculation can theoretically be calculated directly from the initial state, possibly using only semi-empirical equations and without using the microstructural information available in the model.

Furthermore, since the neighbourhood of particles is not considered for the calculation of reaction rates, although the overall progress of hydration for the system may be statistically justified, localised information at the level of particles, which is extremely important for microstructural properties such as pore-connectivity, is lost.

Another major criticism of this model is that only a single reaction product, the one that grows on the surface of the cement particles, is modelled, not accounting for nucleation of products in the pore-space. It is believed that

nucleation in the pore-space was not supported in the interest of performance of the programmes. Formation of outer product could be important to the microstructural properties of cement and limit the applicability of this model.

Since this model treats the entire microstructure in only a statistical fashion, localised information is lost and cannot be used for further analysis. For example, the analysis of pores and connectivity in this model, not to mention autogenous shrinkage, would be an attempt to invent information that is lost in the first basic simplification made in the development of the model. This approach is therefore not well suited to study the evolution of cement microstructure, or any property affected by the microstructure.

2.7.1.6 Integrated Particle Kinetics Model

In 1990s, the integrated particle kinetics model was developed at EPFL by Navi and Pignat^{110,111,112}. This model simulates the hydration of spherical C_3S particles using the vector approach similar to that used in the Jennings and Johnson model earlier. One of the important features of the this model is that, unlike in HYMOSTRUC, it simulates the hydration of every individual particle using kinetics laws that depend not only on the size of the particle, but also on the neighbourhood of every individual particle. This model also supports the nucleation and growth of new nuclei in the pore-space, away from the cement particles, instead of depositing the entire reaction product on the surface of cement particles. This is a more accurate representation of cement microstructure as growth of products away from cement particles is well known. In this model, the hydration of C_3S particles is simulated as shrinking of the reacting cores and the concentric growth of C-S-H on the surface of particles. The CH produced grows at new spherical nuclei forming in the pore-space at an exponentially reducing rate.

The reaction of individual particles is simulated using three reaction regimes, namely nucleation and growth regime, phase-boundary reaction and diffusion

controlled reaction. A typical Avrami-type equation has been used for the initial nucleation and growth regime of reaction. In the first step, as the Avrami equation only predicts the rate of hydration of the entire system and not individual particles, the equation was modified to model the rate of change of radii of particles as in equation 2.10, where r is the radius of the particle, t is time and k and n are coefficients from the Avrami equation (equation 2.8).

$$\frac{dr}{dt} = -r n k t^{n-1} e^{kt^n} \quad (2.10)$$

In the second stage, a phase-boundary reaction was modelled, where the rate of reaction depends on the surface area of the particles. In the third phase of the reaction, the rate of consumption of material is inversely proportional to the thickness of hydrates deposited on the surface of cement particles. All rates are corrected for the available surface area of individual particles. It has been noted by the authors of this model that the unique treatment of individual particles is computationally expensive using the vector approach. This proved to be a major obstacle to modelling cement hydration as the number of particles had to be limited to around ten thousand due to practical constraints, while a sample of real cement of 100 μm size can contain millions of particles.

Various numerical techniques for pore-characterisation were also presented by the authors. As a first approach morphological thinning of the discretised pore-structure was used to analyse the pore-sizes and connectivity¹¹³. A vector approach to modelling the pore-structure was later developed. In this approach, the pore centres were modelled by fitting spheres of largest possible sizes in every space between four particles, and neighbouring pore-centres were connected using tubes with diameters depending on the hydraulic radius of the connection between the pores¹¹². Although this is an extremely powerful technique that can capture the pores and the connections over all sizes important for cement, it was found to be computationally time consuming.

Due to the comprehensive treatment of the microstructure and the possibility to model multiple reactants and products using the approach used by Navi and Pignat, their model was chosen as the basis for the development of the new approach presented in this study.

The above list of models is not exhaustive and other numerical models simulating cement microstructure and other properties directly related to the microstructure can be found in literature^{114,115,116}. This list only broadly represents the approaches used by various researchers to model properties of hydrating cement paste.

2.7.2 Limitations of Currently available Models

It can be seen from the discussion above that our current computational capabilities in the calculation of the properties of hydrating cement paste are seriously limited. The most used model is more than a decade old, which is a considerably long period given the advances in computer science that have taken place over this period. The principles hard-wired into these models also reflect the ideas from the same period and are often out of date. These ideas also tend to be biased towards the opinion of the developers. Most models choose the path of oversimplification in the interest of performance, either by compromising some of the critical properties of cement, such as its multi-scale nature, or by ignoring some of the useful microstructural information that is available in the model. The model that was recognised to provide a comprehensive treatment of all the information available and was the closest to cement, is also limited due to performance issues limiting its usability to only small simulations.

Another important factor limiting the current models is the availability of knowledge concerning cement hydration. As has been seen in the earlier discussion in this chapter, many aspects of cement hydration that are crucial to the development of microstructural or hydration models are still not understood. Still,

most of the currently available models have built-in laws and mechanisms that cannot be easily modified. This “hard-wired” approach to modelling makes models obsolete the moment any theory used in the model is found to be inaccurate or insufficient.

2.8 Current Study

The current study presents a new microstructural modelling framework, called μic , which derives its basics from the Navi and Pignat approach. Although the Navi-Pignat model was limited to the hydration of C_3S , it contains all the necessary features for extension to any type of cementitious system. This is mainly due to the fact that since the hydration of each particle is simulated, multiple cement phases can be included in the hydration. Also, since this model supports nucleation of products in the pore-space, away from the cement grains, any type of hydration product can be modelled. Although the vector approach is known to be computationally expensive, the fact that it does not depend on a resolution makes it suitable for modelling a multi-scale material like cement. For these reasons, the principles used in the Navi and Pignat model were used as the basis for the development of μic .

μic addresses the performance issues associated with the vector approach and it has been developed as a modelling platform which has not been hard-wired with any mechanistic, chemical or physical information, enabling the simulations on μic to evolve as our knowledge of cement evolves. μic is aimed at improving our understanding of cement by enabling the users to observe own new their ideas at work in four-dimensions.

Chapter 3: μ ic the Model

A new modelling platform, called μ ic (pronounced Mike) has been developed to model the microstructural evolution of hydrating cement paste. Deriving its basics from the Navi and Pignat model¹¹⁰, which uses the vector approach, μ ic has been developed as an engine for modelling particulate reactions and can be used to model the hydration of many different cementitious and other particulate systems. In this chapter, the ideas behind the development of μ ic and its main features are discussed. The model has the primary short-term objective of aiding, rather than replacing experiments, therefore the complexity of cement hydration and the gaps in our current understanding of cement are kept in mind.

3.1 Why a Microstructural Model

Before being mixed with water, concrete is a mixture of granular material with no cohesive properties. As cement hydrates, it acts like glue, holding together the different grains in concrete. Hydrated cement paste is the most porous and also the most chemically active part of concrete, making properties of concrete highly sensitive to cement microstructure. Understanding cement microstructure and its variation over time is therefore of utmost importance.

The mechanical properties of concrete vary over time, directly dependent on hydration and the development of cement microstructure. Mechanical strength of materials is known to reduce with increasing porosity and several relations linking the two have been proposed for different materials^{89,90,91}. On the basis of a wide experimental programme, Powers proposed an empirical relationship linking the

gel-space ratio to mechanical strength of mortars⁹ (figure 2.13). It would be, however, be a gross generalisation to assume that the changes in arrangement and structure of porosity and the microstructure do not play a role. It has been shown that the large variations in mechanical strengths between different mixes with the same porosity can be found⁹². The microstructure, therefore, plays an important role in the mechanical properties of cement paste.

While mechanical strength continues to be the most important factor governing concrete design, durability concerns are gaining increasing importance as many countries face the problem of ageing infrastructure. Cement microstructure plays an even bigger role in durability. A majority of durability related problems are associated with ion and mass transport through the pores and hence depend on pore-properties. Microstructural modelling can play an important role in modelling the transport properties of cementitious systems providing a valuable method for predicting durability.

Another important application of microstructural models lies in understanding cement science. Cement microstructure evolves over time with hydration as different phases, present in particles of different sizes, react to form different hydrates and intermediate products at varying rates. The extent of different reactions are generally difficult to isolate as most experimental techniques depend on indirect measurements and many aspects of hydration are still poorly understood. Since it is possible to treat different phases and cement particles separately in a model, microstructural modelling can prove to be an effective tool to study the process of hydration and to test the accuracy of hypothesis concerning microstructural development. Microstructural modelling has therefore an important role to play, not only for prediction and practical applications, but also in bridging the gaps in our knowledge of cement science.

3.2 Requirements from μic

μic has been designed as a framework for highly customisable simulations of particulate reactions. The vector approach, which is a resolution-free method for representation of geometrical information, was implemented using object-oriented programming in Java. While the model was designed keeping in mind the special requirements for cement, the framework can be used to model a wide variety of particulate reactions.

For the design of any model, it is important to first identify the requirements from the model. Since models are by definition a simplification of the problem, the requirements from a model affect the simplifications and assumptions that can be justifiably made in order to satisfy these requirements. The following sections discuss some of the requirements from μic and the simplifications used in the model in the course of satisfying these requirements.

3.2.1 Extensibility

Even as cement science continues to progress at a tremendous pace, many aspects of hydration are still not well understood. Since models generally involve large number of assumptions and simplifications, the capabilities of models are generally limited to the information available to the developer and newer findings can quickly render a model outdated and of little use. Additions to models due to both, the advances in science and the introduction of newer materials, would require regular extensive developments to the models, which are not always practically possible. Extensibility was therefore considered an essential feature during the design of μic . The model was designed to allow users to input and test their own ideas in simulations, making experimentation with the model possible. This unique feature of μic can make it an important tool for understanding cement chemistry.

3.2.2 Ease of Development

As it would be unreasonable to assume that the model will not require future development, the model has been designed in a programmer-friendly manner, with object-oriented programming in Java. The programmes make the task of editing and development by different and multiple developers easier as the programmes are segmented into smaller modules, resulting in smaller sized, easier to maintain programmes. Java was chosen as the programming language as it is considered to strike the right balance between ease of learning and power. Being a modern language, Java contains all the necessary features and built-in libraries to support advanced development. Java is also known for encouraging better coding practices, resulting in easier-to-read codes. The syntax of Java is easier to learn, making it ideal also for researchers without much prior experience in programming. Furthermore, Java is a platform-independent language, and its compiled programmes can be executed on most operating systems and hardware platforms. Although many programmers question the speed of execution of Java programmes, the advantages of Java were considered to outweigh this limitation and Java was chosen as the language for the development of μic .

3.2.3 Multi-scale Microstructural Representation

Particles of cement extend over a wide range of sizes, from over a hundred micrometers to just a fraction of a micrometre and particles of all sizes play an important role in the progress of hydration and the development of the microstructure. So, in order to correctly simulate the evolution of microstructure,

Figure 3.1: Dimensional range of solids and pores in a hydrated cement paste

it must be possible to represent particles of all sizes in the model. *mic* uses the vector approach in order to preserve the multi-scale nature of cement as it has the advantage of being relatively resolution-free. The vector approach is discussed in more detail later in this chapter.

3.2.4 Performance

It was considered important that problems of significant size be solved within reasonable amounts of time. Performance is an important requirement from the models, specially since the vector approach is known to be computationally expensive. The manner in which the information is usually stored in the vector approach makes the calculation of interactions difficult and time-consuming. The performance issues associated with the vector approach were dealt with, as an integral part of the design of the model. These issues are discussed in more detail in later sections.

3.2.5 Accessibility

As *mic* has been designed as an experimentation tool, easy accessibility is an important feature required from the model. Keeping this in mind, the model has been designed for use on normal desktop computers. This is an important requirement from the model since access to large work-stations is generally limited. In order to encourage a wider use of the model, emphasis was given to more advanced and efficient algorithms, rather than parallelization, to enhance the performance of the model. Simulations on larger work-stations and mainframes are still possible owing to the platform-independent nature of Java.

3.3 The Vector Approach

The vector and discrete approach are the two main alternatives for representation of geometry. In the discrete approach, the geometrical information is represented using an assembly of simpler shapes. The computational volume can

be modelled more closely to the actual geometry as the elements become finer. This, however, increases the number of elements that have to be modelled and, in most cases, a trade-off is made between the size of the problem and the accuracy of the representation. While the size of the computational volume would depend on the size of the largest particle in the system, the size of the mesh would depend on the size of the smallest particle to be modelled. As the sizes of cement particles vary over more than four orders of magnitude, the proper representation of all particles could necessitate meshing the computational volume using from billions to trillions of elements. As problems of such large sizes might not be possible to solve due to practical and computational limitations, only a limited range of particle sizes is generally modelled when this approach is used.

Even if a high-resolution representation of cement were to be possible, the information about a large fraction of capillary pores will be lost (see figure 3.1), reducing the usefulness of the simulated microstructure.

In vector approach, the features to be modelled are represented by their location, size and shape information. This way all features can be represented in the computational volume, independent of their size. Using the vector approach,

Figure 3.2: Slices from the same cubic microstructure using the discrete approach with 1 million pixels (left) and using the vector approach (right)

the size of the problem in the memory depends on the number of features to be modelled, as opposed to the number of mesh elements in the discrete approach. For example, in cement, the particles can be represented as spheres of known radii and centres, making the representation of particles of a wide range of sizes possible, thereby preserving the multi-scale nature of cement.

The vector approach is known to be computationally expensive due to the manner in which the information is usually stored. The main problem lies in the calculation of interactions, for example the calculation of overlap between two spheres. In the discrete approach, phases are represented as elements that are stored as three-dimensional arrays with neighbouring elements being stored in neighbouring locations of the array. This makes calculations of interactions with neighbours fast as all information about the neighbourhood is instantly available. However, in the vector approach, only the locations and sizes of the particles are available and the simplest approach to calculate overlaps would be to calculate the distance of every sphere from every other sphere. This means that the number of calculations required to check for all interactions can be written as in equation 3.1, where n indicates the number of particles.

$$\text{number of checks} = \frac{n(n-1)}{2} \tag{3.1}$$

While for a small number of particles the number of checks is small and can be easily handled, as the number of particles increases, the number of checks required increases approximately as the square of n , seriously affecting the performance of the approach. Earlier models using this approach have used different simplifications in order to bring the performance of this approach to practically acceptable levels. Some of these simplifications are discussed in the following sections.

3.3.1 Possible Assumptions in Vector Approach

3.3.1.1 Spherical Assumption

The first important simplification used by most models using vector approach is the representation of all particles as spheres^{106,110,114}. Being the most regular geometrical shape, computations of geometrical features and interactions are fastest with spheres, making them the most suitable shape for the purpose of modelling. Handled correctly, the effects of this simplification can be easily managed and need not significantly affect the results.

One of the features of spheres is that they have the smallest surface area to volume ratio of all shapes. While this artificially reduces the specific surface area of the samples, it can be easily accounted for numerically, and is therefore not considered a significant restriction. Another, less manageable problem, is that the use of any predetermined regular geometrical shape for the development of hydration will affect the shapes of boundaries between phases. While this might affect the results, the use of irregular shapes in vector approach would make the problem computationally too expensive for practical applications.

Any simplification in a model need not cause too many problems as long as the user of the model is aware of and accounts for the limitation and its possible implications. In this case, the main effect of the shapes is seen on the shapes of the pores and artificially created angular contacts between particles. Depending on the application, these features can be accounted for and smoothed out. Based on these considerations, the spherical approximation was considered acceptable for μic .

3.3.1.2 Statistical Homogeneity

In order to avoid the computationally expensive calculation of interactions, in some models, the localised effect of geometry is ignored and only a statistically calculated global correction is applied¹⁰⁶. However, since this models aims to allow users to calculate the overall effect of localised laws input at the level of particles,

the explicit calculation of the interaction between particles was considered an important requirement from the model. Also as the model is expected to provide information about pores and pore-connectivity, localised information is an important output from the model. The assumption of statistical homogeneity was not considered acceptable and μic was built with support-libraries to enable fast calculation of interactions.

3.3.1.3 Reduced Particle Size Distributions

As shown in equation 3.1, the number of checks required in the model depends on the number of particles, so one of the approaches used to make simulations practically manageable is to reduce the number of particles by reducing the size of the computational volume or increasing the size of the smallest particle, thereby redistributing the volume of the smaller particles to the larger ones^{110,114}. However, since local geometries are important in μic , the effect of smaller particles cannot be ignored. The fine particles have an important effect on the pore-sizes and connectivity (see section 4.1.3).

As μic will be used to study the progress of hydration, in which the smaller particles have an important role to play, specially in the early part of the reaction, these particles cannot be ignored and have to be modelled explicitly. By discarding the finer particles in cement, the main advantage of the vector approach, that with it we can model particles of all sizes, is lost. The possibility to model all particle sizes explicitly was considered an important requirement from μic .

3.3.2 Vector Approach as Used in μic

In μic , hydrating cement particles have been represented as spheres that are assigned a radius and an initial position inside a cubic computational volume using random parking. Simple user-invokable routines have been provided to simulate flocculation and to achieve high-density packings using progressive flocculation during random-parking (figure 3.3). It must be noted that typical unhydrated

Figure 3.3: Slice from a volume with 84% of the volume filled with solids, obtained by progressive flocculation

cement samples contain less than 50% by volume of solid content and high-density packings are rare.

Products can form as concentric layers over the particles or as new nuclei in the pores. Consumption of material from a particle is represented by a reduction in the radii of the spheres or the concentric layers and growth by an increase in the radii.

As hydration progresses, particles grow and impinge upon each other. At each step in hydration, the surface of each particle is sampled to calculate its interactions with other particles. This can be done in two ways, either by using a regular triangular grid on the surface of the spheres, or generating uniformly distributed random points on the surface, as shown in figure 3.4. The latter approach was found to be more efficient with acceptable accuracy, and was used in *µic*. Interactions and available surface areas of the particles are calculated by finding if these sampling points lie inside other particles. The deposition is carried out in such a manner that new material grows only on the available surface of the

Figure 3.4: Surface sampling using regular triangular grid¹¹⁴ (left) and using random sampling points^{117,118} (right)

particle. As the particles grow they continue to fill the empty space in the matrix and the microstructure evolves.

Since the spheres overlap, there are parts of the microstructure that lie inside more than a single sphere, although in reality the space can be occupied only by a single particle. If it is required to identify the particle in which a point lies, when it lies inside more than one sphere, one would have to go through the history of the evolution to check which particle occupied that space first. This can be important in applications where the resulting microstructure is required to be discretised into elements.

The only simplification of the vector approach used in μic is the spherical approximation. As even with the use of this approximation, earlier researchers have found computing times to be too large to be practically acceptable, in the first part of the development of μic , the enhancement of the vector approach, to bring its performance to practically acceptable levels, was focussed upon. As many features of the model depend upon these enhancements, they are an integral part of the development of the model. The methods used to improve the performance are discussed in section 3.3.3.

3.3.2.1 Periodic Boundary Conditions

This model uses the periodic boundary conditions for the representation of information. The size of samples simulated is small, typically around $100\ \mu\text{m}$ cubes. In reality, specimens of these sizes are not practical even if possible. So, the computed volume only represents a small computational volume element of the real material. This means that the boundary of this volume would pass through many particles. This effect is represented well in the periodic boundary conditions as particles are allowed to cross boundaries and re-enter the volume from the opposite side, avoiding the wall effect. The periodic boundary conditions make the calculations a bit more complex since now particles can overlap after crossing boundaries. This is illustrated in figure 3.5, where the square 1 shows a two dimensional example of a periodic volume. So, the real specimen can be supposed to be of infinite size and composed of these smaller elements tiled next to each other in all directions. The figure shows the tiles in the immediate neighbourhood of the primary volume.

In order to find the sphere closest to the surface of sphere A in the set-up in figure 3.5, the coordinates of the centres of the spheres cannot be directly used. The sphere closest to the surface of sphere A in this set-up is in fact sphere C with its centre in volume 6. So, in order to find the closest sphere, the centre of sphere A has to be compared with spheres B and C in all nine volumes and that of sphere A in volumes 2 to 9. However, in most cases, this problem can be simplified. In

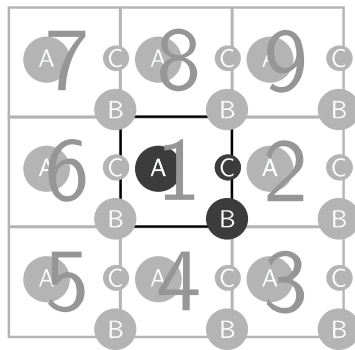

Figure 3.5: Schematics of periodic boundary conditions in two-dimensions

this case, if the absolute values of the individual components of the vector between the centres of the two spheres are not more than half the side of the volume the smallest distance between the two spheres is the length of that vector. If any component has an absolute value greater than half the side of the cube, it can be subtracted by the side of the cube to get the required value, simplifying the calculation of the shortest distance between two spheres.

3.3.3 Algorithms for a Faster Vector Approach

Since the calculation of free-surfaces was, speed-wise, the most critical step in the hydration simulation, the first objective was to speed up the process of locating overlaps between spheres. For this different new and previously employed methods were compared. All these methods were developed using object-oriented programming. In object-oriented programming, the representation of values as objects allows storage of the same information in multiple collections without significant memory overhead. Advanced data-structures, that are an integral part of the programming languages, provide tools to organise and efficiently retrieve information. For example, in this case, the information about reacting particles can be stored in different lists ordered, say, by grain sizes or by grain coordinates. These lists contain only references to centrally stored information and so provide fast access to information without redundancies. Furthermore, since the actual information is stored only at a central location, inconsistencies are avoided. If a change in the information is routed through one of the collections, it is reflected universally. So, data-structures effectively provide tools to overcome problems posed by the storage of information in vector format and ease the development of efficient algorithms.

3.3.3.1 Verlet Lists

In 1967, Verlet introduced a list technique that significantly speeded up simulations of particles with short term interactions¹¹⁹ and is still widely used in

molecular dynamics simulations. In this method, lists of possible interactions of particles are generated before the simulations start, and may or may not be updated during the simulations depending on the application. In the case of hydration, this means the creation of a list of all the other particles that could possibly overlap at the end of hydration, for each particle. A conservative estimate of the growth of each particle is guessed. Now all the particles that could potentially lie in this zone, based on their conservatively guessed final sizes, are added to the list of possible neighbours. The lists are generated keeping in mind the periodicity of the volume.

Using these lists, the comparison between spheres can be limited only to the neighbours and a significant reduction in execution times can be achieved. However, this approach is suitable only for a limited number of particles. With each particle potentially having thousands of neighbours, the memory consumption in this approach again limits the maximum number of particles in the system.

For the use of Verlet lists, the maximum possible size of the zone of possible interactions has to be guessed. All interactions that lie beyond this range will not be recognised. In cases where new particles are formed, the lists would have to be updated at every step in the simulation, leading to additional computational costs. This only provided a minor improvement in the performance of the model to about 40,000 particles.

3.3.3.2 Bounding Box Lists

This new method was developed in this work to allow the use of dynamic, global lists to calculate interactions. In this method, three ordered global lists, one for each of x, y and z axes, are created. Each particle is present at two positions in each of these lists. If the list corresponds to the x axis, the positions of a particle depend upon the lower and higher x bounds of the sphere. That is to say, if the x coordinate of the centre of a sphere is x and its radius is r , the value of $x + r$ and

$x - r$ for each particle is calculated and the list is sorted in the order of these values. These positions are corrected for the periodic boundary conditions. An example of the list in the x direction in two dimensions is shown in tables 3.1 and 3.2. Table 3.1 lists the coordinates of eight spheres in a periodic volume and along with their bounds along the x -axis. The primary volume is a square with one edge at the origin ($x = 0$ and $y = 0$) and a size of 100, with its sides oriented along the Cartesian axes. Each sphere is placed in the ordered list twice based on the value of the two bounds as in Table 3.2. This list can help in quick identification of particles present in a narrow zone. For example, if all the spheres that lie between the x coordinates of 35 and 65 were to be identified, they can be found by locating the bounds 35 and 65 in the list in table 3.2, which are indices 5 and 7, inclusive, respectively. Some spheres might be present in duplicate in this list depending on whether the sphere is completely inside this zone.

Table 3.1: Calculation of bounding x values of spheres

Sphere No.	Radius	x	y	$x - r$	$x + r$	Primary($x - r$)	Primary($x + r$)
0	14.20	98.24	31.55	84.04	112.44	84.04	12.44
1	13.20	23.10	83.94	9.90	36.30	9.90	36.30
2	12.55	27.30	49.56	14.75	39.85	14.75	39.85
3	12.29	25.06	5.08	12.77	37.35	12.77	37.35
4	12.05	92.45	0.32	80.40	104.50	80.40	4.50

Table 3.2: Order of particles in the bounding box list along x axis from data in table 3.1

Index	0	1	2	3	4	5	6	7	8	9
Sphere No.	4	1	0	3	2	1	3	2	4	0
Bound	4.50	9.90	12.44	12.77	14.75	36.30	37.35	39.85	80.40	84.04

These lists are also periodic, meaning that they can be treated as connected in a circular fashion. If one of the bounds of the zone in question lies outside the primary volume, the bound can be translated to the primary volume and the first index in the list can be considered to follow the sphere at the last index. For example, to find the particles in the zone between x coordinates 80 and 110, the

spheres between 80 – 100, and 0 – 10 can be used, as the coordinate 110 can be mapped to 10 within the primary volume.

In three dimensions, three global lists can be created, based on x, y and z coordinates. To identify all spheres in a smaller cube, three sets of spheres based on the three global lists have to be obtained and the common spheres in the three lists have to be identified. A major limitation of this approach is that spheres larger than the width of the zone being checked may be ignored if both their boundaries lie outside the zone. This reduces the efficiency of this approach in a system like cement where the particle sizes vary over several orders of magnitude. While identifying spheres in the bounding box around smaller particles, the larger particles might be ignored. This can be worked around by starting the identification of the interactions from the larger particles and storing the interactions of larger particles with smaller ones for later use. A minimum size of the search box may also be set based on the largest particle in the system. This, however, should not be a problem in systems where the sizes of spheres are in the same order of magnitude.

This approach has been implemented with object-oriented programming in `µic` using standard data structures available in the Java development kit (JDK). Using bounding box lists, it was possible to improve the capacity of the model to around 200,000 particles, above which the computational times for the set operations may be too slow.

The advantage of this approach is that only three global lists have to be stored, reducing memory requirements. Furthermore, these lists are more dynamic in nature as they can be re-ordered after every step of simulation, based on their new positions and sizes, without much processor overhead. This approach can be more useful in applications like molecular dynamics, where the particles simulated are allowed to move and are more closely sized.

3.3.3.3 Grid Subdivisions

This approach uses the principles behind the discrete approach to improve the performance of the vector approach. A cubic grid is overlaid over the vector microstructure with each cube containing a list of spheres that lie in the cube. The search for neighbours can be limited to a smaller number of cubes in the grid. To identify the spheres overlapping with a sphere, the distance of the sphere needs be compared only with the other particles that lie in the cubes that the sphere occupies. For example in figure 3.6, when looking for the overlaps with particle 1, particle 3 can be ignored as it does not share a grid square with particle 1.

This approach has also been implemented with object-oriented programming and was found to be the most effective approach for cement with the capacity of the programmes improved to around 3,000,000 particles for desktop computers. Simulations with over tens of millions of particles can be carried out on workstations and mainframes.

When using this approach, it is important to optimise the size of the mesh. If the size of the mesh is too large, the volume would be divided into a small number of cubes and the number of spheres per cube would be large. When searching for neighbours, too many spheres that are outside the zone of interest are returned and the effectiveness of the method is reduced. While smaller cubes also consume higher memory, they also slow down the computations. The identification of

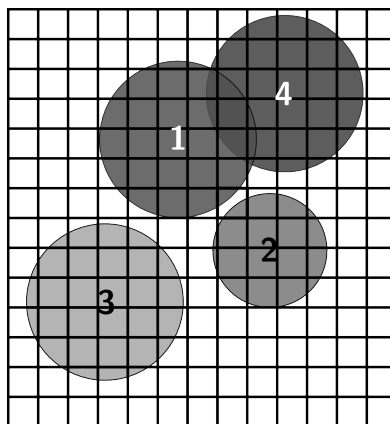

Figure 3.6: A grid of cubic pixels is overlaid on the vector information in *mic*

neighbours of a sphere requires collection of all spheres present in the cubes in which the sphere lies. If the number of elements is too large, it will be required to go through a larger number of cubes in order to collect all the neighbours and the computation time is larger. The time required for maintenance is also larger for a larger number of cubes. Good performance was found when the median radius of a continuous particle size distribution was used as the grid size.

3.3.3.4 Result of Improvements

The grid-subdivision method was found to be best suited for simulation of cement pastes. Since the simulation generally involves growing particles over a large range of sizes, while updating the lists, the earlier occupants of each element need not be cleared and only the new spheres need to be added. As the Navi and Pignat model¹¹⁰ was used as a starting point for μic , a summary of the improvements in the vector approach achieved in the new programmes compared to the Navi-Pignat model is listed in table 3.3.

Table 3.3: Summary of improvements in the vector approach

Navi and Pignat model¹¹⁰	μic
Procedural programming in Fortran	Object-oriented programming in Java
10,000 particles in a few days	3,000,000 particles in a few hours
$\text{time} \propto n^2$	$\text{time} \propto n \cdot \log(n)$
Platform: Unix workstations	Platform independent

3.4 Modelling Cement Hydration

Modelling hydration of cement is a complicated problem. The main problem in modelling cement hydration arises from the complexity of the process and the fact that many aspects of hydration are not well understood. This means that during the design of the model, not only the information available currently, but also possible developments in the future have to be kept in mind. Not only is it, therefore, required that easy developments on the model be possible, but also that extensions may be added to the model at run-time to change the mechanisms of

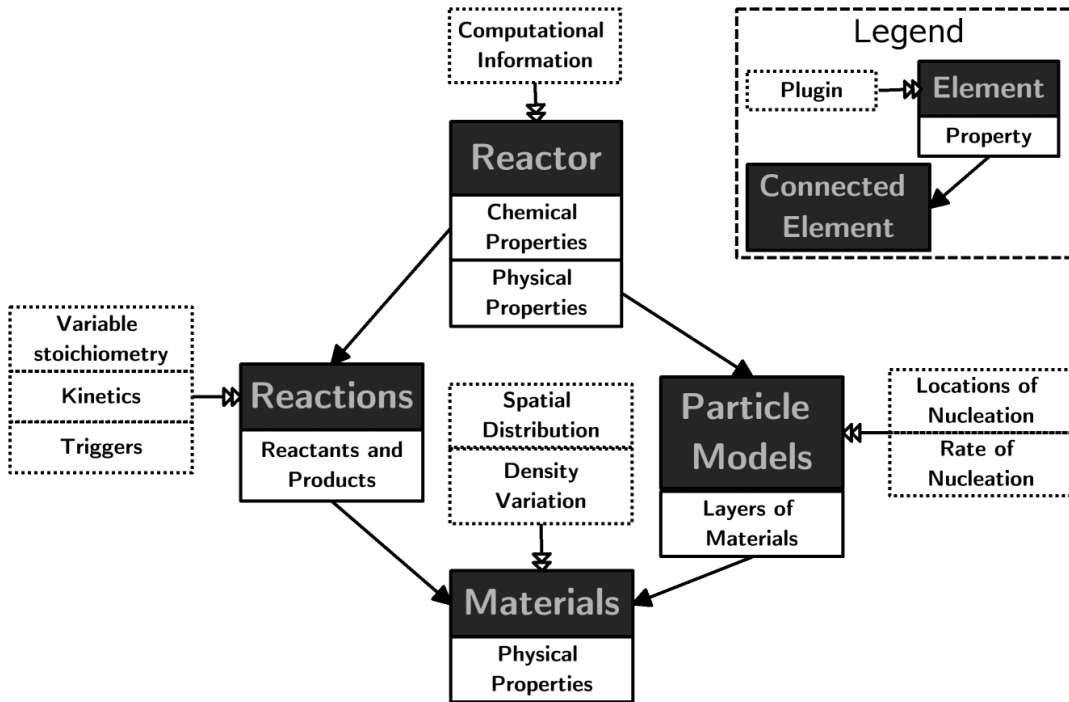

Figure 3.7: Elements with examples of customisable properties and plugins in the Cement Hydration Toolkit

reaction, without the user having to change the structure of the programmes. This is why, the Cement Hydration Tool-kit (CHT) was developed to provide a flexible framework for the simulations. Object-oriented programming was found to be indispensable for the development of the tool-kit.

The idea for this tool-kit was derived from commercial FEM packages where users are given the flexibility to define the properties of materials, design the specimens and even specify behaviour laws as equations. This flexibility is currently not available in other microstructural models of cement and most models are limited by the knowledge of the developer. The existing models are based on fixed laws that control the microstructural development of cement, limiting the control of the user only to certain parameters. The CHT is designed to allow users to define materials with customised properties and reactions. Many of these features have been implemented as plugins. Plugins are programmes that can be compiled separately from the model and can be provided as inputs at execution

time. The users can choose from a wide range of available plugins, or create their own plugins to control mechanisms of microstructural development. The various possibilities considered during the design of the tool-kit are discussed in the following sections.

3.4.1 Materials and Reactions

Cement, which itself is composed of many reactive species, is often used in combination with other reactive additives and the proportions of different components is variable. The most common approach used to model the effect of different materials is through the use of a pre-defined library of materials, the proportions of which can be changed. This, however, limits the model only to the materials that are existent and known at the time of development, and the task of adding new materials to the model would be difficult as it would require development in the programmes. It was therefore sought to allow users to define different materials at execution time. For this purpose, the model was provided with a generic implementation of materials with customisable properties and the user can define both reactants and products to be modelled in the simulations. During simulations, the model treats each material separately according to the user-defined properties of the materials.

The functionality of customisable materials is completed by the possibility to define customised reactions. Multiple reactions can be defined in the model having different materials as reactants and products. Since the order of execution of the reactions can change the course of the simulations, the order in which the reactions are to be executed at each step should also be defined. Other possibilities for customising reactions are discussed later.

3.4.2 Cement Particles

As the hydration of cement progresses, layers of products form over the reacting particles and new clusters grow in the pore-space. The properties of the

progressively formed layers at both locations may vary with time depending on various conditions. While each cement particle can contain a mixture of various phases, the cement may also be blended with other particulate materials, such as pozzolans. At the same time, hydrates can form new clusters in the pore-space. This implies that the particles and clusters in the microstructure can be divided into different categories depending on possibility of materials being present in the particles and the number of layers of products being formed.

In order to allow the model to account for this variability in the number and properties of layers, the model has been provided with a generic implementation of spheres which can have any arbitrary number of resizeable layers, containing different materials, and simulations can contain multiple types of such pre-defined particles in the system. As calculations in a generic implementation can be unnecessarily expensive, specialised implementations for many cases usually found in cement have also been provided. Some of the specialised cases considered common in cement are listed below.

- Unreactive single-layered particle, e.g. for inert fillers,
- Single-layered particle, e.g. for portlandite clusters in pore-space,
- Two-layered particle, e.g. for reacting cement particles with a layer of hydrates,
- Three-layered particle, e.g. for reacting cement particles with layers of inner and outer products, etc.

In order to reduce the complexity of the inputs, once the complete problem is defined, the process of choosing the right implementation for any specific case is done automatically by the model. The users are also allowed to choose the required implementation according to requirements.

In the problem definition, the user has to define “models” for all possible types of particles. The definition of the models involves the definition of all the

Figure 3.8: Different particle types with multiple layers in a single simulation on μic

possible layers of materials in each type of particle. These models are then used by μic to generate particles at the beginning or during the simulations.

3.4.3 Reaction Kinetics

The reaction kinetics of any system depend on the mechanism of the reaction and can depend on many different parameters. Since the exact mechanism of hydration is not well understood, most information on reaction kinetics currently available depends on empirical relations or fitting of relations that were developed for other systems, such as crystal growth in the case of the Avrami equation⁶⁷, the most widely used kinetics model in cement. At the same time, the presence of other species can affect reaction rates and change the mechanism of the reaction. One of the important objectives of μic is to aid in better understanding cement hydration and the development of mechanism-based laws specific to cement. This is why it is important to allow the users of the model to input reaction kinetics, that can depend on different parameters available in the model.

In *µic*, reaction kinetics have been designed as plugins to reactions that can be compiled separately and given as input. In this way, users can develop relations based on reaction mechanisms, using the information available in the model, and test their applicability using *µic*. Reaction kinetics are only one of the possible plugins in the model, and the other aspects of plugins are discussed in more detail in the following sections.

As it is also possible that some reactions be triggered only on the occurrence of certain events or when certain conditions are fulfilled, the model also allows users to define triggers or stoppers for reactions, that can affect the activity of reactions or materials.

3.4.4 Distribution of Materials

Cement grains generally contain a mixture of several phases, while some other phases can be present as separate particles, for example in the case of pozzolans. In cement factories, several centimetre sized nodules of clinker are crushed to produce cement, which generally contains a wide range of sizes of particles. The size of the particles formed can depend on many process parameters, such as the duration of grinding, and the properties of the phases. As some phases may be harder than the others, they may tend to be present in higher proportions in the larger particles. This means that the initial composition of every cement particle may be different and depend on many parameters. *µic* therefore allows the user to control the distribution of phases in particles.

3.4.5 Density Variation

The density of some hydrates, for example C-S-H, is known to increase in some parts of the microstructure with the progress of hydration. As this means that the mass to volume ratio of the product is variable, the microstructure can be by different amounts from the same mass of product. Densification was therefore considered an important factor in the design of materials. In *µic*, the user can

define densification laws that can control the density of the products formed. Again these laws can be based on any of the information available to the model.

3.4.6 Mechanisms of Microstructural Evolution

Cement microstructure evolves with the production of different hydrates that precipitate at various locations. While some products grow on the surface of the reacting particles, others have a tendency to form new clusters in the pore-space. At the same time, hydrates may also tend to grow on the surface of other particles in the system, for example on inert fillers that may be blended with cement. Also, the proportions of materials depositing at different places may vary depending on various parameters. For example, whereas for some processes, the rate of growth of a product may depend on the surface area available on a particle, for some other process it might depend on the proximity to the reaction site. As the distribution of products in the microstructure plays an important role in microstructural evolution, *mic* was designed to allow the user to control all different possibilities of product distribution.

In the case of products growing from nuclei formed in the pores, the evolution of the microstructure can be significantly affected depending on the rate of formation and growth of these nuclei. Therefore, in *mic*, nucleation rates can also be controlled.

It is known that during hydration, cement phases first dissolve as ions and then react to form hydrates elsewhere. In some cases it may be desirable to use the spatial information available to create localised zones of reactions. In *mic*, the user is allowed to build groups of particles that can react together or affect the reaction rates of each other. However, while using this feature it should be kept in mind that since calculation of interactions and distances can be computationally expensive, these calculations should be minimised.

3.4.7 Specific Workarounds

It can be seen from the above discussion that the structure of the programmes can become quite complicated due to the high level of flexibility provided to the user. While this improves the performance and the capabilities of the model, a good balance between functionality and complexity is required to ease any future development of the model. This is why, some parts of the model were intentionally restricted, when it was thought that any problems due to these restrictions can be worked around using other features present in the model or through new simpler features. Some of these restrictions and their workarounds are discussed in the following sections.

3.4.7.1 Multi-Phase Grains

The presence of multiple phases in particles poses a big problem in modelling. Clinker is formed by fusing of different phases together into nodules, and even after grinding, clear boundaries between different phases present in single particles can be observed. However, due to the high computational costs of the vector approach, it is difficult to mark boundaries between phases in multi-phase particles. This is why, in the model, each layer in a particle is considered to be composed of a homogeneous distribution of different phases. In this way, many phases can be distributed in varying proportions in different particles, which can

*Figure 3.9: Assumption of a uniform distribution of materials, without clear boundaries, throughout the layer as implemented in *mic* (left) as against materials with clear boundary demarcation (right)*

be controlled by the user. In the model, every particle keeps track on the amounts and densities of various materials present in every layer.

3.4.7.2 Universal Materials

As it is possible that some reactive species, for example water or dissolved species, may not be present as particles, the model allows definition of “universal” materials. These materials are not allocated space in the microstructure and are assumed to be present in all available space, as opposed to the “discrete” materials that are assigned space in discrete particles. These materials can be consumed or produced in reactions, in a way similar to discrete materials as the model keeps track of the amounts and densities of these materials in the system.

3.4.7.3 Material Variants

In order to simplify implementation of the model, the presence of discrete materials has been restricted to only a single layer in a single particle model. So, in order to allow the growth of the same or similar material at different types of locations, the model allows users to define variants of a material, which may be present elsewhere. Material can be redistributed between variants by creating reactions which only convert one variant of a material into another.

For example, in the case of hydration of C_3S , part of the C-S-H produced, called the inner C-S-H, can grow on the surface of the reacting particles, while the other part, called the outer C-S-H, can form new clusters in the pores. So, outer C-S-H and inner C-S-H can be defined as variants of the material C-S-H and can be redistributed at separate locations.

3.4.7.4 Recalculations and Runtime Redefinitions

As it may be desirable to produce different variants of a material from the same reaction, the amounts of the variants produced may change at each step of the calculation. In order to control the proportions of the variants produced, the

user can change the properties of a reaction before every step of calculation. In fact this feature can be used to make any arbitrary changes in the system as it also allows a user to execute any code before the execution of the next step.

3.4.8 Plugins

Most of the features discussed above have been implemented as plugins, so that users can write small programmes to control the simulations, compile them separately from the model and give them as input to the model during execution. This feature of run-time plugins was only possible because of the “reflective” nature of objects in Java. As instead of being executed directly on the processor, Java programmes are executed on the Java Virtual Machine (JVM), which in turn is executed on the processor, much more information about the process and the programme itself is available to the programme. This allows the programme to access specific parts of the programme chosen dynamically at run-time. In this way, the control-flow of the programme can be moved to code that has been separately loaded in the JVM and is not a part of the original programmes.

The main plugins and their functions in the model are summarised below.

- Particle Proportion Initialisers control the proportions of different materials in particles,
- Reaction Kinetics control reaction rates,
- Reaction Triggers control the activity of reactions,
- Densification Profiles control variation in density of materials,
- Nuclei Generators generate new nuclei for products growing in pores,
- Material Distribution Profiles control redistribution of products over particles,
- Particle Group Choosers control groups of particles that affect reactions of each other,

- Particle Distribution Profiles control the distribution of available space in particles to different materials, and
- Recalculators can be used to make changes to properties of reactions, etc. before each step of simulation.

It can be seen from the above discussion that since the user can control most of the possible mechanisms in a reaction, μic can be used to simulate practically any particulate reaction. A drawback of this approach is that the model requires a large number of inputs and at first the definition of the problem might be cumbersome. However, most input can be reused making definition of future problems simpler. An example definition of a problem is presented in the following section.

3.4.9 An Example Problem definition

The hydration of alite containing an unreactive material in the presence of inert filler particles are defined here as an example. CH and C-S-H are the main products produced from the hydration of alite. While CH generally grows nuclei formed in the pores, a large part of C-S-H grown on alite particles, while the rest can grow over nuclei in the pores. In the presence of inert fillers, part of the C-S-H produced can grow on the surface of the filler particles.

Since the reaction mechanisms of such a system are still not well understood, some assumptions are made for the sake of this example. The C-S-H can grow at three locations, over the reacting particles, in the pores and on the filler particles and the first part of C-S-H is assumed to replace the reacting C_3S . The remaining C-S-H is redistributed over the filler particles, cement particles and new nuclei. The definition of the problem is discussed in the following sub-sections.

3.4.9.1 Materials

The materials are defined based on the requirements of the simulation. Six materials, namely C_3S , water, filler, an unreactive phase mixed in C_3S , C-S-H and

CH, can be clearly seen to be present. Due to the presence of C-S-H at multiple locations, the material has to be split up into five different variants as listed below.

- Variant A – is the inner product that takes the place of the reacting C_3S ,
- Variant B – grows on the C_3S particles outside the original bounds of the particles,
- Variant C – grows on nuclei forming in the pores,
- Variant D – grows on the surface of the filler particles, and
- Variant E – is a temporary material buffer for C-S-H to help redistribution of the product, as is presented later.

The initial amounts and base densities of the materials are defined at this stage. As the model simulates the evolution of geometries, all amounts are dealt in volumes rather than masses. Figure 3.10 shows the different variations of C-S-H in this example.

3.4.9.2 Particle Models

The particle models are then defined as spheres made of layers of materials defined concentrically outwards. In the current case four particle models have to be defined as listed below.

- Model 1 – cement particles with C_3S , C-S-H A and C-S-H B,
- Model 2 – filler particles with filler and C-S-H D,
- Model 3 – CH particles nucleating in the pores with a layer of CH, and
- Model 4 – C-S-H particles nucleating in the pores with a layer of C-S-H C.

As the variant E of C-S-H is only a temporary storage place for redistribution, it is not assigned space in the microstructure and is defined as a universal material. The unreactive material is defined to be dispersed in C_3S and is automatically assigned to model 1. For all models that contain materials that are present in the system at the start of the reaction, the initial particle size

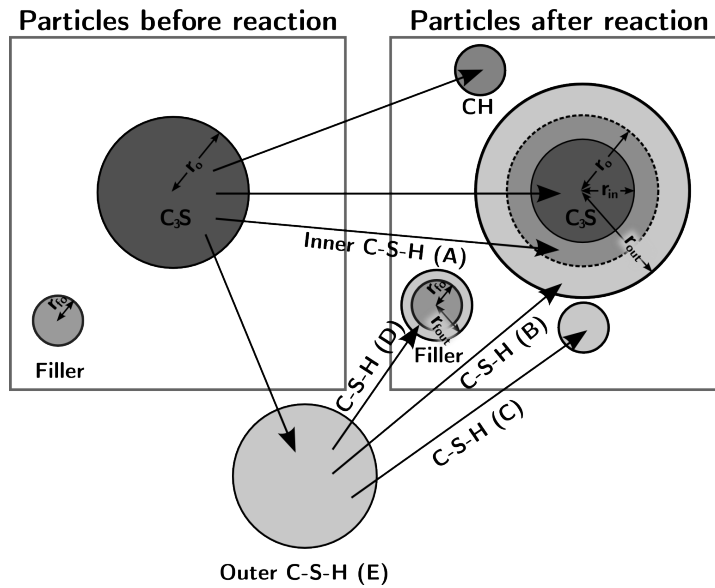

Figure 3.10: Schematics of the example set-up showing different materials, material variants and particle types

distributions are defined. Figure 3.10 shows the different particle-models defined in this example.

3.4.9.3 Reactions

Multiple reactions can be defined to consume different materials in specified volumetric ratios. In the current case two reactions are defined. The first reaction has water and C_3S as reactants and CH, C-S-H A and C-S-H E as products. This means that as the reaction progresses, the space created by the consumption of C_3S is immediately filled by C-S-H produced from the same particle, while some more C-S-H is produced to be redistributed to other locations.

The second reaction defines the rules for redistribution of C-S-H E. As this C-S-H has to be distributed to three types of models, the reaction has C-S-H E as the only reactant and C-S-H B, C and D as products. Although arbitrary initial proportions for the three types of C-S-H have to be defined, the proportions of products forming in this reactions will have to be changed at every step of

simulation, based on the surface area available for each variant of the product. This is done using a plugin and is discussed later.

3.4.9.4 Reaction Kinetics

Reaction kinetics are defined as plugins that calculate the rate of consumption of different materials in a reaction based on various information available in the model. Several kinetics, based on different possible mechanisms, can be defined for a reaction. The kinetics giving the slowest rate is assumed to control the reaction. The controlling kinetics are determined individually for each particle at each step in the simulation. The user is allowed to control the switch between mechanisms by preventing the control to switch back to an earlier mechanism. This is done by assigning different levels to kinetics, and the reaction mechanism is not allowed to switch to kinetics that have a level that is lower than the current mechanism.

For example, if the hydration of C_3S is split into nucleation and growth controlled regime and diffusion through hydrates controlled regime, the regimes are calculated separately for each particle. So by defining nucleation and growth kinetics to be at level 0 and diffusion controlled kinetics to be at level 1, particles are not allowed to calculate their reaction rates from the nucleation and growth kinetics once diffusion controlled reaction has started for that particle.

The second reaction, which controls the redistribution of the C-S-H, also has to be plugged in with kinetics. As C-S-H E is only a transient storage location, kinetics to convert all available C-S-H E to the other three forms at each step of simulation have to be defined.

3.4.9.5 Plugins Controlling Microstructural Formation

For this example, several plugins have to be defined to control the evolution of the microstructure based on well-defined rules. The first plugin sets the initial proportions of the C_3S and unreactive materials in cement particles. As the

unreactive material is interspersed with C_3S , each C_3S particle can contain a different proportion of C_3S and the unreactive material, as defined by this plugin.

The next set of plugins controls the rate of formation of new nuclei forming in the pores, in this case CH and C-S-H C. This plugin calculates the number of new nuclei to be generated at any step in hydration and asks the model to assign locations to these nuclei.

Another more important set of plugins redistributes C-S-H E to the variants B, C and D. The first plugin of this set is a “recalculator” that adjusts the proportions of the different types of C-S-H formed from the second reaction after calculating the available surface area for each type of C-S-H. After the production of different types of C-S-H, each variant has to be distributed on the surface of the particles of each type already present. For this another plugin has to be defined for each variant of C-S-H to calculate the proportion of the generated variant for each particle where that variant is allowed to grow.

As the CH produced from the reaction also has to be distributed over a large number of CH nuclei present in the pores, another plugin, similar to the ones used to redistribute each variant of C-S-H, has to be defined to complete the definition of the problem.

As can be seen from the description above, in μic , the user is allowed to control a large number of parameters and mechanisms, making the creation of inputs a rather long process. In many cases default implementations for plugins are provided in the model, but still given the complexity of cement hydration, these complex definitions cannot be avoided. The input files created for one problem can be later reused to be extended for other problems.

3.5 Output from the Model

The customisability of μic can allow users to simulate a variety of growth mechanisms (figure 3.11). The output from the model is in the form of the

geometry of the microstructure at each step of simulation. This geometry can be used for further analysis, for example for mechanical properties or pore-properties. Information about all materials in every particle and in the entire system is also available. Most experimental results from cement are valid for bulk-samples and localised information that can be more useful for understanding the science behind processes is lost. This model can prove to be a useful tool for researchers as, using a bottom-up approach, laws that govern local or short-term behaviour can be input to the model, and the overall effects of these laws on the entire system,

Figure 3.11: Examples of various growth mechanisms that can be simulated with μic

which can be compared to experiments, can be studied, after accounting for the large number of interactions that occur in a complex system like cement.

Chapter 4: Simulating Microstructures using μic

In this chapter, μic has been used to study some simple systems to demonstrate how a microstructural model, and especially the versatile, high-performance architecture of μic can be used to study cementitious and other particulate systems. In these examples, the model has been used not only to simulate the microstructure, but also to explore growth kinetics that depend on the microstructure. In the first set of examples, traditionally used hydration rules are applied to demonstrate the significant effect of particle size distribution on the microstructure. In the second set of examples, a simple fibrous growth mechanism is investigated and growth kinetics and fill-fractions are calculated using the model.

4.1 Traditional Microstructural Simulations: Particle-Sizes

In the following examples, alite samples with different particle size distributions are simulated according to rules earlier used by Pignat¹¹¹, as summarised in the following sub-sections. It must be noted that the rules listed below are customisable in μic and have been used as input only for the current simulations, in order to reproduce conditions traditionally simulated, especially those used in the Navi and Pignat model. The simulations shown here demonstrate the influence of the particle size distribution on microstructure.

4.1.1 Mechanisms and Rules

4.1.1.1 Generation of Particle Sizes

The particles are generated from the particle size distribution input by the user. The distribution can be input either as discrete sizes with the fraction of particles of this size or smaller than the size, or as functions describing the particle size distribution. If discrete sizes with fractions are provided, a linear variation between these sizes is assumed. As the size of the volume is usually taken to be at least two and a half times the size of the largest particle, it is assumed that the size of the computational volume is sufficiently large to represent the entire particle size distribution. The total volume of the powder is calculated from the water to cement ratio and the size of the computational volume. The first particle is assumed to have a size equal to the largest point in the particle size distribution. With the inclusion of this particle in the volume, the fraction of the powder remaining and the equivalent radius for this fraction is calculated from the given particle size distribution. Another particle of this radius is generated and the process is continued by recalculating the fraction of the powder that remains to be generated. This process is continued until the required volume of particles is obtained.

To explain this process, if the cumulative fraction of particle below the size r is given by the function $f(r)$, and the inverse of this function, which gives the size of the particle below which a fraction f of the powder falls, is defined as $r(f)$, the size of the next particle to be placed (r_{n+1}) is determined by the equation below, where V is the total volume of particles to be placed and n is the total number of particles already placed.

$$r_{n+1} = r \left(1 - \frac{4\pi}{3V} \sum_{i=1}^n r_i^3 \right) \quad (4.1)$$

4.1.1.2 Reaction Stoichiometry

As microstructural models simulate the variation of geometry of the microstructure, it is convenient to represent reactions in terms of volumes rather than masses. The hydration of C_3S (equation 2.1) is rewritten in volumetric terms in the equation 4.2. as presented by Pignat¹¹¹. Here the density of C_3S is assumed to be 3.15 g/cc, 1.0 g/ml for H_2O , 2.0 g/cc for C-S-H and 2.24 g/cc for CH.

While the volume of CH formed per unit volume of C_3S reacting was reported as 0.596 in the original work by Pignat, 0.593, which was found to be a more accurate value based on the densities mentioned above, is used here.

4.1.1.3 Nucleation of CH Particles

As portlandite forms new clusters in the pore-space, the number of portlandite clusters and their rate of formation has to be known. In the model by Pignat, the final number of CH clusters was assumed to be a fifth of the number of particles of cement, based on data from Jennings and Parrott¹²⁰. The number of clusters is assumed to grow according to equation 4.3. The value of a was calculated to be 0.213 from the data by Jennings and Parrott.

$$n(t) = n_{max} \cdot (1 - e^{-at}) \quad (4.3)$$

4.1.1.4 Distribution of Reactants and Products

The reacting alite particles are packed as spheres in the volume. As C_3S reacts, the radius of the reactive core of the particle reduces. C-S-H deposits on the surface of the reacting C_3S particles and CH forms new clusters in the pores as discussed earlier. Since the volume of C-S-H produced is larger than the amount of C_3S reacting, the empty space created by the consumption of C_3S and some additional space outside the particles is filled by the C-S-H produced. Figure 4.1 shows the schematics of the reaction for a particle. In the figure r_o is the original

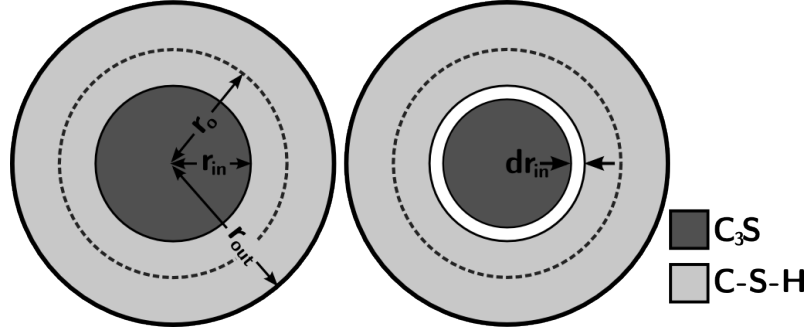

Figure 4.1: Layer of C-S-H on C_3S particles (left) and reaction of C_3S by reduction of inner radius (right)

radius of the particle, r_{in} the radius of the reacting core and r_{out} the outer radius of the C-S-H deposited on the particle. The CH produced is distributed randomly on the available clusters of this phase. The reduction in the surface available for deposition of the new product due to overlaps with other particles is calculated and accounted for, for each particle.

4.1.1.5 Reaction Kinetics

The rate of reaction is calculated for each particle based on three reaction mechanisms assumed for the hydration. In the model by Navi and Pignat, this rate is calculated as the rate of reduction of the radius of the inner reactive core, from the equations 4.4, 4.5 and 4.6.

$$\frac{dr_{in}}{dt} = -r_{in} \cdot k_1^3 t^2 e^{-k_1^3 \frac{t^3}{3}} \quad (4.4)$$

$$\frac{dr_{in}}{dt} = -k_2 \quad (4.5)$$

$$\frac{dr_{in}}{dt} = \frac{-k_3}{r_{out} - r_{in}} \quad (4.6)$$

The above equations represent nucleation and growth mechanism, phase boundary mechanism and diffusion controlled mechanism respectively. Equation 4.4 is a modified form of the Avrami equation (equation 2.5) discussed earlier. It

can, however, be shown that the above relation leads to the same rate of reaction for powders having different particle size distributions for the first few hours of hydration. For this reason, this equation was re-derived from the Avrami equation, assuming a reaction rate proportional to the surface area of the particles. The new form of this equation, shown in equation 4.7, is used in the current simulations.

$$\frac{dr_{in}}{dt} = -3 \cdot k_1 \cdot t^2 \cdot e^{-k_1 t^3} \quad (4.7)$$

Equation 4.5 represents a reaction dependent on the surface area of the reacting core and equation 4.6 is applicable when the reaction rate is controlled by the slow diffusion of ions through the layer of product on C_3S particles, and therefore by the thickness of the C-S-H layer on the particle. At any step, the slowest of the three mechanisms controls the reaction rate. For any particle, the transition between mechanisms is only allowed in one direction. This means that once it is determined that phase boundary kinetics become the controlling mechanism for a particle, the mechanism cannot switch back to nucleation and growth, and a switch to other mechanisms from the diffusion controlled mechanism cannot take place.

4.1.2 The Simulations

The hydration of powders with three different particle size distributions, shown in figure 4.2, was simulated. Cubic computational volumes, 100 μm on the side, were packed with 44.25% of solids, equivalent to 0.4 water to cement ratio. The first particle size distribution contains mainly large particles, with a total of 199 alite particles in the volume. The third particle size distribution is from a commercial cement, with a total of 2,472,151 alite particles in the volume. The second particle size distribution is a close approximation of the third particle size distribution, although containing only 117,679 particles. Based on the values reported by Pignat¹¹¹, k_1 was set at $1.14 \times 10^{-4} h^{-3}$, k_2 at 1.0 $\mu m/h$ and k_3 at

Figure 4.2: Particle size distributions used in the simulations

0.01 $\mu\text{m}^2/\text{h}$. These values were obtained by fits with isothermal calorimetry on C_3S samples. Due to the chosen values of the parameters, the second equation is usually not used. The evolution of the degree of hydration for the three simulations are shown in figure 4.3. A snapshot of the three microstructures around 75% degree of hydration are shown in figure 4.4.

Figure 4.3: Variation of degree of hydration for the three particle size distributions

Figure 4.4: Microstructures at 75% hydration for PSD-1 (left), PSD-2 (middle) and PSD-3 (right), with C_3S in lightest grey-scale, followed by CH and $C-S-H$ and pores in black

4.1.3 Approximate Pore-Size Distributions

The pore-size distributions of the microstructures obtained were calculated using a three-dimensional pixel-erosion method. In the original model, Navi and Pignat had presented a three-dimensional vector approach to characterise the porosity¹¹³. However, the performance of this approach could only be improved to around 200,000 particles. For this reason this approach is not used here.

In the method used here, the vector microstructure was overlaid with a cubic mesh and the voxels were marked to be solid or pore based on their occupancy. The pore voxels sharing a face with a solid voxels were marked with the number 1, and in the next step the pore voxels sharing a face with the voxels marked 1, were

Figure 4.5: Erosion to identify pore-skeleton using pixels (the solids are shown in black)

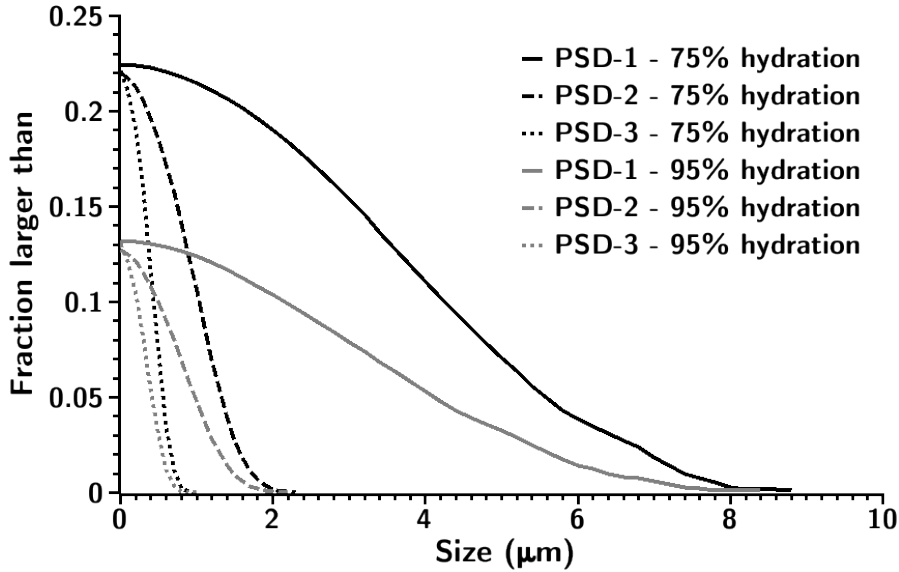

Figure 4.6: Pore size distribution at 75% and 95% degree of hydration

marked with 2, and so on until all voxels were marked with the number of steps required to reach them from solid boundaries. This method allows identification of voxels farthest away from the solid walls in each pore, which are defined as the centres of the pores. The schematics of this algorithm are shown in figure 4.5.

The extent of each pore can be identified by a walk in the reverse direction from the pore-centres. While this is only one of the many possible definitions of pores and pore-sizes, and ignores information regarding pore-topology, it can be used to obtain quick comparative results. The simulations were carried out with a voxel size of $0.2 \mu\text{m}$ for PSD-1 and $0.1 \mu\text{m}$ for PSDs 2 and 3. The different voxel-sizes were used to reduce computational times as a larger voxel size was considered sufficient for the coarser particle sizes in PSD-1. The results obtained from this analysis are shown in figure 4.6.

4.1.4 Observations and Discussion

The importance of accounting for all particle sizes can be clearly seen in the results obtained. The results also demonstrate that the faster implementation of the vector approach in μic can be crucial to the correct representation of the

microstructure. Although the second particle size distribution appears to be close to the third particle size distribution, the pore-sizes of the microstructures are significantly different. The simulations with PSD-3 took less than 2 hours on a desktop computer with μic , while most of the other currently available microstructural models can only simulate a smaller number of particles, requiring the truncation of the particle sizes, thereby seriously altering the microstructural properties. It must be noted that although in this case the analysis has been carried out using voxels having a relatively large size for cement, the vector information contained in the model is resolution-free and also contains information about much finer pores. Still, the voxel size used in this analysis is much smaller than those used in earlier models.

4.2 Non-Traditional Examples with μic

In these examples, μic is used to simulate fibrous growth, and the overall growth kinetics and fill fraction are simulated based on the mechanism described below. Two examples of fibrous growth, without and with branching, are presented here. As micrographs have shown C-S-H forming a fibrillar structure¹²¹, the structures simulated here could be similar to the microstructural development of C-S-H. More details about the simulation are discussed below.

4.2.1 Mechanisms and Rules

In these simulations, spherical seeds occupying only a small fraction of the volume were placed. The growth was simulated by the addition of new spherical particles of the same size at each step of the simulation, to form a chain of overlapping spheres. In the first simulation, new particles form only at the end of the chains, leading to a non-branching growth, while in the second case, new particles are also allowed to grow from inner particles in the chain, leading to a branching growth. The centre of the new particles is generated randomly at the specified distance from from the end particles in the first case, and all particles in

the second case. A new particle is allowed to form if the new particle overlaps only with its seed particle. The random generation of the locations of the new particles leads to a growth in random directions. Similar growth patterns have also been used to study other inorganic and biological growths^{122,123,124}. The main steps in the simulation are listed below.

- Initial spherical particles occupying a small fraction of the volume are randomly placed.
- At each step of the simulation new particles are added to the system, overlapping by a known amount with one of the particles already present. The particles that allow new particles to form overlapping with them are called seed particles. The overlap is made in order to have shapes closer to a fibre than a chain of spheres.
- At each step of the simulation, all seed particles generate a new random centre for a new particle at a given distance from their centres.
- The new particle is placed only if it can be placed without overlaps with particles other than the seed. For this reasons, growth might not occur at some of the seeds at some steps in the simulation.
- As the growth is simulated in three-dimensions, in the case of branching fibres, multiple branches could form from the same particle.

The schematics of the growth are shown in figures 4.7 and 4.8.

Figure 4.7: Schematics for normal (left) and branching growth (right)

Figure 4.8: Example of step-wise addition of spheres in branching growth

In the first simulation it is expected that while the growth will progress at a constant rate in the beginning, as the volume is filled, and less space for new particles remains available, the rate is expected to reduce. Only a relatively small fraction is expected to be filled at the end of this process. In the second simulation, the rate is expected to accelerate in the beginning due to branching and reduce later due to filling of space. In this case a larger fraction of the volume is expected to be filled. However, quantification of the rates analytically can be difficult, and the exact final solid fraction cannot be calculated analytically. It is shown here how μic can be used to quantify processes, which can otherwise be complex to solve.

4.2.2 The Simulations

In the current simulations, initial spherical seed particles occupying 0.1% of the computational volume were placed at random locations. The size of the computational volume is 20 units on each side and the diameter of the seeds is 1 units. The growth is simulated by the addition of new spherical particles of the same size in the volume. The centres of the new particles are located such that the

Figure 4.9: Evolution of the microstructure with non-branching fibres with solid-volume fraction of 13.3% (left), 22.7% (middle) and 32.0% (right)

Figure 4.10: Evolution of the microstructure with branching fibres with solid-volume fraction of 7.1% (left), 31.5% (middle) and 65.7% (right)

new particles overlap with the seeds by 75% of their radii (figure 4.7). Three-dimensional images of the the evolution of the microstructures for the two simulations are shown in figures 4.9 and 4.10.

4.2.3 Results

Figures 4.11 and 4.12 show the evolution of the volume filled and the rate of growth in the simulations. As expected, the volume is filled much faster in the branching case and also reaches a higher fill-density. In the case of non-branching fibres, the final packing density achieved was only around 32.0% and in the case of branching growth the final packing volume of around 65.7% was achieved. It is

Figure 4.11: Evolution of the volume filled by solids with normal and branching fibres

interesting to note that the final packing achieved in the latter case is closed to the reported solid fraction in C-S-H²⁰.

4.2.4 Discussion

It can be seen from the above example that the versatility of μic provides a relatively simple way to simulate a complex process. Taking the local mechanism

Figure 4.12: Rate of reaction with non-branching (left) and branching (right) fibres

of a semi-random process as input, the overall growth rate of fibres was simulated. This was possible in μic as not only the rate of a reaction, but also the location of nucleation can be controlled. The process is relatively complex as the fibres tangle when they grow, thereby inhibiting the growth of other fibres. Still, the overall progress of the reaction can be simulated after accounting for all the interactions and the final volume filled by the particles could be calculated.

One of the interesting observations from the simulations is that, in the case of branching fibres, the final fraction of fill obtained is similar to the solid fraction reported in C-S-H and the shape of the observed rate of fill is similar to the observed rate of hydration of cement.

4.3 Conclusions

In the above examples, the importance of the faster algorithms used in μic in order to properly represent cement microstructure by accounting for all particle sizes was highlighted. It was also shown using simple examples that the versatile architecture of μic can be used to study processes. While the first set of examples show how μic can be used to reproduce local effects, such as pore-sizes, the second set of examples show how localised mechanisms can be used to study the overall progress of the microstructure. It can be seen that due to its performance and customisability, μic provides an effective tool to study reaction mechanisms and microstructural development of growth processes which can prove useful to study cement hydration and other particulate systems.

Chapter 5: Nucleation and Growth Kinetics of Alite

5.1 Introduction

In this chapter, the hydration kinetics of alite are studied using μic . As discussed in the preceding chapters, μic has been designed as a modelling platform that enables explicit simulations of microscopic phenomena at the level of individual cement particles. Here, this feature of the model is used to study various hydration mechanisms of alite and their effect on the hydration kinetics and microstructure.

Reaction kinetics are an important part of microstructural modelling, as not only do they link microstructural development to time, but they also control the relative reaction rates of particles. Particles of different sizes make different contributions to hydration at different stages of the reaction depending on the reaction mechanism. Furthermore, as is presented in the following discussion, reaction kinetics can also provide important information about reaction mechanisms and the microstructure itself.

Over the years, various models for hydration and kinetics have been presented. However, since most of these models are empirical in nature, it is difficult to extract any meaningful information regarding reaction mechanisms from them. μic , however, works in the opposite manner as it uses localised rules to

simulate overall results after taking interactions between various elements into account.

In this chapter, the validity of different hydration mechanisms of alite is studied using μic by comparing the calculated reaction kinetics to experimentally measured values. Only alite is studied here as it is the largest and the most important component of cement. The first 24 hours of alite hydration are studied in this chapter, as this is the most important period in terms of microstructural development.

5.2 Numerical Modelling of Reaction Kinetics

5.2.1 Requirements from Numerical Models of Kinetics

In μic , the reaction rates of individual particles are calculated at each step in time and the development of the microstructure during the next step is simulated accordingly. There are, therefore, some special requirements from the kinetics laws that are implemented in the model, as listed below.

- It must be possible to decompose the kinetics laws to the level of each particle.
- Rules for interaction between particles must be known.
- If several possible mechanisms exist, rules to choose the governing mechanism at any instant in time, for each particle, should be known.
- For more effective modelling of the systems, the kinetics should be based on the actual mechanism of the reaction and only the essential assumptions should be made.

5.2.2 Using Experimental Results in Conjunction with Models

One of the major problems in studying hydration mechanisms is that since most experiments are only possible on bulk specimens and the results only represent the overall effect of all elements acting together; and most of the

information regarding the contribution of individual elements, e.g. inter-particle interactions, is therefore not accessible from these experiments.

Since most microstructural models also use these empirical relations in the simulations, the results are designed to follow the experimental observations. While empirical fits can reproduce the shape of the observed results, they do not necessarily model the processes in action. This is specially true for cement, where isolation of the effects of individual elements is not always possible. Empirical fits of experimental results are, therefore, not well suited for application to models.

Microstructural models work in a manner opposite to experiments. Different processes at the level of individual particles can be implemented in μic and the overall results, calculated from the model, can be compared to experimental results for verification of the applicability of the applied rules. In this way, the model can provide a technique that is complimentary to experiments, helping to reconstruct the information that is otherwise lost in the macroscopic behaviour.

Since μic does not contain any hard-wired rules all simulations are customisable. It is possible to input rules at the level of individual particles and to explicitly calculate the interactions for the calculation of values that can then be compared to the experimental results, to verify the applicability of the mechanisms to the system.

In this chapter, μic is used to study the period of alite hydration, which is most commonly associated with a nucleation and growth mechanism. First the validity of the Avrami equation, which is widely accepted and used to model its hydration is investigated, both analytically and using μic . Then a combination of experimental results and simulations is used to investigate different possible hydration mechanisms of alite.

5.3 The Avrami Equation

The Avrami equation was originally derived to model the growth of crystals and the solidification of metallic melts and its first application to modelling cement hydration kinetics was more than thirty years after it was first published. Despite the fact that its form allows representation of many different nucleation and growth mechanisms, the simplifications behind the derivation of this equation do not necessarily apply to cement. Its sigmoid shape, which resembles the evolution of cement hydration, and its simple form are probably the most important reasons behind the popular use of this equation in cement science. For the sake of completeness, the equation is reproduced in its most commonly used form below.

$$-\ln(1-\alpha)=kt^n \quad (5.1)$$

As described earlier, a is the fraction of volume converted to solid, t the time, and k and n are parameters that depend on the rate of reaction and the mechanism of growth of crystals respectively. The parameter n can be further defined in terms of three other parameters, P , S and Q as in equation 5.2.

$$n=\left(\frac{P}{S}\right)+Q \quad (5.2)$$

In this equation P is a dimensionality constant for the growth of products, being 1 for a one-dimensional growth, 2 for a two-dimensional growth and 3 for a three-dimensional growth. S is related to the rate-limiting mechanism, being 1 for interface controlled growth, where the creation of new surface controls the rate, and 2 for cases where the diffusion of ions to the growth sites controls the rate. Q depends on the nucleation rate, being 1 for a constant nucleation rate and 0 for cases where only an initial nucleation event occurs⁵⁶. The equation can be written in a differential form, as shown below, for comparison with the measured rates of heat-evolution.

$$\frac{d\alpha}{dt} = k \cdot n \cdot t^{n-1} \cdot e^{-k \cdot t^n} \quad (5.3)$$

5.3.1 A Simplified Derivation of the Avrami Equation

In order to better understand the meaning and the applicability of the Avrami equation, a simplified form of its derivation is reproduced here. Here we calculate the volume fraction filled at any instant in time by isotropically growing nuclei that form in a homogeneous manner at random locations in the volume. As the growth is assumed to be isotropic the nuclei will grow to form spherical particles that will overlap with each other as the reaction progresses. It is also assumed in the current derivation that the materials required for growth are available in sufficient amounts throughout the process and that the rate at any moment is only controlled by, and is proportional to, the available surface for growth.

First, we calculate the volume of a single particle if the overlaps are neglected, calling it the extended volume (V'). Since the growth of a particle is proportional to the available surface area on the particle, the radius, r_i , of an individual nucleus i can be related to the age of the nucleus, t_i , as in equation 5.4.

$$\frac{d\left(\frac{4 \cdot \pi \cdot r_i^3}{3}\right)}{dt_i} \propto 4 \cdot \pi \cdot r_i^2 \Rightarrow \frac{dr_i}{dt} = k_1 \Rightarrow r_i = k_1 \cdot t_i \quad (5.4)$$

In the above equation, k_1 is the rate of growth in one dimension. The total extended volume at any instant in time can therefore be related to the age of individual nuclei as in equation 5.5.

$$V' = \sum_{i=0}^{i=n} \frac{4 \cdot \pi \cdot k_1^3 t_i^3}{3} \quad (5.5)$$

If the rate of nucleation (k_2) is assumed to be constant, the number of nuclei formed in a small period dt can be written as below.

$$dN = k_2 \cdot dt \quad (5.6)$$

Equation 5.5 can therefore be rewritten by grouping particles formed in a small period dt in the differential form as shown below.

$$dV' = \frac{4 \cdot \pi \cdot k_1^3}{3} \cdot t_i^3 \cdot k_2 \cdot dt_i \quad (5.7)$$

If it is assumed that the rate of increase of the actual volume, V , is proportional to the rate of change of the extended volume and reduces with the amount of space available, equation 5.7 can be rewritten as below.

$$dV = \frac{4 \cdot \pi \cdot k_1^3 \cdot k_2}{3} \cdot t_i^3 \cdot dt_i \cdot (1 - V) \quad (5.8)$$

Equation 5.8 can be integrated to get:

$$-\ln(1 - V) = k \cdot t^4 \quad (5.9)$$

Where the combined rate constant k can be written as:

$$k = \frac{\pi \cdot k_1^3 \cdot k_2}{3} \quad (5.10)$$

Equation 5.9 has the same general form as equation 5.1, with the parameter n having a value 4. The equation can be similarly derived for other conditions and it can be shown that n changes as shown in equation 5.2.

5.3.2 Limitations of the Avrami Equation

The two parameters in the equation, k and n , are usually fit to experimental results to study the reaction mechanisms. However, in complex systems like cement, these two parameters might not sufficiently represent all the possible variables in the system. It would not be possible to study the contribution of all of the parameters affecting the reaction rate just from the analysis of these two

Figure 5.1: Dependence of reaction rates predicted by the Avrami equation on k and n

parameters. While it can be convenient for fitting that the equation has only two parameters, this limits the applicability of the equation.

Figure 5.1 shows how the predicted rate of reaction depends on the parameters k and n . When applied to cement, the two parameters would have to control at least the following three independent features of the cement hydration curve:

- Initial rate of acceleration of reaction rate,
- Time at peak, and
- Rate of deceleration.

By doing so, the equation satisfies the requirement that the total amount of reaction does not exceed the total availability of space and material. This means that the equation models the compounded effect of at least two of the factors that can affect reaction rates. This results in a reduction in the time of peak, if the initial rate of acceleration is varied by increasing k , or the reaction mechanism is varied by increasing n .

This is because not only does the equation model the reaction mechanisms, it also predicts the variation of geometry. The equation first predicts an increase in rates as the available surface area for growth increases with the progress of the reaction. The rates are then assumed to reduce as different nuclei impinge, reducing the surface available for growth. While the assumption used is not necessarily incorrect, it implicitly assumes the geometry of the growth and the homogeneity of the nucleation, which might not be valid for all cases.

One of the major criticisms of the application of the Avrami equation to cement is that it assumes homogeneous nucleation throughout a volume and cannot be used in cases with heterogeneous nucleation, as is thought to be the case in cement, where the nucleation of C-S-H occurs on the surface of the particles and not randomly in the pore-space. Thomas⁶² showed that a relation derived by Cahn⁸⁷ to model the growth of nuclei that form close to a surface, can provide better fits to cement hydration particularly after the peak. Similar to the Avrami equation, in this derivation, the initial acceleration is attributed the increase in surface area from the growth of nuclei, which are assumed to nucleate only in a narrow zone around the cement particles. The later reduction in rate is attributed to the reduction in the surface available for growth due to impinging of the hydrates from different grains. In this derivation, the author uses the transformation from extended volume to real volume twice, first for the two directions parallel to the surface of the particles and secondly for the direction perpendicular to the surface. Important assumptions regarding the geometry of growth of the products are therefore made in this derivation. The validity of these assumptions is investigated in later sections.

One of the important features of microstructural models is that they can explicitly model the geometry of the system and do not rely on implicit assumptions regarding the geometry. This means that the use of any equation that makes assumptions regarding the geometry could reduce the strength of a

microstructural model to utilise all the information available from the simulated microstructure. For example, while the Avrami equation makes implicit assumptions concerning overlaps between particles, these assumptions are not required as this information can be directly extracted from the model. Therefore, even if the equations predict the correct rates, the values cannot be decomposed to the level of individual particles.

In μic , the basic mechanisms behind nucleation and growth can still be used to calculate reaction rates after explicit calculation of the interactions. In the following discussion, the nucleation and growth mechanism and the applicability of the Avrami equation to nucleation and growth processes are studied using μic . In later sections, the possibility of applying nucleation and growth kinetics to the hydration of alite is explored using experimental and simulation results.

5.4 Simulating the Nucleation and Growth Mechanism

In the following sub-sections, μic is used to study the nucleation and growth process. The applicability of the Avrami equation to cases of homogeneous nucleation, for which the equation was originally derived, and then to cases of boundary nucleation, as is believed to be the case in cement. The systems simulated here also demonstrate how the versatility of μic can be used to study the overall result of mechanisms occurring at the level of individual particles.

In these simulations, the nucleation and growth of a single phase is simulated under different conditions and the reaction rates are calculated. In the first set of simulations, a homogeneous nucleation is modelled, and a heterogeneous nucleation on the surface of spherical particles is simulated in the second case. In the first set the materials are assumed to be present in sufficient quantities, and in the second set, the material is assumed to be derived from the particles on which the nucleation occurs. The details and results from the simulation are discussed in the following sub-sections.

5.4.1 Homogeneous Nucleation and Growth

In this set of simulations, a simple spherical nucleation and growth process is simulated in a cube with periodic boundary conditions. The results obtained are then compared with the Avrami equation.

5.4.1.1 Setup

The model is set up with a single material, which forms nuclei in the available space and grows at a constant rate at all available surfaces. The main set-up parameters used here are listed below.

- **Material:** The growth of a single material has been simulated
- **Nucleation rate:** The material is assumed to form nuclei at a constant rate in time in some cases and it is assumed to have a fixed number of growing nuclei throughout the process in the other cases.
- **Growth rate:** All nuclei are assumed to grow at a constant rate on the surface available for growth. The parts of any growing particle that overlap with another neighbouring particle are considered not to contribute to growth.

A total of five simulations, 1 to 5, were carried out. In simulations 1 to 3, a constant rate of nucleation is assumed and in simulations 4 and 5 only an initial nucleation event at the beginning is assumed. Compared to the other cases, twice the growth rate was used in simulations 3 and 5. The different cases simulated here are listed in table 5.1.

Table 5.1: Parameters used in the homogeneous nucleation and growth simulations

	Sim. 1-BB	Sim. 2-DB	Sim. 3-BD	Sim. 4-OB	Sim. 5-OD
Nucleation rate	Base	Double	Base	Zero	Zero
Growth rate	Base	Base	Double	Base	Double

Figure 5.2: Fraction of volume filled (left) and rate of filling (right) for the first set of simulations

Figure 5.3: Snapshots of slices from the first set of simulations, with fraction of volume occupied approximately 36% (left) and 90% (right)

5.4.1.2 Results

The calculated volume fraction filled and rate of filling are shown in figure 5.2. As expected, the rate of transformation accelerates at first as the surface for growth increases and then starts to reduce as the growing particles start to impinge upon their neighbours, reducing available surface. Snapshots of two-dimensional slices of the microstructures are shown in figure 5.3.

The results demonstrate that the shape of the overall growth rate depends on whether there is only an initial nucleation event or nucleation continues at a

Figure 5.4: Fit of simulations 1-BB and 4-OB with the Avrami equation

constant rate. The rates of reaction are observed to be similar when the nucleation rate is doubled (simulation 2) and when the growth rate is doubled (simulation 3).

5.4.1.3 Fit with Avrami Equation

The calculated rate of solidification for simulations 1 and 4 were fit with the differential form of the Avrami equation. As expected, a near-perfect fit could be obtained with a value of 4 for n for simulation 1 and a value of 3 for simulation 4.

The differential of the equation was fit instead of the original form to demonstrate the accuracy of the results, as differentials are generally harder to fit and the agreement reduces after every differential. This set of simple simulations demonstrates the accuracy of results calculated from μic and also the applicability of the Avrami equation to homogeneous nucleation and growth. As shown in figure 5.4, the values of n for the fits were found to agree with equation 5.2. Only two of the simulations have been shown in this figure for the sake of clarity of the plots.

5.4.2 Heterogeneous Nucleation and Growth

Similar to the last set of simulations, another set of simulations was carried out under slightly different conditions. In these simulations the nucleation was allowed only on the surface of spherical particles already present in the volume. The nuclei are allowed to draw material only from the particle on which they nucleate. The solid-volume increase resulting from the reaction is kept similar to that observed in the hydration of alite and the original volume of the reactive particles corresponds to 0.4 water to cement ratio. The set-up of the problem and the results are discussed below.

5.4.2.1 Setup

The model was set up with a material, which forms nuclei on the surface of spherical particles present at the onset of the reaction. The nuclei grow at a constant rate at all available surfaces of the precipitating material. The main set-up parameters used here are listed below.

- Material: Three materials are defined, the first (material 1) being the reactant that is present as spherical particles at the onset of the reaction, the second (material 2) nucleates on the surface of material 1 and the third (material 3) fills up the space created by the consumption of material 1.
- Nucleation rate: The material is assumed to have a fixed number of growing nuclei on the surface of the particles of material 1 throughout the process.
- Growth rate: All nuclei are assumed to grow at a constant rate on the surface available for growth. In one of the simulations, the growth rate perpendicular to the surface of the particles is set to twice that parallel to the surface, leading to a conical growth, as shown in figure 5.5. The higher perpendicular growth rate was simulated by the agglomeration of a large number of small spherical nuclei outwards from the reacting particles.

Figure 5.5: Different perpendicular and vertical growth rates from spherical nuclei

A total of three simulations, 6 to 8, were carried out. The number of nuclei on the surface of the particles is kept constant throughout the process in all three cases. In simulation 7, the growth rate perpendicular to the surface is fixed at twice the growth rate parallel to the surface. The growth rate parallel to the surface is the same in simulations 6 and 7. The growth rate in simulation 6 is assigned such that the initial rate of reaction observed is similar to that for simulation 7. The different cases simulated here are listed in table 5.2.

Table 5.2: Parameters used in the heterogeneous nucleation and growth simulations

	Sim. 6-BB	Sim. 7-BD	Sim. 8-HB
Nucleation rate	Zero	Zero	Zero
Parallel growth rate	Base	Base	Higher
Perpendicular growth rate	Base	Double	Base

5.4.2.2 Results

The calculated degree of reaction and rate of reaction are shown in figure 5.6. Similar to the first set of simulations, the rate of filling accelerates at first as the surface for growth increases and then starts to reduce as the growing particle start to impinge upon their neighbours, reducing available surface.

The results here are different from the first set of simulations in that while in the first set of simulations, all three dimensions are filled at the same rate, in the current set, the filling of the surface of the reacting particles and that of the space in the direction perpendicular to the surface does not occur at the same time and rate, changing the observed rate of the reaction. The reaction rates for simulations

Figure 5.6: Degree of reaction (left) and rate of reaction (right) for the second set of simulations

Figure 5.7: Three-dimensional snapshots from simulations 6-BB (left) and 7-BD (right)

6 and 8 display a prominent flattish rate of reaction after the peak. This is because while the peak occurs at the moment when surface of the particles gets filled up, the rate does not change much until the nuclei start to impinge in the direction perpendicular to the surface of the particles. Snapshots of the simulated microstructures are shown in figure 5.7.

5.4.2.3 Fit with Avrami Equation

The accelerating parts (up to 20 time units) of the reaction rates of simulations 6 to 8 were fit with the Avrami equation. The fits along with the simulated results and the value of the parameter n calculated from the best fits are shown in figure 5.8. It is interesting to note that the values of n found for these fits are similar to those reported when the Avrami equation is fit with experimental results from cement^{62,64}.

The fit curves have been extended beyond the range of fit in the figure. The fits clearly show that although it is possible to obtain a close fit with the Avrami equation in the range of fit, these fits do not predict the evolution beyond this range. It can be seen from these results that the Avrami equation cannot be used to fit results from a pure nucleation and growth process when the nucleation is heterogeneous.

5.4.3 Results

The results from the simulations show, that the Avrami equation can be used to predict the reaction rates in systems with homogeneous nucleation, with the

Figure 5.8: Best fits of the Avrami equation with results from simulations 6 to 8

required materials available in sufficient quantities, for which this equation was originally derived. However, this equation cannot effectively model systems with heterogeneous nucleation, with limited availability of the reactant, as is the case in cement. Although the equation can be used to fit the early part of the evolution, the fits cannot predict the values beyond the range of the fit, as observed for cement. The observed values of n in these fits are close to those reported for cement, possibly indicating that the nucleation and growth scheme simulated here is close to the mechanism in cement. These results have important implications for microstructural models of cement as they clearly show the inadequacy of the Avrami equation to model processes with heterogeneously distributed nucleation sites. Furthermore, although in the second set of simulations only the growth rate of the nuclei was varied (described by the k parameter in the Avrami equation), the same value of n could not be used for the fit, demonstrating that the equation is not strictly valid even in the part of the reaction where a good fit is possible.

It is seen in simulation 6, that while the peak of the reaction-rate occurs when the entire surface of the particles gets covered, as suggested earlier⁵³, a clear reduction in the reaction rates can only occur when products from neighbouring particles start to impinge. This means that a flat region of nearly constant reaction-rate would be observed just after the peak. However, such a feature is usually not observed in cement hydration and the heat-evolution measured generally displays a clear peak with a large reduction in reaction rate immediately after the peak. In simulation 7, where a shorter peak was observed, the degree of hydration at the peak was observed to be 55.6%, which is much higher compared to that usually observed in cements around the time they exhibit the peak in the reaction-rate. The results presented here also point towards the need for a turn away from curve-fitting of relations that might not correctly represent the processes in action.

The results above demonstrate how μic can be used to model complex phenomenon and verify the applicability of theories to specific cases. This versatility is a unique feature that μic has amongst all currently available microstructural models. The results produced simulate the overall rate of reaction, which can be compared to experimental observations, e.g. heat evolution measured using calorimetry in the case of exothermic reactions, in order to verify the applicability of the laws and parameters used in the simulations. In the following discussion, the possible implications of the above observations, in combination with more simulations and experimental results are discussed.

5.5 Experimental Investigations into Hydration Kinetics

The hydration of alite with different particle size distributions was studied using isothermal calorimetry. Most of the experimental work presented here, including establishment of the production protocol and the production of Alite, fractionation and isothermal calorimetry, has been carried out by Ph.D. colleague

Figure 5.9: Particle size distributions of different fractions of alite

Mercedes Costoya¹²⁵. The alite was prepared in the laboratory and was fractionated into different particle size distributions using sedimentation. The particle size distributions of the fractions, measured using laser granulometry, used in this study and the original powder are shown in figure 5.9. The particle size distribution of the original powder is close to that of cement and the other fractions in this study have been chosen in order to cover the entire range of particle sizes observed in cement. Fraction A is the unfractionated powder and the other fractions, B to G, have been ordered in the reducing order of median radii. Fractions B, C and E have narrow particle size distributions containing only larger particles, fractions D and F contain a wider range of particle sizes and fraction G is mainly composed of fines. The median diameters and the content of fines in the powders is listed in table 5.3.

Table 5.3: Details of the powders and fit parameters with the Avrami equation

Name	Median dia. (μm)	Contains fines	k (hour^{-n})	n	a (J/g)
A	38.5	Yes	$8.89 \times 10^{-4} \pm 5.24 \times 10^{-4}$	2.52 ± 0.47	24.10 ± 14.90
B	82.6	No	$9.51 \times 10^{-4} \pm 1.55 \times 10^{-3}$	2.42 ± 1.07	9.05 ± 10.32
C	38.5	No	$1.47 \times 10^{-3} \pm 1.24 \times 10^{-3}$	2.42 ± 0.71	15.21 ± 13.83
D	20.9	Yes	$1.53 \times 10^{-3} \pm 4.42 \times 10^{-4}$	2.54 ± 0.23	30.11 ± 7.29
E	17.9	No	$6.37 \times 10^{-4} \pm 3.21 \times 10^{-4}$	2.79 ± 0.27	25.36 ± 4.27
F	15.4	Yes	$1.54 \times 10^{-3} \pm 3.91 \times 10^{-4}$	2.22 ± 0.22	36.79 ± 16.59
G	6.2	Yes	$1.22 \times 10^{-4} \pm 2.94 \times 10^{-5}$	3.74 ± 0.13	59.32 ± 3.90

Around 5 grams of paste with 0.4 water to cement ratio was used in each sample for the calorimeter. The measured heat evolution curves per gram of paste are shown in figures 5.10 and 5.11. The rate of heat evolution was observed to vary depending on the particle size distribution, with the finer fractions reacting faster. The heat evolution curves have been studied in more detail in the following sub-sections. It must be noted that all heat-evolution curves have been normalised by the weight of paste.

Figure 5.10: Rate of heat evolution for alite fractions A, B, C, E and F

Figure 5.11: Rate of heat evolution for alite fractions A, D and G

5.5.1 Avrami Fits of Curves

Figure 5.12 shows fits of the Avrami equation, as an example of nucleation and growth type kinetics, with three of the fractions. It can be seen that it is possible to reproduce a shape similar to that observed in experiments, using a

combination of an exponential decay resulting from dissolution and a nucleation and growth curve, without the assumption of an induction period. While this does not necessarily mean that the induction period does not exist, the curves show that it is possible to explain the short period of flattish heat-evolution without the requirement of a separate chemical process. The equation used for the fit is shown in equation 5.11, and the fit parameters are listed in table 5.3. It must be noted that since an effort to fit all curves with the same value of the factor n was not made, the values of the factor k are not directly comparable. Only three of the fits are shown here for the sake of clarity of the plots.

$$\frac{d\alpha}{dt} = a \cdot k \cdot n \cdot t^{n-1} \cdot e^{-k \cdot t^n} \quad (5.11)$$

5.5.2 Rate of Acceleration

An approximately linear rate of heat evolution was observed in most samples at around 4 to 6 hours of hydration. The slope of this quasi-linear part was measured and compared to the specific surface area of the powders measured using three different techniques. Firstly the specific surface area was calculated using μic for powders using spherical particles with matching particle size distribution. A set

Figure 5.12: Fits of the Avrami equation with three fractions without an induction period

of particles following the particle size distributions was generated and their total surface area and mass was used to calculate the specific surface area. The fineness was also measured with nitrogen adsorption using the BET theory and with Blaine permeametry. The specific surface of the fractions, along with the slope of the linear part are listed in table 5.4. The experimental measurements for some of the fractions are not available. The specific surface values, normalised against those for fraction D, are plotted against the measured slopes, also normalised against fraction D, in figure 5.13.

Table 5.4: Calculated and measured specific surface (m^2/kg) using different techniques and measured slope of the quasi-linear part of the heat-evolution ($mW/g/h$)

Fraction	A-38 μm	B-83 μm	C-38 μm	D-21 μm	E-18 μm	F-15 μm	G-6 μm
Calculated	549.7	26.8	59.1	769.5	160.2	456.4	1273.5
Blaine	190.5	61.0	121.2	525.5	239.3	305.9	-
BET	597.7	376.8	1033.7	592.2	1537.7	-	-
Slope	0.154	0.059	0.110	0.255	0.230	0.178	1.264

The results show that, although a linear relationship between the factors was not found, the reaction is generally faster as the fineness increases. The normalised Blaine fineness values were found to be closest to the measured normalised slopes. One of the important observations from the figure is that the reaction rates do not

Figure 5.13: Renormalised specific fineness' of powders against measured slopes

directly scale with the specific surface of the powders calculated from the particle size distributions. Most nucleation and growth models, on the other hand, will predict an initial reaction rate that is linearly scalable with the specific surface of the cement particles, if the process is assumed to occur homogeneously on the surface of the particles. While this might indicate a non-homogeneous process on the surface of the particles, one of the reasons for the reaction rates not scaling linearly with the specific surface areas could be due to agglomeration of particles during laser granulometry measurements, making the measurements less reliable. Another factor affecting this relationship could be the reduction in the specific surface area during the dissolution period, which has not been considered here. As smaller particles would dissolve faster than the larger ones in the beginning, the specific surface available at the beginning of the nucleation and growth process can be different from that at the beginning of dissolution. This is supported by the relatively good trends observed in the measured Blaine fineness. Since this technique is not able to measure the finer particles, it compensates for the reduction in the specific surface area during the initial rapid dissolution period.

5.5.3 Effect of Inert Fillers

The effect of the presence of fine inert fillers on hydration kinetics of alite was studied. Isothermal calorimetry was carried out on samples with alite replaced by rutile (titanium dioxide) and silica fume to extents varying between 5% and 15% by weight. The particle size distributions of the alite and the fillers used are shown in figure 5.14. While both fillers were found to be much finer than the alite, the silica fume was found to be finer than the rutile used. As the alite was used directly after grinding, its particle size distribution was found to vary between batches (alites 1 and 2 in the figure). Alite from one batch was used with rutile and alite from the other batch was used with silica fume. The rate of heat-evolution measured are shown in figures 5.15 and 5.16.

Figure 5.14: Particle size distributions of alite and fillers used

It can be seen from the above results that different fine filler particles, which are not known to react, at least in the first 24 hours of hydration, can affect hydration in different ways. It is observed that the rate of hydration during the acceleration period is visibly higher in the case of silica fume, although the rates during this period are similar to the neat-alite when rutile is used. Still the addition of both fillers leads to higher peaks, which occur later than the neat alite

Figure 5.15: Heat evolution from samples with alite replaced by rutile

Figure 5.16: Heat evolution from samples with alite replaced by silica fume

sample in the case of rutile and slightly earlier in the case of silica fume. Rutile also appears to have a slight delaying effect on hydration. Some of the important implications of these results are presented in later sections.

5.5.4 Summary of Experimental Results

The experimental results presented above illustrate the variation of hydration kinetics with the variation of the particle size distribution of cement and with the addition of fine inert filler particles. Some of the key points observed in the results above are listed below.

- Finer powders were observed to show higher peaks,
- While the position of peaks changed only slightly with the particle size distributions, finer particles exhibit earlier peaks,
- Alite with finer particle size distributions hydrate faster but no clear relationship between the rate of reaction and the specific surface area was observed,
- Acceptable fits with the Avrami equation could not be obtained,

- The replacement of alite by inert fine fillers was observed to enhance the rate of hydration.

In the following sections, an explanation of the observed results based on the nucleation and growth mechanism is attempted. The results presented above are compared with simulations to study the possibility different mechanisms explaining the experimental observations. This comparison provides important information concerning alite hydration.

5.6 Key Questions before Modelling Alite Hydration

The five main stages of alite hydration were discussed earlier. The nucleation and growth period is generally assumed to start at the end of the induction period and end somewhere between stages four and five. Before the process is modelled using μic , some of the key questions about alite hydration that could affect numerical modelling of hydration, and especially its nucleation and growth period are discussed below.

5.6.1 Induction Period

One of the most important questions concerning the nucleation and growth period is the existence of the induction period. While it is generally accepted that the initial rapid evolution of heat in stage 1 is due to the dissolution of alite, the cause of the short flattish period observed between the “dissolution peak” and the following increase in the heat evolution rate is debated. It has been argued that the induction period is not a separate chemical process, and is the period during which the nucleation and growth process is too low to be measured^{1,53,62}. As can be seen in figure 5.17, a sum of exponential decay and the differential form of the Avrami equation can reproduce the shape exhibited in alite hydration, with or without the assumption of an induction period. The rate factors during the nucleation and growth period can, however, depend on the existence of the

Figure 5.17: Heat evolution curve as a sum of exponential decay and Avrami equation with and without an induction period

induction period. For the purpose of the current study, unless explicitly stated, it is assumed that the induction period is not a separate process, but is the period when the rate of hydration is too low to be observed.

5.6.2 Accelerating Stage

One of the important reasons why the reaction mechanism of alite is considered to be related to nucleation and growth is the acceleration observed in stage 3. It has been shown that as the surface for growth increases, the reaction

Figure 5.18: Evolution of heat-flow measured by isothermal calorimetry (left) and surface area measured by NMR relaxometry (right) by Zajac¹²⁶

rate increases, until the surface available for growth starts to reduce¹²⁶, as shown in figure 5.18. At the same time, it is also generally accepted that the growth takes place on the surface of cement particles. However, the increase in the surface area due to the increasing radii of the particles due to the deposition of layers of products alone cannot explain the observed increase in the reaction rates. In order to explain the acceleration stage, it has been proposed that before the peak, the surface of the reacting particles is only partially covered with product and the product grows outwards from the covered part of the surface. The rate accelerates as more of the surface continues to be filled^{53,62}.

For the purpose of the current study, in order to explain the acceleration in hydration, it is assumed that for the first few hours, the hydrates cover only a part of the cement particles and that the nuclei of C-S-H grow at different rates parallel and perpendicular to the surface of the particles.

In the following discussion, three different hydration mechanisms are simulated in *mic* and fit against the experimentally measured calorimetry curves to study the applicability of these mechanisms to cement hydration. In the first set of simulations, the traditional approach to nucleation and growth, where C-S-H, having a uniform bulk-density, nucleates on cement particles and grows outwards into the pore-space is simulated. It is shown that while this mechanism can reproduce the observed acceleration in the rate of hydration, the deceleration observed just after the peak is not reproduced. In the second set of simulations, the possibility of a diffusion controlled regime controlling the deceleration is studied and it is shown while such a mechanism can explain the observed rates of hydration, widely varying transport properties of C-S-H have to be used in order to obtain the fits.

In the third set of simulations a modified nucleation and growth mechanism is studied. In this mechanism, C-S-H nucleates on the cement particles and grows outwards into the pores, similar to the first mechanism. However, in these

simulations, it is assumed that the C-S-H forms at a lower bulk-density initially and its density increases with time. It is shown in these simulations that while such a mechanism can explain the rate of hydration during most of the first 24 hours of hydration, the fit parameters may vary by large extents. However, a clear trend in the fit parameters was observed. The results from the simulations demonstrate the necessity of more investigation into hydration mechanisms using numerical methods.

5.7 Modelling Traditional Nucleation and Growth in μic

In this set of simulations, the applicability of the traditionally accepted nucleation and growth mechanism to alite hydration is investigated using μic . As discussed earlier, numerical studies of the nucleation and growth mechanism in two dimensions⁵³, have shown that the rates of reaction observed can be explained by the slow growth of product over cement particles, with the peak occurring when the entire surface gets covered by the product. However, these simulations were made in two-dimensions and the effect of space-filling and the effect of other particles was not considered. In μic it is possible to model a similar processes in three-dimensions, taking the overlaps between particles into account. Here the process of nucleation and growth is simulated on particle size distributions similar to those used in experiments earlier. It must be noted that due to the large amount of missing information, these simulations are not intended to provide perfect fits to experimental results, and that they only explore the possibility of various mechanisms explaining the observed behaviour.

The information used in these simulations is as follows:

- Particle size distribution of the alite fractions as discussed earlier,
- A water to cement ratio of 0.4,
- A specific heat of hydration of 500 J/g of alite, and
- The measured calorimetry curves shown earlier.

The simplifications used in the simulations are as follows:

- The particles are assumed to be spherical and randomly distributed in space,
- The product formed inside the original boundary of the particle, referred to as the inner product here, is assumed to uniformly fill the space created by the dissolving particles, and
- The surface filling process is assumed to be the same for all particle sizes, such that at any moment the same fraction of all particles is covered.

It is understood that the effect of the above simplifications on the calculated values may not necessarily be negligible. However, the current simulations only seek to provide possible explanations for the observations through approximate fits with the use of limited amount of information available from the experiments. It is expected that the effects of these simplifications is within the error from the input. These simplifications are also not expected to alter the accuracy of the investigative simulations presented in the following discussion. It must be noted that, apart from the first assumption, the others are not essential in μic and have only been used in order to simplify the calculations.

As a microstructural model, μic ensures the following in the calculations:

- Mass is conserved by strictly following the stoichiometry of the defined reactions,
- All space is accounted for in the calculations, such that products grow only at locations that are not already occupied, and
- The available surface for growth is calculated individually for each particle and all possible overlaps are calculated.

In the following simulations, a uniformly dense product is assumed to grow over the covered portion of the particles. As the outward growth is only assumed to occur at locations where the particles are covered, the growing front around the

particles is rough, similar to the nucleation and growth simulations shown earlier. However, unlike simulations 6 to 8 shown earlier in section 5.4.2, the nuclei are not explicitly modelled here. It is assumed that the nuclei are small enough to consider the roughness uniformly spread over the surface growing products.

The volumetric stoichiometry used here is the same as that shown in equation 4.2. This equation assumes a density of 3.15 g/cc for alite, 1.0 g/ml for water, 2.0 g/cc for C-S-H and 2.24 g/cc for CH. For convenience, the equation is reproduced below.

$$1.0 \cdot V_{C_3S} + 1.318 \cdot V_H \rightarrow 1.569 \cdot V_{C-S-H} + 0.593 \cdot V_{CH} \quad (5.12)$$

5.7.1 Kinetics

In this case the hydration mechanism is assumed to be purely governed by the nucleation and growth of the product on the reacting particles. Small nuclei of the product form at uniformly distributed random locations on the surface of the reacting particles. The nuclei grow at a fixed rate, continuously covering the surface of the particles and filling the pore-space. The outwards rate is defined to be different from that parallel to the surface. The schematics of this mechanism are shown in figure 5.19.

Figure 5.19: Schematics of the nucleation and growth mechanism with different parallel and outwards growth rates for a single particle (top) and between particles (bottom)

The schematics are only representative in nature and the nuclei are not simulated explicitly in these simulations. Instead, the covered fraction of the particle surface, f , at time t , is calculated using the Avrami equation in two-dimensions, which is reproduced again below.

$$f = 1 - \exp(-k_1 \cdot t^n) \quad (5.13)$$

In this equation k_1 is the rate factor in the direction parallel to the surface. Since it is assumed that the product grows outwards at a uniform rate k_2 , the age of the product at a distance r from the surface of the particle can be written as:

$$t_r = \left(t - \frac{r}{k_2} \right) \quad (5.14)$$

The fraction of the volume f_v filled at a distance r from the centre of the particle, with an original radius r_0 , can therefore be calculated as:

$$f_v = 1 - \exp \left(-k_1 \cdot \left(t - \frac{(r-r_0)}{k_2} \right)^n \right) \quad (5.15)$$

The total amount of product around a grain, m_i , at time t can be calculated as:

$$m_i = \int_{r_0}^{r_0+k_2 \cdot t} 4 \cdot \pi \cdot r^2 \cdot f_v \cdot dr \quad (5.16)$$

However, since a part of the volume can be occupied by other particles, only a fraction of the surface, f_{free} , at any moment is available for growth. This factor depends on the distance from the surface and is calculated explicitly in μic . The actual amount of products around the grain at time, t , can therefore be written as:

$$m_i = \int_{r_0}^{r_0+k_2 \cdot t} 4 \cdot \pi \cdot r^2 \cdot \left(1 - \exp \left(-k_1 \cdot \left(t - \frac{(r-r_0)}{k_2} \right)^n \right) \right) \cdot f_{free} \cdot dr \quad (5.17)$$

5.7.2 Fit Parameters and Results

Equation 5.17 is input as a reaction kinetics plugin to μic and is solved numerically to calculate the amount of product around each grain at any moment in time. Since nucleation and growth is a demand based mechanism, the amount of product that can form governs the amount of reactant. The results from the simulations are shown in figure 5.20 along with the experimental results for the corresponding powders. The parameters used in the simulations are listed in table 5.5. In the table, the factor k_1 has been replaced by the more intuitive $t_{2/3}$, which was arbitrarily chosen to be the time at which two-thirds of the surface of the particles is covered. The experimental degrees of hydration in the curve have been reduced by the factor a_0 , to make the measured and calculated curves overlap for better comparison. This parameter corrects for the difference in the values due to the rapid heat evolution during the initial dissolution period, which is included in the calculation of the experimental degree of hydration and is not accounted for in the calculations.

Table 5.5: Parameters used in uniform density nucleation and growth simulations

Fraction	A-38 μm	B-83 μm	C-38 μm	D-21 μm	E-18 μm	F-15 μm	G-6 μm
$t_{2/3}$ (hours)	7.0	8.0	6.5	6.0	7.3	7.3	6.4
n	3.0	3.0	3.0	3.0	3.0	3.0	3.0
k_2 ($\mu\text{m}/\text{hour}$)	0.0045	0.0315	0.0290	0.0070	0.0215	0.0061	0.0078
a_0 (%)	2.8	2.4	1.9	3.5	2.1	4.2	0.7

In the simulations, the factors were modified to obtain heat-evolution curves close to the experimentally measured values by manual trial and error. Perfect fits were not sought in the simulations and the trials were stopped when it was considered that a fair comparison with the experimental results was possible. It was also not aimed to obtain the same fit parameters for all powders and the different particle size distributions were simulated only to obtain more reliable and reproducible results. It must be noted that since the early slope and the time of peak are the only two features that are fit in these simulations, and three factors,

Figure 5.20: Comparison between simulations and experimental results of heat-evolution rates and degrees of hydration

namely k_1 , k_2 and n can be varied, a non-unique solution for the fit-parameters exist. The value of n was therefore fixed to remove this redundancy.

The value of n was fixed at 3 as better results were obtained throughout the tests with this value. This value of n theoretically corresponds to a two-dimensional growth with continuing nucleation, at least at the early ages. Therefore, in effect, the two other parameters, $t_{2/3}$ and k_2 , were varied in the simulations to obtain the fit. While the position of the peak was found to depend on $t_{2/3}$, the rate of heat evolution depends on k_2 . The results were found to be extremely sensitive to both values.

5.7.3 Discussion

For all the powders simulated, it was found that it is possible to approximately follow the rate of heat evolution in the rising part of the curve. The value of n used indicates that in the first few hours of the process, new nuclei continue to form close to the surface. This is not completely improbable since during this period, a large part of the surface of the particles is exposed to the pore-solution with generally high ionic concentrations.

Although a good agreement was observed in the accelerating part of the curves, it was found that, for all samples simulated, the heat-evolution after the peak continued to be significantly higher than the experimentally observed values. This is because, while the peak is reached due to the entire surface of the particle being covered, a reduction in the heat-evolution rate can only happen when the surface of the product available for growth reduces. In the present scenario, free surface of the product can be reduced only due to overlap between neighbouring particles. However, it can be seen from the simulations, that although the vertical rate of growth has been set to closely match the observed heat-evolutions, the overlap between the particles is not high enough to cause a reduction in the reaction rates, at the experimentally observed rates.

Figure 5.21: A slice from the simulation of fraction F-15 μm at the peak. The pores are shown in black, alite in dark-grey and hydrates in white.

Figure 5.21 shows a slice of the simulated microstructure of sample F-15 μm at the peak of heat evolution. The white hydrate rims indicate the outermost layers of the rough product surface. While the solids in the two-dimensional figure appear to be much less connected than in reality in the three-dimensional structure, it can nevertheless be seen that only a small fraction of the volume is

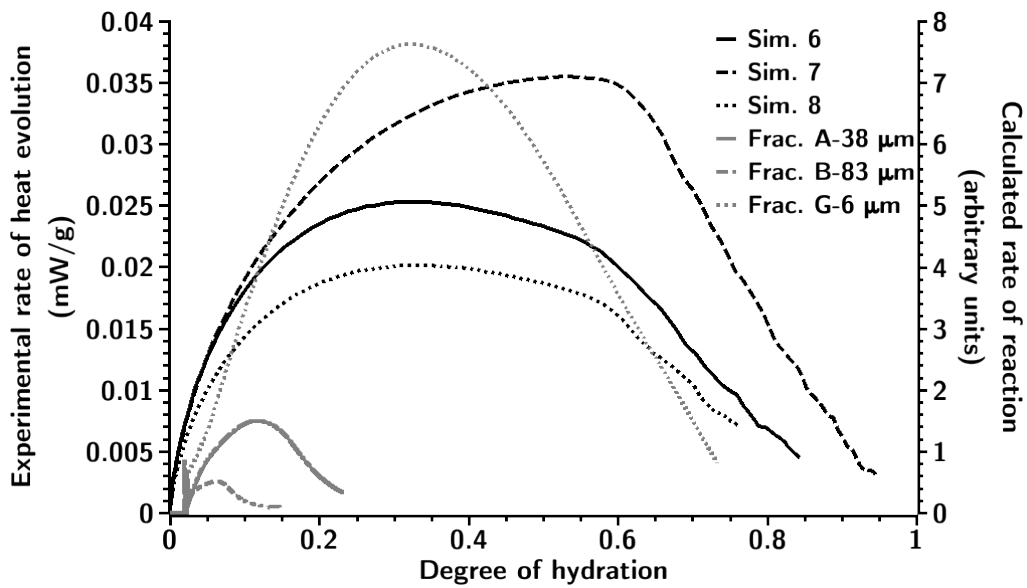

Figure 5.22: Degree of hydration against rate of reaction for calculations and experiments

filled by solids, and the inter-particle overlaps are too little to lead to a reduction in the reaction rate.

To better understand the results, the results here have been compared to results from simulations 6 to 8 shown earlier. In these simulations, the reaction stoichiometry had been kept the same as that for cement and the volumetric ratios were equivalent to a 0.4 water to cement ratio paste. The rate of heat evolution is plotted against the degree of hydration for both cases in figure 5.22. As can be clearly seen in the figure, in the experiments, the peak occurs at much lower degrees of hydration than those observed in the simulations. This is because the volume of product produced at these degrees of hydration in the simulations is not large enough to cause sufficient overlaps, if a uniform density product is assumed.

The above results show that a nucleation and growth process on the surface of the particles, and an outward growth rate that corresponds to the experimentally measured heat-evolutions alone cannot explain the post-peak behaviour of hydration. In order to obtain a clear peak, without a following plateau, a significant overlap of the product from different particles is required. As this overlap cannot be explained with the assumption that a uniformly dense product is produced, the possibility of a lower density product that increases in density with hydration is investigated in the later sections.

It is often argued that the slow diffusion of ions through the layers of hydrates depositing over the cement particles controls the rate of reaction leading to the deceleration. It is shown in the following discussion that evidence suggesting that diffusion does not play an important role in hydration at least during the first 24 hours of hydration exists. It is also shown that the observed behaviour points towards the nucleation and growth mechanism controlling the reaction well into the fifth stage of hydration.

5.8 Existence of a Diffusion Controlled Regime

The deceleration in the fourth and fifth stage of hydration is often explained by a diffusion regime, where the layers of hydrates depositing on the cement particles inhibit the exchange of ions³⁸. It has been shown in the last section that the accepted mechanism of nucleation and growth is able to explain the acceleration observed in the third stage of hydration, but a reduction in the reaction rates following the peak is not obtained. Another set of simulations were carried out to study the fit parameters obtained when the diffusion controlled regime is used to reproduce the measured heat-evolution.

5.8.1 Simulations with a Diffusion Controlled Mechanism

In these simulations, the accelerating part of hydration was simulated using a modified form of the Avrami equation. In this form of the equation, the Avrami equation is decomposed to the level of individual particles with the assumption that the rate of hydration of a particle is proportional to its surface area. This assumption is assumed to be justified as both the nucleation and growth and the dissolution process depend on the surface area. The equation is reproduced below for convenience.

$$\frac{dr_{in}}{dt} = -k_1 \cdot n \cdot t^{n-1} \cdot e^{-k_1 t^n} \quad (5.18)$$

The relation used to simulate the diffusion controlled process is shown in equation 5.19. In this equation, the rate is assumed to be inversely proportional to the thickness of the layer of hydrates around the particles. Being in Cartesian coordinates, the equation is approximate and it is assumed that the layer of hydrates offer a uniform resistance to diffusion. The rate is corrected for the reduction of free surface of particles due to overlaps.

$$\frac{dr_{in}}{dt} = \frac{-k_{diff}}{r_{out} - r_{in}} \quad (5.19)$$

Equation 5.18 was fit to the accelerating part of the evolution such that the calculated rate of hydration fit closely with the measured values up to as close to the peak as possible. While this equation does not perfectly fit the measurements and does not model the correct mechanism, its current form where the reaction rate depends on the surface area of the particle is assumed to provide a good starting point for a switch to the diffusion controlled mechanism. It is used only to reproduce the thickness of the layer of hydrates at the measured degree of hydration and time at the peak for the powders. The mechanism is assumed to switch from the first to the second equation when the reaction rate predicted by the second equation is lower than that from the first equation. This switch is allowed to occur at different moments independently for each particle and can happen only in one direction. The single parameter in the equation simulating diffusion controlled regime was then varied to fit the decelerating part of the curve.

The fits along with the original curves are shown in figure 5.23. The parameters obtained from the fits are shown in table 5.6. The parameter n in the Avrami equation was kept constant at 2.6 for most simulations. This value was chosen as, on an average, it provided the best fits in the simulations 6 to 8 shown earlier. A higher value of n was required to obtain an acceptable fit for fraction G-6 μm . Also, an period with no reaction lasting 2.5 hours was required to be assumed for this fraction.

Table 5.6: Parameters used in Avrami equation and diffusion equation simulations

Fraction	A-38 μm	B-83 μm	C-38 μm	D-21 μm	E-18 μm	F-15 μm	G-6 μm
k_1 (hours^{-n})	1.25×10^{-4}	5.60×10^{-4}	6.70×10^{-4}	2.60×10^{-4}	4.50×10^{-4}	1.54×10^{-4}	2.00×10^{-4}
n	2.6	2.6	2.6	2.6	2.6	2.6	3.2
k_{diff} ($\mu\text{m}^2/\text{h}$)	4.00×10^{-4}	4.80×10^{-3}	2.80×10^{-3}	1.20×10^{-3}	2.00×10^{-3}	4.00×10^{-4}	3.20×10^{-3}
t_0 (hours)	0.0	0.0	0.0	0.0	0.0	0.0	2.5
a_0 (%)	2.3	2.0	1.3	2.0	0.9	3.0	2.0

The smallest diffusion coefficient fit over the range was found to be 12 times smaller than the largest one. The rather large spread of the parameters indicates

Figure 5.23: Comparison between simulations and experimental results of heat-evolution rates and degrees of hydration

that the thickness of the layer of product on the particles, when the switch to the diffusion control occurs, differs by at least an order of magnitude between particle size distributions.

The observed variability in the thickness of the product layer between particle size distributions could either indicate that the properties of the hydrate change dramatically depending on the particle size distribution, or that although the equation produces the right shape of the evolution, it does not model the actual mechanism controlling hydration. Since such a large difference in the properties of C-S-H due to different particle size distributions is not expected, the above results clearly show that a slow diffusion of ions through the layer of hydrates cannot explain the dependence of the behaviour on the particle size distributions.

In the following discussion the rate of change of the hydration kinetics are studied to get more insight into a possible point of switch between mechanisms.

5.8.2 Rate of Change of Hydration Kinetics

The rates of heat evolution for all fractions were smoothed using Savitzky–Golay smoothing filter¹²⁷ with a window size of eleven points. The values were then differentiated and the results are plotted in figure 5.24. The rate of reaction and its differential calculated from an Avrami equation, with an arbitrary value of k and the value of n set at 3, is also plotted in the figure.

The information for the first two-three hours of the experiments is missing due to the dissolution peak. The results for fraction B – 83 μm are not very clear possibly due to a bimodal particle size distribution leading to observed reaction rates being a combination of two widely different particle sizes reacting together at different rates. For the other samples, the differential of the reaction rate was found to be either constant or increasing almost linearly for a few hours. Before the peak of heat-evolution the second order differential starts to reduce, almost

Figure 5.24: Heat-rates and differential of heat-rates for the fractions and calculated from the Avrami equation, as marked

linearly, up to a few hours after the peak. When compared to the calculated values, the trend starting a few hours before the peak, up to 24 hours is similar to that observed for the curve calculated from the Avrami equation. It must be noted here that the Avrami equation is used here only as an example of the nucleation and growth process since it represents the shape of the evolution quite well.

The smooth, almost linear, variation of the second order differential from a few hours before the peak to a few hours after the peak suggests that the mechanism of the reaction does not change in this period, pointing towards the nucleation and growth mechanism continuing well beyond the peak. A similar conclusion was drawn by Thomas⁶² on comparing a relation derived for heterogeneous nucleation and growth with measured heat evolution values.

One of the important prerequisites for the reaction to be controlled by a diffusion mechanism is the presence of a thick and continuous layer that inhibits a free exchange of ions. However, in order to explain the accelerating part of the reaction using the nucleation and growth mechanism, as discussed earlier, it is necessary to assume that the surface of the particle is not completely covered by product until the peak. This implies that the surface of particles is still partially exposed to the pore solution, without any diffusion barrier inhibiting reaction. It is therefore only logical that the diffusion controlled regime can only become the controlling mechanism after the peak.

5.8.3 Dependence of Reaction Rate on Hydrate Thickness

The approximate dependence of the reaction rate on the thickness of the layer of hydrates was studied. The thickness of the product was calculated from the degree of hydration, assuming mono-sized spherical particles. The size of the particles was set at the median radius of the distribution. The variation of the rate of heat evolution with the thickness of the product is shown in figure 5.25. While it is understood that the calculated thickness of the product is only an approximate

Figure 5.25: Dependence of the rate of hydration on the approximate thickness of products

value, it can be seen that, depending on the particle size, the rate of hydration can vary to a large extent even when the thickness of the product is the same.

The arguments above strongly point towards the diffusion controlled mechanism not reducing the hydration rate at least up to a few hours after the peak. In the following discussion, a modification to the nucleation and growth mechanism, which could explain most of the observed behaviour during the first 24 hours, is presented.

5.9 C-S-H with Age-Dependent Density

5.9.1 Kinetics

In this set of simulations, the kinetics used are similar to those used in the earlier case where the nucleation and growth mechanism was simulated on the particles, with the C-S-H only partially covering the surface of the particles during the first few hours. The main difference in these simulations is that the density of the product formed is variable. Here, it is assumed that the product formed from the reaction is low in density and that its density increases with time.

This process of 'densification' is assumed to occur as a nucleation and growth as well. The presence of C-S-H with variable density has been proposed earlier to explain surface area measurements by nitrogen adsorption^{12,20}. It was also shown that the specific surface area of C-S-H reduces with time, indicating an increase in density of the product. To explain the measured specific surface areas and phenomenon such as drying shrinkage, creep and visco-elastic deformation, a colloidal structure for C-S-H has been proposed²¹. In fact, a progressive densification of the product was also proposed much earlier by Powers³³.

A mechanism of growth, similar to that in the previous section, is used here to explain the observed reaction rates. In this study, the rate of hydration is assumed to be controlled by a nucleation and growth mechanism, the main points of which are as follows:

- The surface of the particles is only partially covered by product, and the nucleation and growth mechanism controls the growth of product over the surface,
- Fresh outer product has a low density and a high internal specific surface area,
- The internal surface of C-S-H serves as growth sites along with the exposed outer surface of the growing clusters, and
- The internal surface area of C-S-H is assumed to decrease linearly as its density increases.

The schematics of this mechanism is shown in figure 5.26.

The amount of material around a particle at any moment in time can be calculated in a way similar to the last set of simulations as follows:

$$m_i = \int_{r_0}^{r_0+k_2 \cdot t} 4 \cdot \pi \cdot r^2 \cdot \left(1 - \exp \left(-k_1 \cdot \left(t - \frac{(r-r_0)}{k_2} \right)^n \right) \right) \cdot f_{free} \cdot \frac{\rho(r)}{\rho_o} \cdot dr \quad (5.20)$$

Figure 5.26: Schematics of the nucleation and growth mechanism with different parallel and outwards growth rates and densification of the product for a single particle (top) and between particles (bottom)

The above relation includes a variable density, $\rho(r)$, which depends on the distance from the centre of the particle. It is assumed that the internal surface area (s_i) of the product varies linearly with density, as follows:

$$s_i \propto \frac{\rho_{max} - \rho}{\rho_{max} - \rho_{min}} \quad (5.21)$$

In the above equation, ρ_{min} and ρ_{max} are the minimum and maximum possible densities of the product respectively. Since, the internal densification is proportional to the available internal surface area, the rate of change of the density of the product, ρ , can be related to time, t , as follows:

$$\frac{d\rho}{dt} = k_{den} \cdot \frac{\rho_{max} - \rho}{\rho_{max} - \rho_{min}} \quad (5.22)$$

In this equation, k_{den} is a rate constant. Rearranging we get:

$$\int_{\rho_{min}}^{\rho} \frac{\rho_{max} - \rho_{min}}{\rho_{max} - \rho} \cdot d\rho = \int_0^{t_r} k_{den} \cdot dt \quad (5.23)$$

Where t_r is the age of the product at any point at a distance r from the centre of a particle. Integrating we get:

$$(\rho_{max} - \rho_{min}) \left(\ln \left(\frac{\rho_{max} - \rho_{min}}{\rho_{max} - \rho} \right) \right) = k_{den} \cdot t_r \quad (5.24)$$

Rearranging we get:

$$\rho = \rho_{max} - (\rho_{max} - \rho_{min}) \cdot \exp \left(\frac{-k_{den} \cdot t_r}{\rho_{max} - \rho_{min}} \right) \quad (5.25)$$

As in the last case, t_r can be related to the distance of the product from the original surface of the particle, r , and time, t , using the vertical rate of growth, k_2 , as follows:

$$t_r = \left(t - \frac{r}{k_2} \right) \quad (5.26)$$

5.9.2 Fit Parameters and Results

Equations 5.20, 5.25 and 5.26 were given as an input plugin in μic and solved numerically to calculate the amount of product around the grains at any moment in time. Similar to the last set of simulations, the rates of reaction were calculated from the demand generated from the nucleation and growth process described above. The results from the simulations are shown in figure 5.27 along with the experimentally measured values for the corresponding powders. The fit parameters used in the simulations are listed in table 5.7. The value of q_{max} was set to 2.0 g/cc for all simulations, which was also assumed to be the density of the inner product.

In the simulations, the parameters were varied using manual trial and error. Like in the previous case, perfect fits were not sought and the trials were stopped when it was considered that the calculated results fairly replicate the experimentally measured values. The value of n was again fixed at 3.0 and the other four parameters were varied for individual simulations. It must be noted that since the density of the inner product was fixed at the highest possible density of the product, the actual average density of the product is higher than q_{min} .

Figure 5.27: Comparison between simulations and experimental results of heat-evolution rates and degrees of hydration for simulations with variable density of product

The position of the peak was observed to depend on $t_{2/3}$, and k_2 and k_{den} were observed to have a combined effect on the rate of hydration. The factors k_2 , k_{den} and q_{min} have a combined effect on the time and heat evolution at peak and also the rate of heat evolution after the peak. Once again, the fits were found to be extremely sensitive to all four parameters and obtaining good fits was time-consuming. Due to time-constraints, in some cases the trials were stopped when a reduction in the rates was observed at degrees of hydration similar to those in the experiments. Figure 5.28 shows the variation of the curves with the parameters. The parameter k_2 was found to have a large dependence on the particle size distribution. The value of this parameter was found to be lower for finer particle

Figure 5.28: Dependence of simulated heat-evolution on parameters for fraction E-18 μm

Figure 5.29: Variation of k_2 with the number of particles per unit volume in the simulations

size distributions. The variation of this factor with the number of particles per unit volume is shown in figure 5.29. The data used for this figure is listed in table 5.7.

Table 5.7: Parameters used in variable density nucleation and growth simulations

Fraction	A-38 μm	B-83 μm	C-38 μm	D-21 μm	E-18 μm	F-15 μm	G-6 μm
$t_{2/3}$ (hours)	6.2	8.0	7.0	8.0	8.0	8.4	10.2
n	3.0	3.0	3.0	3.0	3.0	3.0	3.0
k_2 ($\mu\text{m}/\text{hour}$)	0.04	1.10	0.78	0.12	0.34	0.08	0.23
k_{den} (g/cc/hour)	0.0050	0.0020	0.0052	0.0095	0.0110	0.0090	0.0050
Q_{min} (g/cc)	0.214	0.100	0.109	0.150	0.182	0.127	0.245
α_0 (%)	2.90	2.20	2.30	4.70	3.15	5.90	0.80

Table 5.8: Details of simulations with densifying C-S-H

Fraction	A-38 μm	B-83 μm	C-38 μm	D-21 μm	E-18 μm	F-15 μm	G-6 μm
Number of particles	2034071	241	244	2096401	2173	805725	843168
Size of C.V. (μm)	100	400	175	125	100	75	40

Similar to the earlier fits, there is a redundancy in the fit parameters in these simulations. While four parameters, not including n , could be varied, three main features of the curves, viz. the time of peak, the height of the peak and the rate of deceleration were sought to be reproduced. However, despite the redundancies, in these simulations all the four parameters were varied together in order to avoid biasing effects resulting from fixing one parameter to a value that might not work well for some of the simulations.

5.9.3 Discussion

For all particle size distributions, it was found that, using the proposed mechanism, it was possible to obtain reasonable fits to the experimental results for a large part of the first 24 hours. Although the best possible fits were not achieved in some cases, the trends demonstrate that the experimentally measured reaction kinetics can be obtained using the described mechanism. The variation in the fit

parameters, specially k_2 , is quite large, however a large number of unknowns and assumptions exist in the simulations, some of which are listed below.

- The variation of specific surface area with density is not known. The first order approximation used here can affect the shape of the results.
- The inner product is assumed to always have a high density. While this assumption should not affect the results much and is only expected to scale the parameters, some side-effects might occur.
- No induction period was assumed. The shape of the curves is affected if an induction period precedes the nucleation and growth process.
- At any moment, the same fraction of all particles is assumed to be covered by product.

Apart from the numerical factors discussed above, one of the most important factors affecting the results is that, as discussed above, the measured calorimetry results do not scale with the specific surface areas calculated from the measured particle-size distributions. The nucleation and growth mechanism simulated here assumes that the rate of nucleation and therefore the rate of initial growth depends on the surface available, which, in the current case, is proportional to the specific surface area of the cement. This observed variation might be either due to errors in the measured particle size distributions, or in the nucleation and growth process being non-homogeneous on the surface of the particles. While the initial dissolution of cement, which is not considered in the simulations, would also affect the surface available for nucleation, it is not expected to lead to the large deviation observed in the trend (figure 5.13).

Figure 5.30 shows a slice of the simulated fraction B-83 μm at the peak, with the outer boundary of the hydrates marked in white. It can be seen in the figure, at the peak, the low density product has filled a significant portion of the microstructure, explaining the sharp peak observed in the simulations. The high outward growth rates simulated here quickly increase the reach of the reaction to

Figure 5.30: A slice from fraction B-83 μm close to the peak, with pore-space in black, anhydrous grains in dark grey and hydrates in white

almost the entire microstructure, covering the entire volume with a fine mesh of low-density product, converting the process into a volumetric process.

It was also observed that the fit parameter k_2 was lower for simulations with larger number of particles per unit volume. In computational volumes with larger number of particles, the average distance between neighbouring particles is lower and grain boundaries are distributed more uniformly throughout the volume. A lower rate perpendicular to the grain boundaries is, therefore, required for impingement between different particles. The observed dependence of k_2 on the average distance between particles indicates that the process of nucleation and growth of C-S-H tends to spread throughout the pore-volume quite rapidly.

5.10 Simulating the Filler Effect

In order to understand the possible mechanism of the observed effect of fine inert fillers on hydration kinetics, simulations using the above-discussed nucleation, growth and densification mechanism were carried out. Here, it is assumed that this C-S-H also forms on the surface of the filler particles and densifies, similar to the product growing on the surface of the alite particles. The particle size distribution used for the alite particles is the same as that shown for PSD-2 earlier in figure 4.2

(page 84). The filler particles were assumed to be of a uniform size with a diameter of 0.4 μm . In these simulations, while the parameters of growth on the alite particles were the same as those used in the simulation with neat alite, additional C-S-H was assumed to grow on the filler particles, with a mechanism similar to that on the alite particles. The rate of outwards growth of C-S-H on the filler particles was assumed to be less than that on the alite particles. The parameters used in the simulations for the rates of growth and densification on the alite and filler particles are listed in table 5.9. The parameters were chosen arbitrarily, based on the simulations presented earlier.

Table 5.9: Parameters used in simulations to study the filler effect

Simulation	I	II		III		IV	
Replacement	0%	5%		10%		15%	
Particle	Alite	Alite	Filler	Alite	Filler	Alite	Filler
$t_{2/3}$ (hours)	7.0	7.0	7.0	7.0	7.0	7.0	7.0
n	3.0	3.0	3.0	3.0	3.0	3.0	3.0
k_2 ($\mu\text{m}/\text{hour}$)	0.30	0.30	0.17	0.30	0.17	0.30	0.17
k_{den} (g/cc/hour)	0.008	0.008	0.008	0.008	0.008	0.008	0.008
Q_{min} (g/cc)	0.15	0.15	0.15	0.15	0.15	0.15	0.15

The calculated rates of heat-evolution are shown in figure 5.31. Due to a large number of unknowns, fits with experimental results presented in section 5.5.3

Figure 5.31: Calculated rates of heat-evolution from simulations with inert fillers

earlier have not been attempted. Still, the above results show that the enhancement in hydration on the addition of inert fillers can be explained by the additional growth of C-S-H on the filler particles, which provide additional surface for nucleation of the product. As a larger fraction of the product grows close to a surface, the average density of C-S-H is higher at the same degree of hydration. These simulations also predict a denser and less-porous microstructure with the addition of fine fillers resulting from the more uniform distribution of hydrates in the microstructure.

5.11 Deductions from the Simulations

Based on the simulations discussed above, given that the assumptions made above are not incorrect, the following deductions can be made:

- The low heat evolution during the 'induction period' and the acceleration of the hydration rate afterwards can be explained by the nucleation and growth mechanism.
- In the nucleation and growth mechanism, nuclei of product form on the surface of the particles and grow at a constant rate. The rate may be different in the directions along the surface and outwards from the particle.
- The peak in the hydration curve corresponds to the time when the surface of the particles is almost fully covered.
- A pure nucleation and growth process with the formation of a uniformly dense material cannot explain the post-peak behaviour of the hydration curves.
- In order to explain the observed deceleration with the slow diffusion of ions through the layers of hydrates, a large variability in the transport properties of C-S-H has to be assumed.
- Almost the entire hydration kinetics during the first 24 hours can be fit if it is assumed that the initial density of the product formed is low and that

there is an internal surface associated with the low density product, which is available for growth.

- The process simulated in the simulations with variable densities, is close to a volumetric homogeneous nucleation and growth, and models the formation of a fine low-density mesh of the product through a large portion of the volume, which grows in density with the progress of hydration.
- The fit parameters obtained from these simulations vary to a large extent. However, a clear relationship between the rate of perpendicular growth from the particle boundaries, k_2 , which is the parameter showing the largest scatter, and the number of particles per unit volume was observed. This might indicate that the process tends to spread throughout the pore-volume quite rapidly.
- The enhancement in the rate of hydration observed on the replacement of alite by fine inert fillers can be explained by the nucleation of C-S-H on the filler particles, and the faster densification of C-S-H occurring due to a larger proportion of the product being present close to grain boundaries.

5.12 Discussion

The results above indicate that the nucleation and growth process in hydration is more volumetric in nature than being confined to the surface of the particles. The results indicate the presence of a loose product, holding all the particles together, from quite an early age. Although such a microstructure is not seen in micrographs of cement paste, this could be attributed to the process of sample preparation required for microscopic observations, which involves drying. As this outer product would be suspended in the pore-solution like a colloid, drying of the paste will lead to a collapse of the structure. Still, a loose, low-density structure of C-S-H, growing as a loose packing of fibres or sheets can be observed in many micrographs^{36,27,24}.

Although with a much higher density, a colloidal structure of C-S-H was postulated by Jennings, in order to explain its specific surface, creep and visco-elastic behaviour²¹. Since the techniques reported measure only the bulk values, only an average estimate of the values is obtained and a much higher localised variation in the properties could still lead to similar bulk values. Therefore, although only two possible densities of C-S-H have been proposed by Jennings¹², the actual variation at the level of individual particles could be much higher and more continuous.

Another evidence in the support of a low density product filling a large part of the microstructure is that when pore-sizes are measured using Quasi Electron Neutron Scattering and NMR relaxation, which are two of the few techniques that can explore the pores without having to dry the samples, capillary pores are not observed^{128,129,130}. In these measurements, mobile water was not observed after just one hour of hydration, indicating that most of the water at this stage is present only in smaller pores. This observation has been explained by the hypothesis that since the water is present close to surfaces its mobility is limited, similar to water in supercooled state¹³¹. It was also proposed that the water continues to get “glassier” as it penetrates into the colloidal particles of C-S-H, increasing its immobile fraction. However, the absence of large capillary pores, and the increase in the glassiness of the water with hydration observed in these experiments could also support the argument that a low density product quickly fills a large amount of the space available in the system and continues to get denser.

This process of densification can also explain the early setting of paste even at low degree of hydration, when just a small amount of product can lead to the transformation of the paste from a viscous liquid to a visco-elastic solid. The presence of a low-density product can improve the bond between the particles leading to a set and the progressive densification of the product would lead to a stiffening of the matrix.

Figure 5.32: Degree of hydration against the rate of heat-evolution from different alite samples with and without fine filler particles

In figure 5.32, the observed rate of hydration is plotted against the degree of hydration at around 24 hours, just after the reaction reaches a more constant rate. In this figure, data points from different series of experiments, first series with variable particle size distributions, second series with rutile as a fine filler and the third series with silica fume as a filler, which were presented in section 5.5.3, are plotted using different shapes of points.

Contrary to intuition, it is observed that the rate of hydration is higher when the degree of hydration is higher. One of the points, corresponding to fraction G-6 μm , was found to be much higher than the rest of the trend as data points beyond 21 hours of hydration were not available. The results show that around 24 hours the rate of hydration is approximately proportional to the volume of the product present in the microstructure. This is consistent with the hypothesis above that the process of hydration at this time is volumetric in nature.

Although, conclusive photographic evidence of the presence of this low-density product is currently not available, the current study points towards an important possibility in microstructural development, which requires further

investigation. It is not claimed that the presented hypothesis is an accurate representation of the hydration mechanism. Even if the basic mechanism is correct, the current version of the theory has many gaps and uses many assumptions that may not necessarily be justified. The spread in the fit parameters also indicates significant missing information in the input and the mechanism.

More importantly, it has been conclusively shown that in the form it is currently accepted, the nucleation and growth mechanism cannot explain the observed reaction rates beyond the peak of hydration. It was also shown that in order to explain the decelerating part of hydration using the diffusion controlled mechanism, hydrates with widely varying diffusion properties have to be assumed.

The simulations presented also shows the adaptability of μic to different simulation scenarios and in predicting results based on different mechanisms that can be input to the model. The results also show that as long as unreasonable simplifications are not made, microstructural models can be used to study hydration mechanisms.

5.13 Conclusions

In this chapter, the hydration kinetics of alite were investigated using μic . The rates of hydration for different particle size distributions were studied and were observed to be higher for finer powders. Powders of similar particle size distributions close to the measured particle sizes of the powders were simulated in μic using two different nucleation and growth mechanisms. It was shown that the nucleation and growth of a uniformly dense material alone cannot explain the observed hydration kinetics of alite. It was also shown that in order to explain the deceleration using a diffusion controlled regime, drastic changes in the transport properties of C-S-H, only with the variation of cement particle sizes would have to be assumed. If a low-density C-S-H is assumed to be distributed in the pore-space,

the reaction kinetics for most of the first 24 hours of hydration can be explained using a nucleation and growth mechanism.

The versatility of μic in enabling the simulation of a wide range of phenomenon in three-dimensions was demonstrated. The simulation of kinetics, taking into account both the consumption of particles and space-filling would not be possible in two-dimensions. Although there is a lot of information regarding the simulated processes missing, this study demonstrates how μic can be used to identify the important parameters in the process, to help in the design of further experiments.

Chapter 6: Conclusions and Perspectives

6.1 Microstructural Modelling and μic

In the current work it was shown that microstructural models can provide important information about cement hydration. It was also shown that a flexible modelling platform, which enables an easy inclusion of new mechanisms in the simulations, can help in the better interpretation of experimental results. The design of better algorithms can help us to avoid unnecessary simplifications in the models and can lead to more accurate results. For example in the case of cement, the possibility to simulate the microstructure, with every particle included in the simulations, can provide more accurate results and a better understanding of the mechanisms.

With this objective in mind, μic has been designed to provide cement scientists with a powerful and flexible modelling tool. μic uses the vector approach to enable the multi-scale representation of the cement microstructure. The performance of the vector approach has been improved to allow modelling of millions of cement particles. The flexible architecture of μic allows simulations of a wide range of particulate growths. The user is allowed to define the materials, particles and reactions in the simulations and to control the reaction mechanisms by creating short programmes, called plugins, that can be given as input at execution-time. The high amount of flexibility offered by μic can help achieve a better understanding of cement hydration.

Some of the important numerical and scientific advances made with the development of μic are listed below.

- The vector approach was improved to enable simulations with millions of particles with the explicit calculation of all interactions.
- A microstructural modelling platform with the ability to simulate user-defined materials, reactions, particles and mechanisms was developed.
- The flexibility of μic enables the easy inclusion of more cement phases and hydration conditions in simulations.
- The flexibility is also useful for studying the macroscopic effects of microscopic phenomena for comparison with experiments.

6.2 Hydration Kinetics

It has been shown that a simple nucleation and growth mechanism cannot explain the deceleration in reaction rates observed after the peak. In order to explain the deceleration by a diffusion controlled mechanism, the transport properties of C-S-H would have to vary drastically between samples. The nucleation and growth of a low-density product and its subsequent densification can explain the experimentally observed hydration rates at least during the first 24 hours of hydration. Experimental evidence, such as the absence of large capillary pores when pore-sizes are studied using QENS or NMR without prior drying of the samples^{129,130}, and the fibrous low-density structure of C-S-H seen in TEM images^{24,27}, supports the presence of a dispersed C-S-H that can fill a large part of the microstructure from the early hours of hydration. Simulations of the nucleation and growth mechanisms demonstrate the synergy between hydration kinetics and microstructural development. Nevertheless, many aspects of the hypothesis presented here have to be refined.

Still, since these suppositions are mostly speculative and are based on microstructural fits of hydration kinetics, perfect accuracy of the model presented

is not claimed. In fact, the main aim of the current study is to demonstrate the need for a better understanding of the hydration mechanisms and shows that the mechanisms that are mostly assumed to be true might not be as accurate as they are believed to be. It is also demonstrated that computers and numerical models can aid in better understanding of cement hydration and also in the verification of the currently accepted theories on microstructural development.

Some of the important conclusions from the numerical study of the hydration kinetics of alite are listed below.

- The simple nucleation and growth mechanism cannot explain the deceleration of hydration after the peak.
- In order to explain the deceleration using the slow diffusion of ions through the layer of hydrates growing on the surface of the particles, large changes in the transport properties of C-S-H across particle size distributions have to be assumed.
- The rate of hydration during the first 24 hours can be fit with simulations modelling the nucleation and growth of a loosely packed C-S-H, which densifies with hydration, but a large variation in the fit parameters is observed.
- The fit parameters were observed to depend on the number of particles per unit volume in the simulations, with the trends indicating that the loosely packed C-S-H spreads throughout the pore-volume within a few hours.
- This study demonstrates the important role that numerical modelling can play in further developing our understanding of cement hydration.

6.3 Perspectives on Microstructural Modelling

μ ic, like most other microstructural models, is currently limited to spherical particles. While it is possible to build most shapes as an assembly of smaller

spherical particles, this can be computationally expensive and less accurate than explicit modelling of other shapes. The modelling of certain microstructural features might necessitate the presence of non-spherical shapes in the simulations. It is therefore important to develop algorithms that can enable fast calculation of interactions between non-spherical shapes such as rods, cubes, prisms and ellipsoids.

A resolution-free, or even high-resolution, characterisation of the porosity poses a great challenge to modelling the microstructure and other important properties, such as ion-transport, that can affect the durability of concrete. Currently two different pore-characterisation methods have been implemented in μic . One of the techniques implemented uses the vector approach to characterise the pores and their connectivity. However, this approach is currently limited to 200,000 particles and requires further improvement before it can be applied to cement. In the other approach, a regular mesh with 1 billion pixels has been used to obtain the approximate pore-sizes. However, for typical simulations, the voxel-size in this approach is limited to $0.1 \mu m$, which, although smaller than the voxels used in other voxel-based models, is much larger than the smaller capillary pores. In order to be able to use the simulated microstructures to calculate durability-related properties of cement, a better characterisation of the pores is needed.

In all the simulations presented here, thermodynamics and ion diffusion are ignored and only processes that depend on physical characteristics have been modelled. While thermodynamic calculations have not been included in the current version of μic , because of the flexible and extensible design of μic , a thermodynamic engine could be easily added to the model. A discrete model simulating local thermodynamic properties and ion transport could be overlaid on the vector information in the model in order to obtain a better representation of cement hydration. The current architecture of μic already provides tools to overlay discrete information on the vector-encoded geometry and also to facilitate

communication and inter-conversion between the vector and discrete information. Further development would still be required for efficient modelling of the coupled chemical and physical processes.

6.4 Perspectives on Hydration Kinetics

While it has been demonstrated that our current understanding of hydration kinetics is limited, the implications of the kinetics on the microstructure and vice-versa have also been shown. The study points towards the need for new ideas to be developed and tested in order to better explain cement hydration. As kinetics depend directly on the mechanism, it is more important to achieve a better understanding of hydration mechanism than to obtain blind fits to widely accepted equations. Significant amount of work is still required to understand the hydration mechanism of alite and other phases in cement in order to allow comprehensive modelling of cement hydration. The results also show that many of the currently accepted ideas may have to be reverified using the newer computational and experimental techniques.

While only limited evidence supporting the hypothesis presented in this study is present, the real mechanism of hydration could still be similar to that presented here. A refinement of the assumptions and the information used in the current study could provide important information pertaining cement hydration. The early dissolution of cement phases, which can potentially alter the surface available for the growth of products, and also cause a variation between different particle sizes has not been studied here. This process could, however, be easily included in the calculations, if the dissolution mechanisms and saturation concentrations were known.

This study demonstrates the importance of the importance of using a combination of experimental techniques and a good balance between experimental and analytical studies. Many possibilities of development in cement science still

exist and tremendous development can be made using the right combination of experimental, numerical and analytical techniques.

Materials Science Doctoral Student

Laboratory of Construction Materials
Ecole Polytechnique Fédérale de Lausanne
EPFL-STI-IMX-LMC, Station 12
Lausanne 1015, Switzerland
Ph : (+41)-21-693-68-59

Home Address:

Ch. du Bochet 18
1024 Ecublens
Switzerland

Email: shashank.bishnoi@epfl.ch

Personal

Date of Birth : 13 December 1980
Nationality : Indian

Educational Qualifications

- Masters of Engineering, Civil Engineering (September 2004)
University of Tokyo
 - *Awarded the Furuichi award for best Masters thesis presentation in Department of Civil Engineering, University of Tokyo*
 - *Monbu-kagaku-sho scholarship awarded by Ministry of Education, Culture, Sports, Science and Technology, Government of Japan*
- Bachelor of Technology, Civil Engineering (May 2002)
Indian Institute of Technology Kanpur
 - *Awarded the Prof. A.S.R. Sai Memorial Medal for "Outstanding all round achievements among students graduating in B.Tech. programme in Civil Engineering"*

Journal Publications submitted

- Smilauer V., Bittnar Z., Bishnoi S. and Scrivener K., "*The differences in homogenized elastic properties between discrete and vector cement hydration models*", submitted to Materials and Structures
- Bishnoi S. and Uomoto T., "*Strain temperature hysteresis in concrete under cyclic freeze-thaw conditions*", Cement and Concrete Composites (accepted, in press)

Conference Publications

- Bishnoi S. and Scrivener K., "*Micro-structural modelling of cementitious materials using vector approach*", Proceedings of the 12th International Congress on the Chemistry of Cement, Montreal, Canada, July 2007
 - Costoya M., Bishnoi S., Gallucci E. and Scrivener K., "*Synthesis and hydration of tricalcium silicate*", Proceedings of the 12th International Congress on the Chemistry of Cement, Montreal, Canada, July 2007
 - Guidoum A., Jaouadi I., Bishnoi S. and Navi P., "*Modelling mechanical properties of cement-based materials from their microstructure*", Proceedings of the 12th International Congress on the Chemistry of Cement, Montreal, Canada, July 2007
 - Bishnoi S. and Scrivener K., "*Multi-scale numerical characterisation of cement porosity*", Proceedings of the 5th International Essen Workshop on Transport in Concrete, Essen, Germany, June 2007
 - Bishnoi S. and Scrivener K., "*Modelling the hydration of portland cement using μic^2* ", Modelling of Heterogenous Materials with Applications in Construction and Biomedical Engineering, Prague, Czech Republic, June 2007
-

- Bishnoi S. and Scrivener K., "*Optimised continuum cement hydration modelling*", Proceedings of the 2nd International Symposium on Advances in Concrete through Science and Engineering, Quebec, Canada, September 2006
- Costoya M., Bishnoi S., Gallucci E. and Scrivener K., "*Effect of particle size distribution of alite on its hydration*", Cement and Concrete Science, Sheffield Hallam University, U.K., September 2006
- Gallucci E., Scrivener K., Bishnoi S., Groso A. and Stampanoni M., "*3D imaging of the pore network of hydrated cement pastes. Experimental and modelling approaches*", Cementitious Materials as Model Porous Media: Nanostructure and Transport Processes, Monte Verita, Switzerland, July 2005
- Bishnoi S. and Uomoto T., "*Strain variations in concrete under freeze-thaw conditions*", Proceedings of the 59th Annual Meeting of Japan Society of Civil Engineers, 2004, Nagoya, Japan
- Bishnoi S. and Uomoto T., "*Temperature and strain variation in concrete under freeze-thaw conditions*", Proceedings of the Annual Convention of Japan Concrete Institute, 2004, Kochi, Japan
- Bishnoi S., Singh A. and Misra S., "*Parameters affecting steel anchorages under shear*", Proceedings of the Annual Convention of Japan Concrete Institute, 2003, Kyoto, Japan

Lecture

- Lectured on "*Modelling of Cement Microstructure*" as part of the Second Marie Curie Research and Training Network course for doctoral students funded by the European Union at Ljubljana, Slovenia, March 2007

Work/Field Experience

- Actively involved in several doctoral and other research projects at current laboratory. Supervised several interns and one undergraduate project.
- Part time job at International Center for Urban Safety Engineering, Institute of Industrial Science, University of Tokyo, Japan (Dec. 2002 – Mar. 2004)
- Intern at Laboratory of Construction Materials, EPFL (June – August 2002)
Worked on computer modelling of evolutionary cement microstructure to study progress of hydration and change in porosity characteristics
- Industrial Trainee on Construction Site, M/s Gammon India Limited, Guwahati, India (May – June 2001)
- Project Fellow in Structural Engineering Laboratory, Department of Civil Engineering, Indian Institute of Technology Kanpur (May – July 2000)

Computer Skills and Experience

- Programming Languages : Java, C, Fortran

Languages

- English : Speak, read and write
- Hindi : Speak, read and write
- French : Speak, read and write imperfectly
- Japanese : Speak imperfectly
