1 Introduction

1.1 Synaptic transmission in chemical synapses

The communication between neurons takes place at synapses, which are among complex structures of the central nervous system. According to the mechanisms of the signal transmission, synapses are classified into two types: chemical and electrical. The majority of the synapses in mammalian nervous system are chemical. Thus, transmission is mediated by fusion of small synaptic vesicles with the presynaptic plasma membrane (Fig.1-1A).

Figure 1-1. The chemical synapse. *A*, Scheme visualizing fundamental steps in synaptic transmission (refer to the text for details). *B*; Electron micrograph of synaptic contact, showing active zone, with small synaptic vesicles that are docked to and clustered around active zone, which faces postsynaptic density of the postsynaptic neuron.

This process of transmitter release occurs at specialized contact sites between pre- and postsynaptic plasma membranes. Membrane bound organelles, the neurotransmitter containing synaptic vesicles, are found to be docked to and clustered around the presynaptic density, called active zone (Fig.1-1B). The active zone contains Ca²⁺ channels and molecular machinery controlling fusion of the vesicles with the plasma membrane. The postsynaptic density on the other hand contains neurotransmitter receptors and ligand-gated ion channels. Transmission is initiated upon arrival of an action potential (AP) at the presynaptic terminal, where it opens voltage-gated Ca²⁺ channels. The influx of Ca²⁺ ions leads to a rapid increase in the intracellular Ca²⁺ concentration that activates certain molecular machinery, which causes vesicles to fuse with the plasma membrane. By fusing with the plasma membrane, synaptic vesicles release their neurotransmitter

content into the synaptic cleft and thereby activate ligand-gated ion channels on the postsynaptic membrane (Fig.1-1A, B).

Based on the postsynaptic effect, the synapses in the central nervous system (CNS) can be either excitatory or inhibitory. The primary type of excitatory synapse in the CNS operates by the release of glutamate to act on glutamate receptors which are pharmacologically classified based on specific ligand binding as AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) and N-methyl-D-aspartate receptors (NMDA). Activation of these receptors will generate excitatory postsynaptic currents (EPSCs), which depolarizes postsynaptic neuron. Rapid inhibition in the central nervous system is mediated by GABAergic or glycinergic inhibitory synapses, the activation of which leads to inhibitory postsynaptic currents (IPSCs) that either hyperpolarize, or stabilize the postsynaptic membrane potential.

Acute changes in synapse activation patterns may induce alterations in its transmitter release characteristics, which are reflected in different forms of synaptic plasticity. If the strength of the synapse increases after bursts of presynaptic activity, this process is referred to as synaptic enhancement, whereas a decrease in synaptic strength is called synaptic depression. Depending on the duration of a particular form of synaptic plasticity, it could be further classified into short or long-term plasticity. Long-term potentiation (LTP) can last from a few hours to a lifetime. On the other hand, short-term enhancement (STE), which was originally thought to reflect a single process, was shown to have at least four unique components (Fisher et al., 1997; Zucker and Regehr, 2002): fast-decaying facilitation (lasting tens of milliseconds); slow-decaying facilitation (lasting hundreds of milliseconds); augmentation (with a decay time constant of \sim 5-10 s) and post-tetanic potentiation (PTP, which lasts for 30 s to several minutes).

There are multiple cellular mechanisms, most likely acting simultaneously, which could be responsible for different forms of synaptic plasticity (Goda and Stevens, 1996; Zucker, 1999; Cohen-Cory, 2002; Zucker and Regehr, 2002). To understand in which ways the synaptic strength can be modified, the quantal theory was developed, which was originally introduced by Del Castillo and Katz in 1954. This quantal analysis is based on binomial statistics, with three parameters determining the size of a stimulus-evoked response: the average size of quantal unit, the number of sites that can release a quantum, and the probability of release in response to stimulation at each release site (Johnson and Wernig, 1971). This set of parameters correlates with the morphology and the function of synapses and can be modulated by different pre- and postsynaptic mechanisms.

1.2 The calyx of Held synapse

The calyx of Held synapse is one of two giant synapses in the auditory brainstem neuronal circuitry (Fig.1-2A), which is formed between globular bushy cells (GBCs) in the anterior ventral cochlear nucleus (aVCN) and the principal neurons in the contralateral medial nucleus of the trapezoid body (MNTB).

Figure 1-2. Schematic representation of auditory neuronal circuitry. *A*, The cells responsible for the perception of sound (inner and outer hair cells) of the organ of Corti in the cochlea send information via axons of the spiral ganglion to the cochlea nucleus (CN). These axons branch to make synaptic contacts in the anterior (aVCN) and posterior ventral and in the dorsal CN. The CN of both sides project to the SOC, which is composed of three principal nuclei: LSO, MSO and MNTB. The ‘calyx of Held’ synapses arise from a projection of globular bushy cells onto inhibitory principal cells of the contralateral MNTB. The balance of synaptic excitation (from the VCN) and inhibition (from the MNTB) in the LSO is thought to play a role in sound source localization (circuitry scheme is modified from (von Gersdorff and Borst, 2002)). *B*, Image of a calyx of Held nerve terminal filled with a fluorescent Ca²⁺ indicator dye via a whole-cell patch-clamp pipette (Pre). Scale bar, 10 μm . Reproduced, with permission, from (Schneeggenburger and Neher, 2000).

Each MNTB neuron receives only one giant synapse (von Gersdorff and Borst, 2002). The calyx of Held consists of multiple, thick “fingers” that clasp the postsynaptic cell. In addition, these terminals contain multiple conventional active zones (~ 600 in P9 rats, (Satzler et al., 2002)), where synaptic vesicles cluster, facing the postsynaptic density. The individual active zones are found to be similar to those in other synapses in the central nervous system. This unusual morphology and the multiple sites of synaptic vesicle fusion ensure fast, reliable synaptic transmission, such that incoming presynaptic action potentials (APs) trigger postsynaptic EPSPs, which reliably exceed the threshold

for postsynaptic AP generation, even at high input frequencies. The glutamate, released from the presynaptic cell, generates dual component postsynaptic currents. The fast component results from activation of AMPA-type glutamate receptor, while the slow component is generated by activation of NMDA-type. The calyx of Held synapse represents a very useful model system to study synaptic transmission and its modulation, because both the presynaptic terminal and the postsynaptic neuron are electrophysiologically accessible (Fig.1-2B).

1.3 The development of the auditory brainstem network

The auditory brainstem neuronal circuitry shows a highly ordered organization. One of the interesting questions that arises is how such precise connections are established?

Synapse formation and stabilization in the central nervous system (CNS) is a dynamic process. Numerous mechanisms coordinate where and when synapses are made in the developing brain. These mechanisms were classified into two major groups, i.e., genetically determined (or activity-independent) and activity-dependent that can be further subdivided into those associated with spontaneous activity and those depending on sensory-evoked responses (Friauf and Lohmann, 1999; Cohen-Cory, 2002).

Within the scope of this study, we were interested in evaluating the activity-dependent plasticity, which could play a role during the early postnatal (P0–P4) development of the neuronal auditory brainstem circuit and particularly of the calyx of Held.

In rats, afferent fibers, which later give rise to the future calyces, start to grow out of aVCN at embryonic day 15 (E15, 7 days before birth) and the most advanced already cross the midline at E15 (Fig.1-3, upper panel). It was shown in the study of Kandler and Friauf (1993) that the first contacts onto the principal cells of the MNTB are already established between P0 (postnatal day 0, the day of birth) and P3 (Kandler and Friauf, 1993). To trace the synapse development, authors used carbocyanine dye DiI and biocytin labelling of axonal fibers in an *in vitro* fixed-slice preparations. They found that within the next week further axonal growth and synaptic maturation occur. By P10, almost all calyces had achieved a morphology that resembled a mature calyx and by P14 they were almost indistinguishable from those of adults (Fig.1-3, lower panel).

Along with the morphological modifications, different functional changes take place at the calyx of Held synapse. In the Figure 1-3 (lower panel, left) a postsynaptic response

is shown that was obtained from P0 rat by the local axon stimulation (see Methods). Usually, evoked EPSCs at this age were only in the order of a few hundred pA, fluctuated extensively in amplitude and occurred in marked asynchrony. With development of the animals, EPSCs increase in amplitude, become synchronous and phased-locked (Fig.1-3, lower panel). This synchronization of neurotransmitter release was shown to be dependent on the intracellular Ca^{2+} dynamics and Ca^{2+} clearance mechanism during maturation (Chuhma and Ohmori, 1998, , 2001, , 2002). At the same time maturation of the synapse is accompanied by several other fine-tuning processes both pre- and postsynaptically: (i) an increase in the expression level of Ca-binding proteins (Felmy and Schneggenburger, 2004); a developmental switch in Ca^{2+} channel subtypes from a mixture of R, N and P/Q to solely P/Q subtype (Iwasaki et al., 2000); a change from AMPA/NMDA to mainly AMPA-receptor –mediated EPSCs (Takahashi, 2005); an increase in the size of a readily-released pool (RRP) of vesicles with parallel reduction in release probability (Taschenberger and von Gersdorff, 2000; Ishikawa et al., 2002; Joshi and Wang, 2002; Fedchyshyn and Wang, 2005).

Figure 1-3. A schematic representation of the calyx of Held maturation. At embryonic day E15 axon growth cones travel to the contralateral side, where they will form first contacts with principal neurons before birth. Once the synapse is established, further maturation occurs, during which the calyx changes its shape from cup-like to a highly branched structure. At the same time synaptic responses increase in amplitude, become synchronized and fast to provide the phase-locked high-fidelity transmission.

One can see that the main maturation changes occur before the onset of hearing, which is around P12 in rats. Thus, the assembly of the calyx of Held occurs in the absence of acoustically evoked activity. At the same time, it was shown by Lohmann and coworkers (1998), that activity plays a vital role during the first 1-2 postnatal weeks. These authors made organotypic slice cultures from auditory brainstem and found that the circuitry could be maintained correctly only when voltage-gated Ca^{2+} channels of the L-

type (which are expressed at the cell body of the globular bushy cells (GBCs)) were activated, for instance by application of high (25 mM) KCl to the keeping medium.

Thus, several lines of evidence point towards a participation of activity-dependent forms of synaptic plasticity in the development of the calyx of Held synapse. However, what can be the source of activity for the calyces before the onset of hearing? It was proposed that spontaneous activity of inner ear cells (Beutner and Moser, 2001) and subsequent activation of the auditory nerve fibers, may play an important role in this process (Friauf and Lohmann, 1999). Indeed, spontaneous firing rates of the auditory nerve and fibers in the trapezoid body vary from several Hz to nearly 200 Hz and can approach 500 Hz, when driven by intense acoustic stimuli (Warchol and Dallos, 1990; Chen et al., 1996; Trussell, 1999).

1.4 The role of synaptic plasticity in development of neuronal connections

As was already discussed above, activity-dependent forms of synaptic plasticity, and especially synaptic potentiation, were shown to be important for the synapse establishment and maturation. Among them, long-term potentiation (LTP) has received special attention, because of its probable role both in memory and learning and because of its putative role in integration of AMPA receptors into the postsynaptic membrane during development of synapses. The experimental paradigm used for its study, which represents repetitive high-frequency stimulation (HFS), gave rise to synaptic potentiation that is accompanied by structural and molecular changes at the single synapse level (Goda and Stevens, 1996; Atwood and Wojtowicz, 1999). It was proposed that some synaptic connections between neurons could be ineffective or “silent”, especially at the immature age. This could be due to presynaptic and/or postsynaptic factors (for review see (Voronin and Cherubini, 2003)). “Presynaptically silent” synapses produce no response, because either there are no quanta to be released or these quanta have low probability of release. “Postsynaptically silent” ones are unable to detect release due to a lack of postsynaptic receptors. Interestingly, repetitive stimulation of “silent” synapses can convert them into functional ones (Goda and Stevens, 1996; Atwood and Wojtowicz, 1999). For example, during early postnatal development (P2-P5) a significant proportion of thalamocortical synapses in rat somatosensory (barrel) cortex are functionally silent and these are converted to active synapses during LTP. These silent synapses disappear by postnatal

day 8-9, the exact time at which the susceptibility of these synapses to LTP is lost (Isaac et al., 1997).

1.5 Synaptic plasticity at the calyx of Held synapse

It was shown that in young rats or mice synaptic depression dominates during HFS at the calyx of Held synapse (Borst et al., 1995; von Gersdorff et al., 1997), which is mediated both by presynaptic and postsynaptic mechanisms (Schneggenburger et al., 1999; Wu and Borst, 1999; Neher and Sakaba, 2001; Scheuss et al., 2002). Briefly, presynaptic mechanisms include Ca^{2+} current inactivation (Forsythe et al., 1998; Xu and Wu, 2005), feedback activation of mGluRs known to down regulate presynaptic Ca^{2+} currents (Takahashi et al., 1996) or a transient decrease in the number of readily-releasable vesicles (Schneggenburger et al., 2002). Postsynaptic mechanisms include AMPA receptor desensitization (Scheuss et al., 2002). Facilitation of transmitter release can also be observed when release probability is decreased (Felmy et al., 2003); for example, by reducing the extracellular Ca^{2+} concentration. The finding that depression is the prevalent form of short-term plasticity has initially led to the view that the release probability at this synapse must be quite high (Chuhma and Ohmori, 1998; Weis et al., 1999).

Evidence has accumulated, however, that a presynaptic AP releases a surprisingly small fraction of the pool of readily releasable vesicles (RRP), which was shown to be quite large at the calyx of Held synapse by using voltage clamp or Ca^{2+} uncaging methods (Schneggenburger and Neher, 2000; Sakaba and Neher, 2001; Sun and Wu, 2001). This small release fraction is a property shared with other CNS synapses (Reim et al., 2001; Hallermann et al., 2003) and indicates that potentiation of transmitter release might occur under certain physiological conditions.

Based on the above described studies, we have hypothesized that during the early postnatal development, the calyx of Held might also show activity-dependent forms of synaptic potentiation like LTP, that contribute to driving the profound morphological and functional changes of this synapse during the early postnatal development (Kandler and Friauf, 1993; Taschenberger and von Gersdorff, 2000; Iwasaki and Takahashi, 2001; Joshi and Wang, 2002).

1.6 Aims and scopes of this work

The aim of this work was to study the properties and approach the mechanisms of activity-dependent synaptic plasticity in early postnatal development of the calyx of Held synapse.

For this, we performed recordings in auditory brainstem slices from young rats (postnatal day, P4-P7) and probed synaptic responses by applying prolonged HFS. Repetitive stimulation of the synapse induced a robust form of short-term potentiation at the calyx of Held, which shared many properties with posttetanic potentiation (PTP) studied previously at CNS synapses and at neuromuscular junctions, but which was unknown at the calyx of Held.

Developmental regulation of PTP was investigated by performing experiments in different age groups. PTP was also found later postnatally, but synapses had a decreased sensitivity to the induction of PTP compared with early developmental stages.

To investigate the mechanisms underlying posttetanic potentiation at the calyx of Held, we made intracellular presynaptic $[Ca^{2+}]_i$ measurements, combined with paired pre- and postsynaptic electrophysiological recordings. These experiments indicated an important role of residual $[Ca^{2+}]_i$ in the induction of PTP. Different pharmacological manipulations identified protein kinase C (PKC) to play an additional role in this process besides residual Ca^{2+} as a key mechanism of PTP.

2 Methods

2.1 Electrophysiological recordings

2.1.1 Brain slice preparation

The preparation of transverse auditory brainstem slices followed the general procedure of making thin slices from the tissue of mammalian central nervous system described in (Edwards et al., 1989). Postnatal day 0 (P0) to P14 Wistar rats were decapitated. The whole brain was carefully removed from the cut-open skull with forceps and kept cold throughout sectioning. For this purpose, the tissue was submerged into ice-cold standard extracellular solution (composition described in section 2.1.2). Dissection and slicing was done in low $[Ca^{2+}]$ (0.1 mM) extracellular solution to down-regulate metabolic processes and to avoid hypoxic damage of the nerve cells. The brainstem containing the region of interest (MNTB), together with the caudal part of the cerebrum and the cerebellum, were separated from the rostral parts of the brain by a slightly inclined transverse cut with a scalpel (Fig. 2-1A). After that, the pia mater and arachnoidea were carefully removed from the ventral surface of the brainstem using small forceps to facilitate cutting of the slices. The tissue block was glued onto a Teflon block of a slice chamber with the rostral plane oriented towards the block using cyan acrylic glue (UHU Sekundenkleber, UHU GmbH & Co. KG, Baden, Germany). The Teflon block could be turned around one axis. If necessary, it was turned slightly such that the fibers projecting from the ventral cochlear nucleus (VCN) to the medial nucleus of the trapezoid body (MNTB, labeled "Tz" in Fig. 2-1) ran parallel to the slicing plane. Transverse 200- μ m-thick slices were made with a vibratome slicer (Integraslice 7550 MM; Campden Instruments, Leicester, UK). The 7th nerve (Nervus facialis) was used as a marker for the start of the region of interest (containing MNTB and VCN, Fig. 2-1B). Depending on the age of the animal, one could obtain three to six slices containing the MNTB region. A schematic drawing of a slice used for recordings is shown in Fig. 2-1B.

After sectioning, each slice was immediately placed into an incubation chamber containing oxygenated (95 % O₂, 5 % CO₂) extracellular solution containing 2 mM Ca²⁺. Slices were maintained at 37 °C for up to four hours.

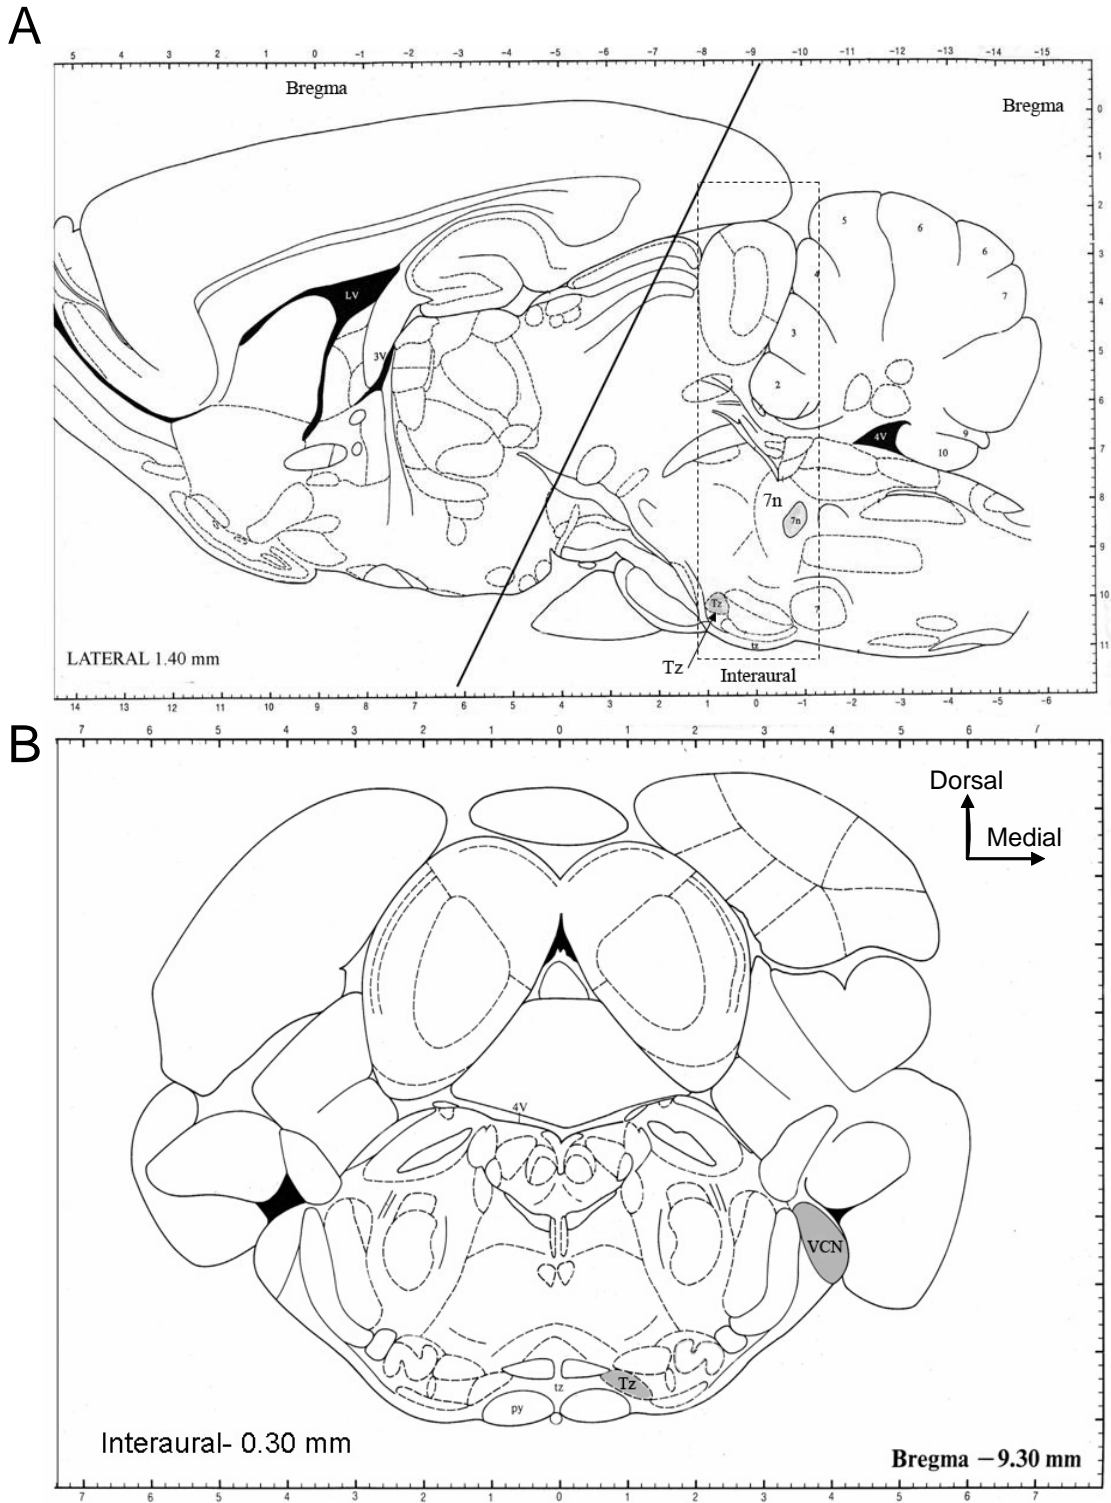

Figure 2-1. Slice preparation procedure. *A*, Lateral view of the adult rat brain (rostral to caudal from left to right; picture is modified from “The rat brain atlas”, (Paxinos G, 1986)). The inclined black line shows the position of the transverse cut. Dashed rectangle outlines the region of interest: medial nucleus of the trapezoid body (MNTB), marked “Tz” (black arrow), and VCN (ventral cochlear nucleus, which anterior part contains globular bushy cells, giving rise to the calyx of Held synapses). *B*, Schematic map of a transverse slice, containing the region of interest. The important nuclei are labelled in gray.

2.1.2 Solutions and drugs used for electrophysiological recordings

This section includes the compositions of extra- and intracellular solutions that were used for experiments. The composition of two basic extracellular solutions is listed in Table 2-1. The standard (Ringer) extracellular solution (middle column) was used during slice incubation and electrophysiological recordings. The Ringer solution with low Ca^{2+} (right column) was used for the slice preparation.

Table 2-1. *Extracellular solutions*

Substance	Standard Ringer [mM]	Ringer used for the slice preparation [mM]
NaCl	125	125
NaHCO_3	25	25
NaH_2PO_4	1.25	1.25
KCl	2.5	2.5
CaCl_2	2	0.1
MgCl_2	1	3
Glucose	25	25
Ascorbic acid	0.4	0.4
Na-pyruvate	2	2
Myo-inositol	3	3

Extracellular solutions had a pH of 7.4 when bubbled with 95% O_2 and 5% CO_2 with an osmolarity of ~310 mOsm. The salts NaCl, NaHCO_3 , NaH_2PO_4 , KCl, CaCl_2 , MgCl_2 were obtained from Merck (Darmstadt, Germany). D (+)-Glucose, myo-inositol, Na-pyruvate and L- ascorbic acid were purchased from Sigma (Steinheim, Germany).

Table 2-2 summarizes the pharmacological compounds and their particular concentrations that were used in different subsets of experiments. These substances were added from 100-1000 fold higher concentrated stock solutions of each substance (in H_2O). The Ro-31-8220, Gö-6976, BIS, Calphostin C, Calmidazolium stock solutions were made in DMSO. In these cases, the final DMSO concentration did not exceed 0.1% volume. The particular application mode and incubation times for each substance will be outlined in the Results section.

Table 2-2. *Drugs and concentrations used*

Substance	Final concentration	Purchased from
Strychnine	1 μ M	Tocris (Bristol, UK)
Bicuculine	10 μ M	Tocris (Bristol, UK)
TTX (tetrodotoxin)	1 μ M	Alamone labs (Jerusalem, Israel)
Tetraethylammonium chloride (TEA-Cl)	10 mM	Sigma (Germany)
D-AP5 (D-(-)-2 amino-5-phosphonopentanoic acid)	50 μ M	Tocris(Bristol, UK)
CTZ (cyclothiazide)	0.1 mM	Tocris(Bristol, UK)
Kynurenic acid	1 mM	Tocris(Bristol, UK)
Ro-318220	3 μ M	Merck, Calbiochem
CPPG (<i>(RS)</i> - α -cyclopropyl-4-phosphonophenylglycine)	300 μ M	Tocris
Gö - 6976	10 μ M	Merck, Calbiochem
BIS	10 μ M	Merck, Calbiochem
Calphostin C	20 μ M	Merck, Calbiochem
Calmidozolium	20 μ M	Merck, Calbiochem
EGTA-AM (tetra-acetoxymethyl ester)	200 μ M	Molecular Probes

Some of the above-mentioned substances, for example like Ro-31-8220, could not reach the intracellular space of the cells when applied acutely to the slices. Therefore, we used “preincubation” technique, in which slices were incubated with these particular drugs for ~30 min to 2 hours that significantly improved the output of experiments. To do so, we designed a small slice-keeping chamber (of ~40 mL volume). The stock solution of a particular substance was mixed with 30 mL of extracellular solution to have final desirable drug concentration. After the brain dissection procedure, some of the slices, containing the region of interest, were placed in this chamber and incubated for the above-mentioned time. During experiments, slices were continuously perfused with

recording solution containing the same drug concentration as during preincubation. For the control experiments, we placed some of the slices, which were obtained by brain dissection from the same animal, in extracellular recording solution without corresponding drug.

The following tables describe the constituents of the intracellular (patch-pipette) solutions. In most of the experiments cesium-gluconate based intracellular solution was used both for pre- and postsynaptic recordings (Table 2-3).

Table 2-3. *Cs-gluconate pre- and postsynaptic intracellular solution*

Substance	Final concentration [mM]	MW [g/mol]	Purchased from
Cs-gluconate	140	328	Self-made according to (Meyer, 1999)
HEPES	10	238	Sigma, Germany
TEA-Cl	20	1M stock	Sigma, Germany
Mg-ATP	4	507.2	Sigma, Germany
Na ₂ Pcreatine	5	255.1	Sigma, Germany
Na ₂ GTP	0.3	567	Sigma, Germany

A potassium-based intracellular solution was used for the presynaptic current-clamp recordings (Table 2-4).

Table 2-4. *K-Gluconate presynaptic intracellular solution*

Substance	Final concentration [mM]	MW [g/mol]	Purchased from
K-gluconate (D-gluconic acid)	140	234.2	Sigma, Germany
HEPES	10	238	Sigma, Germany
KCl	20	74.55	Sigma, Germany
Mg-ATP	2	507.2	Sigma, Germany
Na ₂ Pcreatine	5	255.1	Sigma, Germany

Na ₂ GTP	0.3	567	Sigma, Germany
---------------------	-----	-----	----------------

All intracellular solutions were adjusted to pH 7.2 and had an osmolality of about 300-310 mOsm.

2.1.3 Electrophysiology

For recordings, a slice at a time was placed into the glass bottomed recording chamber and covered with a platinum U-shaped flattened wire with a grid of parallel nylon threads. This grid prevented the slices from any dislocation during the recordings. During experiments, the slice was continuously perfused with extracellular recording solutions from a gravity-fed system of syringes and Teflon tubing with a flow rate of about 1 mL/min. The solution level in the chamber was controlled by overflow suction tubing connected to a vacuum pump. The slices were positioned and visualized under an upright microscope BX50WI (Olympus, Tokyo, Japan) using a five× objective. Desirable calyces of Held or somata of the postsynaptic principal neurons were identified under infrared gradient contrast illumination (Luigs and Neumann, Ratingen, Germany) with a 60× water immersion objective (NA=0.9, LUMPlanFI, Olympus, Japan). The recordings were made at room temperature (22-25⁰C) with an EPC-9/2 patch-clamp amplifier (HEKA, Lambrecht, Germany). Electrical currents and/or potentials were sampled with the computer running Pulse software (Version 8.63, HEKA, Germany).

If not otherwise stated, patch pipettes were pulled from a borosilicate glass (2 mm diameter, 0.3 mm wall thickness) using a vertical two-step temperature controlled pipette puller (PIP-5, HEKA, Lambrecht, Germany). To minimize the capacitance resulting from the immersion into the bath, the outer tip-proximal wall of the pipette was coated with Sylgard (Sinus Electronics GmbH, Untereisesheim, Germany). The voltage- and/or current-clamp configuration of the “whole-cell patch-clamp technique” was used in experiments (Fig.2-2). The first step in this technique is to obtain a high resistance contact between the pipette and the cell membrane (formation of a “gigaseal”) by touching the cell surface with the pipette tip and applying gentle suction. A patch of membrane under the pipette is then ruptured by application of a short pulse of negative pressure, reaching the whole-cell configuration. Following patch disruption, the solution inside the patch pipette will enter into and equilibrate with the cell interior. In whole-cell experiments, both the electrical and chemical components of the driving force may be regulated; the electrical component by means of the patch-clamp amplifier and the concentration

gradient by adjusting the composition of the intra- and/or extracellular bathing solutions (Fig.2-2). In whole-cell voltage-clamp configuration, the membrane potential is held constant (*i.e.*, "clamped") while the current flowing through the membrane is measured. In the case of current-clamp recordings, a constant current is injected into the cell, while the membrane potential is measured.

Postsynaptic recordings were performed in the voltage-clamp mode at a holding potential of -70 mV. Compensation of the pipette capacitance and of the cell membrane capacitance was done by using internal, software controlled compensation circuits of the EPC-9/2 amplifier. Series resistance (R_s ; range, 4–15 M Ω) was compensated up to 80%, so that the uncompensated R_s never exceeded 3 M Ω . EPSC traces were corrected off-line for the remaining R_s error (Meyer et al., 2001).

Figure 2-2. Schematic representation of different configurations of the patch-clamp technique. By seal formation, one obtains the “cell-attached” configuration (upper panel, right), which is the precursor to all other configurations of the patch-clamp technique. Breaking the patch by application of a suction pulse through the patch pipette will create the “whole-cell” configuration (lower panel, left). From the whole-cell configuration, one may proceed further by withdrawing the pipette from the cell, which results in the “outside-out” patch (because the outside of the membrane will face towards the bath solution; lower panel, middle). Withdrawing the pipette directly from the cell-attached mode will isolate a patch of membrane and lead to the excised patch configuration, which is called “inside-out” patch. We mostly used the “whole-cell” configuration of the patch-clamp technique.

The presynaptic recordings were mainly done under current clamp, and the membrane potential was kept close to -70 mV by injecting a small (range -60 to -30 pA) holding current. EPSCs were evoked by stimulating presynaptic axons with a concentric, bipolar stimulating electrode (MCE-100; Rhodes Medical Instruments, Woodland Hills, USA), which was placed between the medial border of the MNTB and the midline of the brainstem. Stimulation pulses were generated with an isolated pulse stimulator (A-M Systems, Model 2100, Kirkland, Washington, USA). Voltage pulses were 100 μ s long with amplitudes varied between 5 and 35 V. Prior to recordings, the cells in the MNTB region had to be identified, whose input was activated by fiber stimulation. Cells were screened using a patch pipette filled with extracellular solution. Suitable postsynaptic cells (~10–20% of superficial cells) were selected by measuring the presynaptic and postsynaptic action currents after afferent fiber stimulation (Borst et al., 1995; Meyer et al., 2001). In some experiments, the afferent fibers were stimulated by a monopolar stimulation electrode mounted inside a wide-opening (5–10 μ m) patch pipette, which was placed in the vicinity (~20–50 μ m) of a recorded MNTB principal cell. In this case, the whole-cell recording of an MNTB cell was first established, and the stimulation pipette was then lowered onto a neighboring region in the slice until a large EPSC could be reliably stimulated. With both methods, we found robust PTP after 100 Hz stimulation trains. Postsynaptic patch pipettes contained the intracellular Cs-gluconate solution (self-made according to (Meyer, 1999)). The pipette solution for presynaptic whole-cell recordings contained either K-gluconate (in case of current-clamp) or Cs-Gluconate (in case of voltage clamp) intracellular solution. The compositions of these intracellular solutions are described in section 2.1.2.

Baseline synaptic strength was assessed by applying pairs of afferent fiber stimuli at an intersimulus interval of 10 ms, which were repeated every 10 s. During the intervening intervals, 9.6 s stretches of postsynaptic current were recorded (sampling frequency 20 kHz, low-pass filter 6 kHz) to evaluate the amplitude and the frequency of spontaneous miniature postsynaptic currents (mEPSCs). The mEPSCs were detected off-line with a template-matching routine with a function kindly provided by Dr. Holger Taschenbereger and Dr. Volker Scheuss. Amplitude histograms of mEPSCs were constructed for control conditions and for short time periods (~30 s) after the induction of PTP. For the plot shown in Figure 3-6E, the average mEPSC frequency was calculated for each 9.6 s sampling interval.

2.1.4 Perforated patch-clamp recordings

During our investigation of PTP at the calyx of Held, we found that PTP was absent under conditions of the presynaptic whole-cell recordings (Fig. 3-10, Results). Therefore, we decided to employ the perforated patch-clamp configuration (Fig. 2-3) in a subset of experiments. The term “perforated” means that an electrical access to the cell is provided through the channels, which are formed in the membrane by antibiotics that are included into the pipette solution. We used Amphotericin B (Calbiochem, Germany). The channels formed by this perforating compound are permeable to monovalent cations and Cl^- , but impermeable to divalent ions such as Ca^{2+} or Mg^{2+} (Holz and Finkelstein, 1970; Rae et al., 1991). Therefore this technique has several advantages over conventional whole-cell patch-clamp (AxonGuide, 1993): (i) recordings of whole-cell currents can be done without dialyzing metabolites or second messengers, which are impermeable through the pores; (ii) intracellular multivalent ions, for example, such as Ca^{2+} , are not affected; (iii) moreover, the perforated-patch technique is less damaging to the cells, and can be therefore used in case long lasting recordings are needed.

Figure 2-3. Schematic representation of access formation into the cell interior in perforated patch-clamp (left panel) and in whole-cell configuration (right panel). The electrical connection between cell and pipette is established not by suction as in “whole-cell” configuration (right panel), but by incorporation of a channel-forming antibiotic in the cell-attached mode (“perforated patch”). We used Amphotericin B, which diffuses (red small lines, left panel) to the pipette tip and gradually increases the pipette-cell conductance. This process can be monitored by observing current response to repetitive voltage steps (lower panel, left).

The perforated-patch technique has some disadvantages when compared to the conventional whole-cell approach. For example, the perforation process requires longer time for achieving good electrical access as measured by the series resistance (R_s). This resistance represents a combination of the resistances of the patch pipette tip and of the perforated patch membrane itself. Therefore, some considerations have to be taken into account to minimize series resistance. First, it is better to use pipettes with larger tips of $\sim 3 \text{ M}\Omega$ (but small enough in order to form a “gigaseal”). Second, optimal pipette geometry is important for fast antibiotic diffusion to the pipette tip and for a bigger surface area available for the insertion of pore-forming channel. We used patch pipettes, pulled from soft thin-walled glass (WPI, Sarasota, USA), which allowed to fulfill both requirements mentioned above.

An Amphotericin B stock solution was prepared every day at a concentration of $3\text{mg}/60\mu\text{L}$ (54 mM) according to the protocol developed in the laboratory of Prof. Dr. Tobias Moser for cochlear inner hair cells, see also (Albillos et al., 2000). Because of limited solubility in water this compound was dissolved in dimethylsulphoxide (DMSO, Sigma) by ultrasonication (5-10 min), preceded by gentle shaking and warming-up to $\sim 30^\circ\text{C}$ for ~ 10 min. Amphotericin B in stock solution loses activity upon prolonged storage and freezing. Therefore, it is best to prepare it freshly before experiments and use within 1 hour. Amphotericin B was added (final concentration of $325 \mu\text{M}$) to the Cs-Gluconate intracellular solution and dissolved through further sonication for 15 min in darkness. Because DMSO perturbs seal formation, the patch pipette tip was first dipped for 1 min in an antibiotic free solution and then the pipette was back-filled with Amphotericin B containing pipette solution. After the formation of a “gigaseal”, the cell was kept in the cell-attached configuration (Fig.2-3) and the membrane potential was held at -70 mV until permeabilization reached a steady state. The progress of perforation was monitored by the slow increase in the amplitude of the transient capacitance current in response to 10 mV hyperpolarizing voltage steps (Fig.2-3, lower panel). Usually, a final series resistance (R_s) of $15\text{-}26 \text{ M}\Omega$ was obtained after $\sim 20\text{-}40$ min. A sudden change in the size of the capacity transients normally indicated the rupture of the patch membrane (switching into whole-cell configuration). In this case, the respective cells were discarded from analysis. In order to ensure that the perforated patch mode was maintained during the whole recording, we included into the presynaptic pipette solution low concentration ($25 \mu\text{M}$) of the fluorescent dye fura-2 (pentapotassium salt, Molecular Probes, Oregon, USA), which due to its structure can not permeate the pores formed by Amphotericin B.

The fluorescence was periodically checked by exciting the dye at 380 nm. Under perforated patch-clamp one could see only fluorescence in the patch pipette, whereas a staining of the calyx of Held could be observed if the patch was ruptured into whole-cell.

2.2 Cytosolic Ca^{2+} measurements

2.2.1 Estimation of intracellular $[\text{Ca}^{2+}]_i$ by fluorescent indicators

One of the common methods to estimate intracellular $[\text{Ca}^{2+}]_i$ is to use fluorescent Ca^{2+} indicators, which shift their excitation spectra upon binding Ca^{2+} . A number of factors should be considered when choosing a fluorescent Ca^{2+} indicator. Some of the important criteria are excitation/emission spectra and Ca^{2+} -binding affinity, which is reflected by the dissociation constant (K_D). Calcium indicators shift their absorption or emission spectra according to $[\text{Ca}^{2+}]_i$ in the concentration range of detectable responses ($0.1 \times K_D$ to $10 \times K_D$). However, the Ca^{2+} sensitivity of a dye is generally most reliable in a $[\text{Ca}^{2+}]_i$ range near the K_D value. Depending on the Ca^{2+} concentration range to be measured, one can select between low-affinity (high K_D) or high-affinity (low K_D) Ca^{2+} indicators. High-affinity dyes are used to detect small changes in Ca^{2+} concentrations. They may emit bright fluorescence, but rapidly buffer calcium and become saturated at relatively low $[\text{Ca}^{2+}]_i$. Therefore, if changes in $[\text{Ca}^{2+}]_i$ are in the order of several tens of micromoles or if one needs to assess the kinetics of $[\text{Ca}^{2+}]_i$, one should use high K_D -fluorescence indicators.

In our study, the changes in $[\text{Ca}^{2+}]_i$ during posttetanic potentiation (PTP) were monitored by using fura-4F (pentapotassium salt, Molecular Probes, Oregon, USA), which has a K_D for Ca^{2+} of 1.4 μM (the average value, obtained from the calibration procedure, see below). Because PTP could not be studied in whole-cell presynaptic recordings (see Results, Fig.3-10), we introduced fura-4F into the terminal via brief (1-2 min) presynaptic recordings with an intracellular K^+ -gluconate solution (see above) containing 200 μM fura-4F. After 1-2 min of whole-cell recording, the pipette was carefully withdrawn. We estimated that this procedure resulted in the loading of calyces with 80–120 μM fura-4F, based on the fluorescence intensity of calyces measured during longer-lasting presynaptic whole-cell recordings with 100 μM fura-4F. Quantitative estimation of calcium concentration can be done by ratiometric measurements of fluorescent intensity at different wavelength of excitation light (Grynkiewicz, 1985):

$$[Ca^{2+}]_i = K_{eff} \frac{R - R_{min}}{R_{max} - R} \quad (1)$$

where R is an experimentally measured ratio of fluorescence intensities at two different excitation wavelength of 350 and 380 nm (2); R_{min} is ratio in the absence of Ca^{2+} ; R_{max} is ratio of Ca^{2+} -saturated dye; K_{eff} is the effective dissociation constant of the indicator.

$$R = F_{350} / F_{380} \quad (2)$$

The calibration constants K_{eff} , R_{min} , R_{max} , mentioned above, were determined in a calibration procedure (Schneeggenburger 2004, see also 2.2.2) that combines *in vitro* measurements in thin quartz-glass capillaries and *in vivo* measurements of the limiting ratios at low and at a suitable intermediate $[Ca^{2+}]_i$ (1.04 μ M for fura-4F). $[Ca^{2+}]_i$ imaging was performed using a Polychrome IV monochromator (TILL Photonics, Grafelfing, Germany) to excite fura-4F at 350 and 380 nm. A slow-scan water-cooled CCD camera IMAGO (TILL Photonics, VGA chip with 480×640 pixels) with on-chip binning (8×15 pixels) and 10 ms exposure time captured the resulting fura-4F fluorescence signals. Pairs of images at each wavelength were taken at 0.5 Hz before and after the induction of PTP and at 20 Hz during 100 Hz trains. $[Ca^{2+}]_i$ was calculated from background-corrected fluorescence values collected from the six to eight brightest superpixels located in the calyx area, using the equation given in (Grynkiewicz, 1985) and (Schneeggenburger et al., 2002).

2.2.2 Calcium calibration procedures

In vitro calcium calibration

The calibration constants K_{eff} , R_{min} , R_{max} , which are necessary for estimating the absolute $[Ca^{2+}]_i$ in the cell, can be drastically affected by probe-environmental conditions. Thus, it is very important to do calibration in the same conditions as in corresponding experiment. In our calibration procedure, we first performed a five-point calibration to estimate the equilibrium binding constant (K_D) of fura-4F for Ca^{2+} .

R_{min} and the ratio at $[Ca^{2+}]_i$ closest to the K_D of the dye were measured during whole-cell recordings of calyces of Held, using the same solutions as in the *in vitro* calibration. The series of five calibration solutions, containing various free $[Ca^{2+}]_i$, were prepared by mixing intracellular solution, different $CaCl_2$ and Ca^{2+} buffer concentration (K_2 -EGTA and K_2 -HEDTA) to “clamp” $[Ca^{2+}]_i$ to the desired level: (i) one solution

without Ca^{2+} to calculate R_{\min} ; (ii) one solution with very high $[\text{Ca}^{2+}]_i$ saturating all buffers to calculate R_{\max} ; (iii) one solution with free a $[\text{Ca}^{2+}]_i$ of $1.04 \mu\text{M}$ (close to the K_d of fura-4F) and two other intermediate solutions (for example see Table 2-5 and 2-6) to check the calibration quality. Free $[\text{Ca}^{2+}]_i$ was calculated knowing the content of calibration solutions with the help of the custom-written macro FreCon V3.1beta by Dr. Tao Xu and Dr. Jacob Sorensen) for the Igor Pro software (V4.01; Wavemetrics Inc., Lake Oswego OR, USA), taking into account all absolute Ca^{2+} buffer concentrations.

Table 2-5. Stock solutions for *in vitro* calibration of fura-4F

Stock solution	Concentration (mM)
CaCl_2	50 and 100
$\text{K}_2\text{-EGTA}$	100
$\text{K}_2\text{-HEDTA}$	100

Table 2-6. Example of the calibration solutions for fura-4F

Solution	$\text{K}_2\text{-HEDTA}$		CaCl_2		dd- H_2O	K-gluc. (2×)	$\text{K}_2\text{-EGTA}$	pH adjusted
	c_{total} [mM]	V_{add} [μl]	c_{total} [mM]	V_{add} [μl] (mM stock)				
0 μM (R_{\min})	-	-	-	-	120	150	30 (50)	7.24
0.51 μM	10	30	1	6 (50)	109.2	150	-	7.23
1.04 μM	10	30	1.8	10.8 (50)	108.9	150	-	7.22
3.07 μM	10	30	3.7	11.1 (100)	114	150	-	7.21
10 mM (R_{\max})	-	-	10	30 (100)	120	150	-	7.2

Calculations of the calibration solutions were done for the total volume of $V_{\text{total}} = 300 \mu\text{L}$. Solutions of HCl (0.01 or 1M) and KOH (0.01 or 1M) were used to adjust the pH

to ~7.2. Fluorescent Ca^{2+} indicator fura-4F was used at nominal final concentration of 100 μM .

Figure 2-4. In vitro calcium calibration. *A*, Fluorescence spectra of fura-4F at five different Ca^{2+} concentrations, obtained from fluorescence intensity measurements of the calibration solutions at wavelength ranging from 330 to 390 nm *B*, The same fluorescence spectra as in *A*, but normalized to the isosbestic point that corresponds to excitation wavelength 360 nm. *C*, Estimation of the fura-4F K_D , obtained from Michaelis- Menten fitting of the Ca^{2+} -bound fraction of fura- 4F for each free calcium concentration.

Each calibration solution was filled into a small quartz glass cuvette (path length 50 μm). The fluorescence intensities of each calibration solution (Table 2-6) were measured at excitation wavelength ranging from 330 to 390 nm with steps of 10 nm. The background-corrected absolute and normalized fluorescence spectra of these solutions are shown in the Fig. 2-4A and Fig. 2-4B, respectively. Spectra were normalized to fluorescence intensity at the isosbestic point that corresponds to a single wavelength, at which the excitation efficiency of the dye molecules does not depend on the concentration of Ca^{2+} (in Fig. 2-4A this corresponds to the fluorescence intensity at excitation wavelength of 360 nm, at which most of the calibration curves intersect). The K_D of fura-4F was obtained from the Michaelis-Menten fit of the Ca^{2+} -bound fractions of fura-4F for each free $[\text{Ca}^{2+}]$, which were calculated from the normalized fluorescence spectra as described in (Schneggenburger, 2004) (Fig. 2-4C).

In vivo calcium calibration

Based on the previous experience, a possible difference between *in vitro* and *in vivo* calibrations should become apparent in the estimation of R_{\min} . Therefore, we restricted the *in vivo* calibration to R_{\min} and $R_{1.04\mu\text{M}}$. To determine R_{\min} , we loaded calyces with R_{\min} calibration solution (Table 2-6), made ratiometric measurements at 350/380 nm and averaged this ratios over the recording time. The final R_{\min} value used in the equation (1) was obtained by averaging R_{\min} values, measured in five cells. R_{\max} values were obtained from *in vitro* measurements, because calyces of Held did not endure internal dialysis with high CaCl_2 (10 mM). The K_{eff} was estimated by measuring the average fluorescence ratio R at an intermediate Ca^{2+} concentration (1.04 μM , which should be close to the K_D of fura-4F) from the different cells and rearranging Equation (1) for K_{eff} . Loading of the cells with this Ca^{2+} concentration will induce Ca^{2+} extrusion mechanisms (via various Na^+ - Ca^{2+} exchangers), which can cause a wrong $R_{1.04\mu\text{M}}$ estimation. For the $R_{1.04\mu\text{M}}$ *in vivo* calibration, we, therefore, decreased the activity of Na^+ - Ca^{2+} -exchangers by using Na^+ -free extracellular recording solution, which was prepared by substituting NaCl , NaHCO_3 and NaH_2PO_4 with equimolar amounts (150 mM, Table 2-7) of *N*-methyl-D-glucamine (NMDG). The pH was adjusted to 7.4 with HCl.

Table 2-7. Extracellular solution for *in vivo* $R_{1.04\mu M}$ calibration ($V_{total}= 200$ mL)

Solution	MW [g/mol]	Amount to add	Concentration [mM]
K ₂ -HEDTA	278.26	2 mL (100 mM stock)	1
CaCl ₂	110.99	1.36 mL (50 mM stock)	0.34
NaCl	58.44	0.1169 g	10
KCl	74.55	0.0373 g	2.5
HEPES	238.3	0.7149 g	15
NMDG	195.2	5.5437 g	150
HCl to adjust pH=7.4		28.4 mL (1M stock)	150

2.3 Data analysis

Data analysis carried out in IgorPro 4.09 (WaveMetrics, Lake Oswego, OR). PTP was standardly expressed as the relative EPSC amplitude at the time of peak PTP, according to the following equation: $PTP = (EPSC_{PTP}/EPSC_{control}) \times 100$. This corresponds to the following relationship: $PTP = (p/b) \times 100$ (Fig. 3-4B). In Figure 3-4D, the absolute increment of EPSC amplitude during the peak of PTP was analyzed, which corresponds to the amplitude value i in Figure 3-4B. The control EPSC amplitude was determined individually for each PTP induction, by averaging the second (or sometimes third) up to the fifth EPSC-amplitude preceding the 100 Hz train. The first one or two EPSCs were not included in the analysis, because these EPSCs were often larger than the subsequent ones, indicating that some cumulative depression occurred even at the low frequency (0.1 Hz) at which the control EPSCs were elicited (von Gersdorff et al., 1997). The decay times of PTP and residual $[Ca^{2+}]_i$ were estimated by fits with single-exponential functions. For these fits, the baseline values were constrained to the average of the last three or four data points in each series. Average data are reported as mean \pm SEM, with the exception of the plots in Figures 3-3D and 3-7, which show mean \pm SD values. Statistical significance was evaluated with Student's t test, unless otherwise noted.

3 RESULTS

3.1 Identification of posttetanic potentiation at the calyx of Held

The aim of this work was to study activity-dependent longer-lasting forms of synaptic potentiation at the calyx of Held, which could play a potential role in the development of this synapse.

Figure 3-1A–C shows an experiment designed to test whether brief trains of 100 Hz stimulation induce long-lasting potentiation at the calyx of Held. In these experiments, we first assessed baseline synaptic strength with double stimuli (inter-stimulus interval, 10 ms), repeated five times every 10 s (Fig. 3-1A). Subsequently, a 100 Hz train of 4 s duration was applied (Fig. 3-1B). Thereafter, the double stimuli were resumed at 0.1 Hz, to probe the development of synaptic strength (Fig. 3-1C). During the 100 Hz train, EPSCs strongly depressed (Fig. 3-1B, top). The EPSC amplitudes at the end of the 100 Hz train were depressed to $2.8 \pm 0.8\%$ ($n=6$ cells) of the control EPSC amplitude. The earliest EPSCs after the 100 Hz train, corresponding to the light gray traces in Figure 3-1C, were still depressed, but later EPSCs recovered from depression and then showed a marked, approximately twofold overshoot in amplitude at ~20–30 s after the 100 Hz train. Thereafter, synaptic strength returned to baseline over the next 8–10 stimuli. Figure 3-1D shows the corresponding plot of the first and second EPSC amplitude before and after the 100 Hz train. The transient potentiation of the first EPSC amplitude is reminiscent of PTP, which has been described at the neuromuscular junction (Magleby and Zengel, 1975) at crayfish neuromuscular synapses (Delaney et al., 1989), and at hippocampal synapses (McNaughton, 1982; Griffith, 1990).

During the peak of PTP, the first EPSC was potentiated to $202 \pm 31\%$ of the baseline value ($n = 8$ cells; 4 s induction train; P4–P6), whereas the second EPSC, at the time of the maximal potentiation of the first EPSC, was decreased to $73 \pm 11\%$ of its corresponding control value ($n = 8$ cells) (Fig. 3-1D, H). Thus, the paired-pulse ratio (EPSC2/EPSC1) was decreased at the peak of the EPSC potentiation (Fig. 3-1I), indicative of a presynaptic mechanism for PTP. Additional support for a presynaptic mechanism is given by the observation that immediately after the 100 Hz train, the frequency of mEPSCs was strongly increased (Fig. 3-1B, middle, G), whereas the amplitude distributions of mEPSCs were unchanged (Fig. 3-1E,F). In addition, the

Results

Figure 3-1. Posttetanic potentiation at the calyx of Held. *A*, Top, EPSCs in response to a pair of fiber stimulations separated by 10 ms, repeated every 10 s. The middle panel shows a 9.6 s stretch of postsynaptic current, and the bottom panel shows the average trace of $n = 9$ detected mEPSCs. *B*, EPSC in response to a 4 s, 100 Hz train of afferent fiber stimulation, applied 10 s after the last control EPSC shown in *A*. Only the first and the last 10 EPSCs in the train are shown, and the stimulation artifacts have been blanked for clarity. The middle panel shows a postsynaptic current record, starting 3.7 s after the end of the 100 Hz train. Note the strongly increased frequency of mEPSCs throughout the entire record. The bottom panel shows the average trace of all detected mEPSCs from this sweep ($n = 245$). *C*, EPSCs in response to a pair of stimuli repeated every 10 s after the 100 Hz train. The traces are grayscale coded, with the earliest traces after the 100 Hz train shown in light gray. *D*, Time course of EPSC amplitudes for the experiment shown in *A–C*. Filled and open circles represent amplitudes of the first and second EPSC, respectively. Note the transient overshoot of the first EPSC amplitude. *E*, mEPSC amplitude distribution for the control period (hatched bars) and for a period of 30 s after the 100 Hz train (open bars), corresponding to the time of development of maximal PTP. The mean mEPSC amplitudes were 30 and 33 pA for control and PTP, respectively. The data in *A–E* are from a recording in a P7 rat. *F*, Mean of the mEPSC amplitude distributions, plotted for individual cells for control conditions and after induction of PTP. *G*, Mean mEPSC frequencies (freq.) derived from individual cells before and after PTP induction. Note the strong increase in mEPSC frequency after the 100 Hz train. *H*, Maximal potentiation of the first and second EPSC amplitude for $n = 8$ cells. *I*, Paired-pulse ratio (EPSC2/EPSC1) for the control period and during maximal potentiation of the EPSCs. The data shown in *F–I* were obtained from recordings in P4–P7 rats.

finding that PTP was absent during whole-cell recording of a presynaptic calyx (see below, Fig. 3-10) also indicates that PTP at the calyx of Held has a presynaptic origin, similar to that at other synapses (Zucker and Regehr, 2002).

Thus, although we initially looked for long-lasting potentiation (LTP), we found a very prominent posttetanic potentiation (PTP) of EPSCs. After PTP decayed, we did not find evidence for an additional component of potentiation. These experiments, however, were done under postsynaptic voltage-clamp conditions and we cannot exclude at present that with postsynaptic current-clamp recordings, which would have allowed the activation of postsynaptic NMDA receptors, a longer-lasting form of potentiation, like short-term potentiation (STP) (Malinow and Tsien, 1990; Malinow and Mainen, 1996; Wu et al., 1996) or LTP would have been uncovered (see Discussion). However, since longer-lasting forms of potentiation, including PTP and augmentation, were not known before at the calyx of Held, we decided to characterize PTP in more detail, and to study its underlying presynaptic mechanisms.

We next investigated how the amplitude and the time course of PTP depended on the duration of the induction trains (Fig. 3-2). PTP was induced repetitively in a given cell, with varying lengths of the 100 Hz trains. We found that the amplitude, as well as the duration of PTP, increased after prolonging the 100 Hz induction trains. In the example of Figure 3-2A, a short 100 Hz train of 0.2 s duration induced noticeable PTP of 150% of control, which, on average, was $136 \pm 6.6\%$ for the age group of P4–P6 ($n = 10$ cells) (Fig. 3-2B). Prolonging the 100 Hz induction trains led to larger PTP with slowed decay time constants (Fig. 3-2B, C). When the length of the induction trains was prolonged beyond 1 s, the amplitude of PTP was not further increased ($p > 0.5$ for all pair wise comparisons between 2, 4, and 8 s trains), suggesting that PTP was maximal for induction trains of 2 s or longer.

3.2 Developmental regulation of posttetanic potentiation

The data presented in Figures 3-1 and 3-2 were obtained from the calyx of Held synapses from young rats (P4–P6). It is known, however, that the functional properties of transmission at the calyx of Held undergo pronounced developmental changes before and after the onset of hearing around P12 in rodents (Taschenberger and von Gersdorff, 2000; Iwasaki and Takahashi, 2001; Joshi and Wang, 2002). To investigate whether the

properties of PTP might change during postnatal development, we studied PTP in two older age groups, at P8–P10 and at P12–P14 (Fig. 3-3).

Figure 3-2. Dependence of PTP amplitude and duration on the length of 100 Hz induction train. *A*, An experiment at P5, in which PTP was induced several times as in Fig.3-1. The lengths of the 100 Hz induction trains are indicated. The traces at the bottom are the averaged control EPSCs before induction (black trace; $n = 5$) and the first 10 EPSCs after the induction of PTP (light grey). *B*, Normalized amplitude of PTP as a function of the length of the 100 Hz induction train for the age group of P4–P6. The number of cells investigated is indicated for each bar. *C*, Dependence of the decay time constant of PTP, estimated from fitting the decay phase of PTP with single-exponential functions, as a function of the length of the 100 Hz induction train. Error bars represent SEM.

Figure 3-3. Developmental regulation of PTP at the calyx of Held. *A*, An experiment at P13, in which PTP was induced with 100 Hz trains of indicated lengths. Note that the shorter 100 Hz trains (0.5 s, 1s) did not induce notable PTP in this cell. The inset shows sample traces for the 0.5 and 4 s induction trains. *B*, Amplitude of PTP as a function of the length of the 100 Hz induction train, separated for the age groups of P4–P6 (open bars; replotted from Fig. 3-2*B*), P8–P10 (gray bars), and P12–P14 (black bars). Note that the short 100 Hz trains of 0.2–2 s induced significantly larger PTP at P4–P6 than in the older age groups. Asterisks indicate a significant statistical difference determined in pair wise comparisons (* $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$; unpaired t test). Error bars represent SEM. *C*, Scatter plot of PTP amplitude as a function of the control EPSC amplitude. For the data obtained at P4–P6, results from 2 and 4 s induction trains are shown, whereas in the older age groups, only 4 s induction trains were analyzed, with the meaning of each symbol as indicated. The data set was fitted by an inverse function. Note the tendency toward smaller PTP for initially large EPSCs. *D*, Plot of average control EPSC amplitudes from individual cells for each age group. The average \pm SD of each data set is shown superimposed.

At these later developmental stages, we also observed PTP, but longer induction trains were needed to obtain PTP with similar amplitudes as in younger animals. In the example of Figure 3-3A, a recording from a P13 animal is shown. Note that 100 Hz trains with 0.5 and 1 s durations did not induce noticeable PTP at this developmental stage, but PTP was induced by longer induction trains.

Figure 3-3B plots the average PTP amplitude as a function of the length of the induction train for all three age groups investigated here. In the older age groups (P8–P10 and P12–P14), PTP in response to the short trains was significantly smaller as compared to PTP at P4–P6 (0.2–2 s; $p < 0.01$ or 0.001) (Fig. 3-3B). With 100 Hz induction trains of 4 and 8 s, however, PTP was not significantly different between the age groups ($p > 0.5$ for all comparisons). Thus, the maximal amount of PTP was not changed during development, but longer 100 Hz trains were needed in the older animals to induce a given amount of PTP. This data show that the threshold for PTP induction is lower for synapses at P4–P6 compared with the older age groups investigated here (P8–P10 and P12–P14).

In Figure 3-3C, we plotted the amplitude of PTP in response to 4 s induction trains (or 2 s in some cases) as a function of the control EPSC amplitude in each cell. We found that PTP tended to be smaller in cells with large control EPSC amplitudes, indicating that some presynaptic or postsynaptic resource might become limiting for the full expression of PTP, when the initial EPSC amplitude is large. In agreement with previous findings (Taschenberger and von Gersdorff, 2000), we found that the average EPSC amplitudes were not different between P4 and P14 ($p > 0.1$), although the EPSC amplitudes showed a quite large scatter between individual cells (Fig. 3-3D). In the following experiments, we investigated the properties of PTP at young calyces of Held (P4–P6), except for the results in Figure 3-10, in which P8–P10 rats were used.

To summarize, from these results we conclude that PTP is also expressed at mature synapses, although interestingly, the threshold for inducing PTP is lower in young animals. Since PTP depends on an elevation of Ca^{2+} in the nerve terminal (see below), it is possible that the higher threshold for PTP induction in more mature animals represents increased presynaptic Ca^{2+} -buffering and Ca^{2+} -extrusion in more mature animals (see Discussion). Because PTP was not described previously at the calyx of Held, we decided to investigate PTP further at young calyces (P4–P6), where plasticity was more prominent.

3.3 Presynaptic Ca^{2+} requirements for PTP

3.3.1 The Effect of EGTA-AM on PTP

To investigate whether PTP at the calyx of Held depends on a presynaptic $[\text{Ca}^{2+}]_i$ increase, we tested whether PTP is sensitive to the membrane-permeable Ca^{2+} chelator EGTA-AM (Fig. 3-4). EGTA-AM enters the terminals by uptake and “trapping”. EGTA accumulates intracellularly following the cleavage of the AM-ester by unspecific esterases (Cummings et al., 1996) and due to this accumulation the intracellular free EGTA concentration is probably higher than the bath concentration of EGTA-AM. PTP was induced by 100 Hz trains of 4 and 1 s duration applied in an alternating sequence (Fig. 3-4A). After establishing control PTP for each induction length, 200 μM EGTA-AM was applied to the bath. Shortly after the start of EGTA-AM application, the baseline synaptic strength decreased, and it continued to decrease for >900 s (Fig. 3-4A), indicating the continued accumulation of cytoplasmic EGTA. Concomitant with the decrease of baseline synaptic strength, PTP also decreased. This can be seen by comparing PTP under control conditions (Fig. 3-4B), with PTP induced 27 min after the start of the EGTA-AM application (Fig. 3-4C).

In these experiments, we analyzed the baseline synaptic strength, which corresponds to the amplitude value b in Figure 3-4B, the absolute amount of PTP, which corresponds to the amplitude value i , and the relative PTP, given by $(p/b) \times 100$ (Fig. 3-4B) (see Methods, “Data analysis” section). Figure 3-4D plots the average EPSC amplitude and absolute PTP before and during the continuous application of 200 μM EGTA-AM ($n = 6$ cells). Baseline synaptic strength was reduced from a control value of 4.4 ± 0.3 to 0.7 ± 0.1 nA, as analyzed from the baseline EPSC amplitudes averaged from the 10th, 11th, and 12th induction (Fig. 3-4D, bracket), corresponding to a time of > 20 min after the start of EGTA-AM application. The suppression of baseline synaptic strength by EGTA is consistent with previous findings at the calyx of Held (Borst and Sakmann, 1996; Fedchyshyn and Wang, 2005). In parallel with the decrease in baseline synaptic strength, the absolute PTP decreased both for 4 s and 1 s induction trains (Fig. 3-4D, open and filled symbols). The relative PTP (Figure 3-4E, open and closed symbols) decreased faster for 1 s induction trains as compared to the 4 s trains. This differential onset of the effect of EGTA-AM was probably a consequence of the larger Ca^{2+} influx caused by the longer induction trains. It is likely that the approximately four-fold larger Ca^{2+} influx

during the 4 s trains saturated the intracellular EGTA, as long as the intracellular concentration of EGTA had not reached a critical value.

Figure 3-4. PTP and baseline synaptic strength are strongly reduced by the slow Ca^{2+} buffer EGTA. *A*, Plot of EPSC amplitudes versus time in an experiment in which PTP was induced with 100 Hz trains of 1 and 4 s in an alternating sequence. EGTA-AM (200 μ M) was applied at the indicated time. *B*, EPSC amplitudes during PTP in response to 1 and 4 s 100 Hz trains under control conditions. The amplitude values b, i, and p were used to calculate absolute and relative PTP in *D* and *E*. The traces on the right show the average EPSC before (black trace) and single EPSCs after (gray traces) PTP induction with a 1 s 100 Hz train. *C*, Same as *B*, but taken 27 min after the onset of the EGTA-AM application. *D*, Time plot of the average EPSC amplitude (gray symbol) and the absolute PTP (corresponding to the amplitude value i in *B*). Open and filled symbols are absolute PTP for 1 and 4 s induction trains, respectively. The data are from $n = 6$ cells except the last three data points ($n = 4$ cells). *E*, Plot of the relative PTP, calculated according to $(p/b) \times 100$ (see *B*). Open and filled symbols are for 1 and 4 s induction trains, respectively. Average data from $n = 4$ cells. *F*, Relative PTP in control conditions (gray bars) and after prolonged (> 30 min) application of EGTA-AM (open bars). Asterisks indicate statistical significance (* $p < 0.05$; ** $p < 0.01$; paired t-test). Error bars represent SEM. The data shown in this figure were obtained from P4–P6 rats.

In Figure 3-4F, relative PTP is plotted for control conditions (gray bars) and after application of EGTA-AM for $n = 4$ cells that could be recorded for > 30 min after the application of $200 \mu\text{M}$ EGTA-AM. Prolonged bath application of EGTA-AM led to a significant reduction of PTP for both lengths of induction trains ($p = 0.009$ and 0.048 for 1 and 4 s trains) (Fig. 3-4F).

We also observed an interesting effect of EGTA-AM on synaptic transmission during the 100 Hz trains used to induce PTP. In Fig. 3-5A and 3-5B typical examples of 1 s, 100 Hz stimulation trains are shown for the control condition and during EGTA-AM application, respectively. As was described above, application of EGTA-AM caused a large reduction in the size of the baseline transmission (Fig. 3-4A), which is reflected here as the reduced amplitude of the 1st EPSC in train (Fig. 3-5B). Interestingly, the depression of EPSCs, which is usually observed at the calyx of Held during repetitive stimulation, was also reduced. To quantitatively estimate EPSC depression, we analyzed the first 50 stimuli during HFS trains. EPSC amplitudes and cumulative EPSC amplitudes were plotted versus time as shown in Fig. 3-5C (control in black, EGTA-AM in red) and 3-5D, correspondingly. The lines were fitted to the region of cumulative EPSC amplitudes for times in the middle (25th - 50th stimuli) of 1 s 100 Hz train and back-extrapolated to time 0 (Fig. 3-5D). The slope of the lines indicated the amplitude of phasic EPSCs averaged over the corresponding time interval. Average data are summarized in Fig. 3-5E and 3-5F. All EPSC amplitudes were normalized to the peak amplitude of the first EPSC in the control 1 s 100 Hz train (Fig. 3-5A). EGTA-AM application decreased the baseline transmission on average to $44 \pm 4\%$ (mean \pm SEM; $p < 0.001$, $n=6$ paired t -test; Fig. 3-5E). In Fig. 3-5F we compared the average EPSC peak-amplitude normalized to the 1st EPSC in the absence of EGTA both for control (black bars) and for EGTA-AM (open bars). We found that incubation of the slices with EGTA-AM led to a significantly higher ($p < 0.01$, paired t -test; $n=6$) steady-state of the phasic release ($5.4 \pm 0.6\%$ for 25th - 50th stimuli (Fig. 3-5F, left pair of bars); $4.6 \pm 0.7\%$ for 75th-100th stimuli (Fig. 3-5F, right pair of bars)) in contrast to the control conditions ($2.5 \pm 0.5\%$ and $2.1 \pm 0.4\%$, correspondingly). Thus, surprisingly, EGTA increased the absolute EPSC amplitude during the steady-state phase of depression. Since EGTA is Ca^{2+} buffer with a slow Ca^{2+} -binding rate, this might imply that endogenous calcium binding proteins with slow Ca^{2+} binding might be advantageous to maintain phasic EPSCs during prolonged high frequency trains.

Figure 3-5. Effect of slow Ca^{2+} buffer EGTA on the depression during PTP induction train. In *A* and *B*, responses of a cell, presented in Fig.3-4*A*, are shown to the first 50 stimuli of 1 s 100 Hz train in the control conditions (2nd induction, Fig.3-4*A*) and during EGTA-AM application (6th induction), correspondingly. *C*, Analysis of peak EPSC amplitudes, shown in *A* and *B*. *D*, Peak EPSC amplitudes were integrated to give a plot of cumulative EPSC amplitudes. Data points were fitted by a line (dotted line) and back extrapolated to time 0. Estimation of a steady-state depression was obtained by analyzing cumulative EPSC amplitudes in the middle (25th-50th responses) and at the end (75th -100th) of the 1 s 100 Hz train. *E* and *F*, Average ($n=6$) normalized EPSC amplitudes are summarized in bar graphs for the 1st (*E*), 25th-50th (left bar group) and 75th-100th (right) responses (*F*). Asterisks indicate statistical significance (* $p<0.01$; ** $p<0.001$; paired t test). Error bars represent SEM.

In addition, we observed “standing” current, which appeared during prolonged 100 Hz stimulation, was also significantly suppressed by treatment with 200 μM EGTA-AM (Fig. 3-5A and 3-5B, see induction trains). This standing current probably represents a mixture of glutamate spillover current and asynchronous release.

Similar observations were made by Otsu and colleagues (2004) in hippocampal autaptic excitatory neurons, in which HFS led to a strong depression of the evoked release during the train and a parallel increase in asynchronous release. They proposed that depression of evoked release is attributed to depletion of the readily releasable pool (RRP) of vesicles, and that during HFS a competition occurs between asynchronous and synchronous release, with both competing release modes for newly recovered RRP vesicles. However, the ability of asynchronous release to use recently recovered quanta would slow the recovery of phasic release, because relatively few quanta would be able to accumulate within the RRP and be available for the phasic release.

3.3.2 Presynaptic residual $[\text{Ca}^{2+}]_i$ dynamics associated with PTP

We next aimed at imaging presynaptic $[\text{Ca}^{2+}]_i$ during and after the induction of PTP to directly visualize the $[\text{Ca}^{2+}]_i$ signal that might underlie the transmitter release potentiation during PTP. For this purpose, we initially performed presynaptic Ca^{2+} imaging in simultaneous presynaptic and postsynaptic whole-cell recordings. We found, however, that during presynaptic whole-cell recording, PTP was absent (see below, Fig. 3-10). We therefore used an alternative Ca^{2+} -imaging approach, in which calyces were first loaded with fura-4F during a short whole-cell recording episode (60 - 120 s), using a pipette solution containing 200 μM fura-4F (see Methods). After removing the presynaptic patch pipette, a whole-cell recording of the postsynaptic cell was made with a different pipette. This allowed us to measure PTP and to image the presynaptic $[\text{Ca}^{2+}]_i$ simultaneously from the fura-4F fluorescence signal arising from the calyx (Fig. 3-6A).

We imaged $[\text{Ca}^{2+}]_i$ at low sampling rates before and after the 100 Hz train and at higher sampling rate during the 100 Hz induction train (Fig. 3-6B). In the recording shown in Figure 3-6, a 100 Hz train of 2 s duration was applied to induce PTP. During the 100 Hz train, presynaptic $[\text{Ca}^{2+}]_i$ rose in a biphasic manner and reached a value of 9.5 μM (range, 3–10 μM between cells) shortly after the end of the 100 Hz train (Fig. 3-6B, inset). Thereafter, $[\text{Ca}^{2+}]_i$ dropped to ~ 300 nM within 0.5 s and then recovered much more slowly (Fig. 3-6B, arrow).

Figure 3-6. Presynaptic $[Ca^{2+}]_i$ dynamics associated with PTP. The fluorescent Ca^{2+} indicator fura-4F was preloaded into calyces by a brief whole-cell recording episode. *A*, Fluorescence images taken after the experiment (high resolution; top) and during the experiment (bottom). $n = 7$ superpixels used for deriving the $[Ca^{2+}]_i$ traces shown in *B* and *C* are indicated. *B–E*, Time course of $[Ca^{2+}]_i$ (*B*, *C*), of EPSC amplitudes (*D*), and of mEPSC frequency (*E*). At time point 0, a 2 s 100Hz train was applied. In *B*, $[Ca^{2+}]_i$ is shown for the entire protocol and for an expanded time during the 100 Hz train (inset). In *C*, the $[Ca^{2+}]_i$ scale is increased, such that only $[Ca^{2+}]_i$ up to 350 nM is visible. With this scale, the slow component of decay of residual $[Ca^{2+}]_i$ becomes clearly visible, which was fitted by an exponential function with time constant $\tau = 32$ s. The decay of PTP in *D* was also fitted with an exponential function, giving $\tau = 44$ s. Horizontal brackets in *C* and *D* indicate the time of maximal PTP. The traces in *D* show the EPSCs before and after induction of PTP. In *E*, mEPSCs are shown for the time points indicated with a, b, and c in the time plot of *E*. *F*, Plot of mEPSC frequency as a function of presynaptic $[Ca^{2+}]_i$ during the decaying phase of PTP. *G*, Same data as in *F*, but on double-logarithmic scales. The logarithmized data were fitted with a line, giving a slope of 1.06. The data in this figure were obtained from a P5 rat.

The slowest phase of $[Ca^{2+}]_i$ recovery can be seen more clearly in Figure 3-6C, which displays the $[Ca^{2+}]_i$ signal at a higher gain. The late phase of the $[Ca^{2+}]_i$ decay was fitted with an exponential function, with a time constant of 32 s in this example (Fig. 3-6C). In this recording, the baseline synaptic strength was 4.1 nA, and the EPSC amplitude rose to 10.6 nA at the peak of PTP, corresponding to a relative PTP of 260 % (Fig. 3-6D). PTP then decayed with an estimated time constant of 44 s (Fig. 3-6D).

In these experiments, we also measured the average frequency of mEPSCs before and after PTP induction, with the aim to relate these to the presynaptic $[Ca^{2+}]_i$. In the recording of Figure 3-6, the mEPSC frequency rose to a peak value of 25 Hz in the 10 s-interval immediately after the 100 Hz train and then returned to baseline values (~ 1 Hz) with an estimated time constant of 18 s (Fig. 3-6E). A plot of mEPSC frequency versus $[Ca^{2+}]_i$ for the time after PTP induction is shown in Figure 3-6, *F* and *G*, on natural and double-logarithmic scales, respectively. There was a good correlation between mEPSC frequency and presynaptic $[Ca^{2+}]_i$ measured during the slowest phase of the decay of residual $[Ca^{2+}]_i$ (Fig. 3-6G), indicating that the increase in mEPSC frequency was driven by presynaptic residual $[Ca^{2+}]_i$. The logarithmized data set of Figure 3-6G was fitted by linear regression, giving a slope of 1.73 ± 0.2 (range, 0.68–2.49; $n = 9$ measurements in $n=5$ cells; $[Ca^{2+}]_i$ range of 40–270 nM). This slope is significantly lower than the high power relationship of ~ 4 –5, with which Ca^{2+} regulates transmitter release in a range of 2–8 μ M $[Ca^{2+}]_i$, as estimated by Ca^{2+} uncaging at the calyx of Held (Bollmann et al., 2000; Schneggenburger and Neher, 2000; Felmy et al., 2003). This indicates that elevations of $[Ca^{2+}]_i$ close to the resting value regulate the rate of transmitter release with a significantly smaller Ca^{2+} cooperativity (~ 1), in agreement with a recent study at the calyx of Held (Lou et al., 2005).

The Ca^{2+} -imaging experiments showed that the slowest phase of the decay of residual $[Ca^{2+}]_i$ has a similar time course as the decay of PTP (Fig. 3-6C,D), as observed previously at the crayfish neuromuscular junction (Delaney et al., 1989; Delaney and Tank, 1994). Figure 3-7A plots the decay time constants of PTP and residual $[Ca^{2+}]_i$ for the entire data set ($n = 18$ measurements in five cells). Shorter 100 Hz trains, represented by open and light gray symbols in Figure 3-7A, induced rapidly decaying PTP, whereas longer 100 Hz trains, represented by dark gray and black symbols, tended to induce longer-lasting PTP, in agreement with the results shown in Figure 3-2C. There was a good correlation between the decay time constant of PTP and the decay time constant of residual $[Ca^{2+}]_i$ ($r = 0.81$) (Fig. 3-7A), suggesting that the time course of decay of residual

$[Ca^{2+}]_i$ determines the decay of PTP. Note, however, that most data points were located above the unity line (Fig. 3-7A, dotted line). This indicates that on average, the decay of PTP was slightly slower compared with the decay of residual $[Ca^{2+}]_i$.

Figure 3-7. The Ca^{2+} dependence of PTP at the calyx of Held. *A*, Plot of the decay time constants of PTP as a function of the decay time constants of presynaptic residual $[Ca^{2+}]_i$. The data points are grayscale coded according to the length of the 100 Hz induction train, as indicated. The data were fitted by linear regression. *B*, Decay time constant of mEPSC frequency as a function of the decay time constant of presynaptic residual $[Ca^{2+}]_i$. The data were fitted by linear regression. In *A* and *B*, the dashed line represents the unity slope line. *C*, Plot of the PTP amplitudes as a function of the presynaptic $[Ca^{2+}]_i$ at the time of maximal PTP. Linear regression gave a correlation coefficient of $r = 0.44$. $[Ca^{2+}]_i$ is given as the increment over baseline $[Ca^{2+}]_i$. The average \pm SD of all data points 40 nM $[Ca^{2+}]_i$ are superimposed. The data in this figure were obtained from P4–P6 rats.

There was also a good correlation of the decay time constants of mEPSC frequency with the decay time constants of presynaptic residual $[Ca^{2+}]_i$ (Fig. 3-7B). In this case, however, the data points fell below the unity line, indicating that decay time constants of the mEPSC frequency tended to be smaller than the decay time constant of the underlying residual $[Ca^{2+}]_i$. This is expected if the exponent in the power relationship relating

mEPSC frequency to $[Ca^{2+}]_i$ is somewhat larger than 1, and indeed, this value was 1.73 on average (see above; Fig. 3-6G). In Figure 3-7C, the amplitude of PTP is plotted as a function of residual $[Ca^{2+}]_i$, measured at the time when PTP was maximal (at ~ 20–30 s after the 100 Hz train) (Fig. 3-6C, D, brackets). It can be seen that robust potentiation of EPSCs of ~ 200% is observed for elevations of residual $[Ca^{2+}]_i$ as low as 40–120 nM over base line $[Ca^{2+}]_i$. The average of the data points > 40 nM $[Ca^{2+}]_i$ indicates that for an average $[Ca^{2+}]_i$ increment of 74 ± 26 nM, PTP was $208 \pm 42\%$ of control (Fig. 3-7C, see average \pm SD data point). Thus, a relatively small elevation of basal $[Ca^{2+}]_i$ after a high-frequency train induces a robust potentiation of transmitter release during PTP. The correlation between the amplitude of PTP and the increase in residual $[Ca^{2+}]_i$ in this plot was not strong, however ($r = 0.44$) (Fig. 3-7C). This might indicate the influence of other factors on the relative PTP amplitude. For example, we have already shown above (Fig. 3-3C) that the PTP amplitude inversely dependent on the baseline synaptic strength of a given cell. Thus, cells with different EPSC amplitudes might introduce additional scatter in the plot of Fig. 3-7C.

3.4 Glutamate spillover and PTP

Repetitive stimulation of glutamatergic synapses might lead to accumulation of glutamate in the synaptic cleft and its diffusion either to neighboring synapses or retrogradely to the nerve terminal. This phenomenon is known as “spillover” (Diamond, 2002). Glutamate spillover exerts its effect via activation of either NMDA receptors (as opposed to AMPA receptors, because NMDA receptors have a much higher affinity for glutamate, therefore lower concentrations of glutamate can be effective) or metabotropic glutamatergic receptors (mGluRs) (Asztely et al., 1997). Special attention was attracted to the G-protein-coupled mGluRs, which were shown to be involved in a broad spectrum of physiological functions, such as the generation of slow excitatory and inhibitory synaptic potentials, modulation of synaptic transmission, and integration and plasticity (Coutinho and Knopfel, 2002). The calyx of Held expresses mGluRs (group II and III), in particular mGluR 2/3 and mGluR 4, which are presynaptically localized and might contribute to an autoreceptor function (Pilkington et al.). Takahashi and colleagues (Takahashi et al., 1996) have shown that these receptors are negatively coupled to calyceal P/Q-type voltage-gated Ca^{2+} channels, which elicit release at this synapse. von Gersdorff, 1997 #62} investigated whether synaptically released glutamate might feed back onto mGluRs

and contribute to depression. They found that antagonists of these receptors only slightly (~6 %) altered depression induced by short 10 Hz stimulus trains.

Figure 3-8. Glutamate spillover does not contribute to PTP at the calyx of Held. *A*, The time course of the 1st (closed circles) and the 2nd (open circles) EPSC amplitudes from the paired pulses, used to check the transmission during PTP induction protocol (4 s, 100 Hz), which was applied several times in this example cell. CPPG (300 μM) was applied at the indicated time. *B*, Summarized data are shown for the relative PTP amplitudes (left histogram plot) and decay times (right histogram plot) in control condition and after application of CPPG. Error bars represent SD.

In this study, to induce PTP, we applied prolonged (1-4 s) 100 Hz stimulation to the calyces, which might cause significant accumulation of glutamate in the extra-synaptic space and activate presynaptic metabotropic glutamate receptors. To investigate a possible role of glutamate spillover in PTP at the calyx of Held, we used a specific group III mGluR antagonist-CPPG ((RS)- α -cyclopropyl-4-phosphonophenylglycine) at a concentration (300 μM), which was shown in a previous study of the same laboratory (von Gersdorff et al., 1997) to completely suppress the inhibitory effect of 50 μM of the group III mGluR agonist L(+)-2-amino-4-phosphonobutyric acid (L-AP4). PTP was induced by 100 Hz trains of 4 s duration (Fig. 3-8*A*). After establishing control PTP by two consecutive 4 s 100 Hz trains, which induced PTP of similar amplitude (Fig.3-8*A*), 300 μM CPPG was applied to the bath. However, no difference was observed between

control conditions and after CPPG application neither on PTP amplitude (control, 179 ± 24 %; CPPG, 190 ± 34 %, $n=6$ cells; Fig.3-8B) nor on its decay time (control, 64 ± 9 s; CPPG, 70 ± 14 s; Fig.3-8C). These results suggest that glutamate spillover does not play a significant role in modulating PTP at the calyx of Held.

3.5 Mechanisms of PTP at the calyx of Held

In order to understand the mechanisms underlying the posttetanic potentiation at the calyx of Held, quantal parameters and their changes have to be evaluated. The synaptic response in terms of a voltage-clamped excitatory postsynaptic current (EPSC) is determined by the quantal size q (or mEPSC amplitude), number of synaptic vesicles N , available for release, and by the probability p_r that an available vesicle will be released (Sakaba et al., 2002):

$$EPSC = q \times p_r \times N \quad (3)$$

The observed potentiation of synaptic transmission during PTP might be due to a change in any of these three parameters. For example, q reflects postsynaptic changes such as number or sensitivity of the postsynaptic receptors. N mainly depends on the number of docked and fusion-competent vesicles at each active zone, multiplied by the overall number of active zones. The factor N , as defined here, corresponds to the readily releasable pool (RRP) of vesicles. Release probability p_r is highly influenced by intracellular $[Ca^{2+}]_i$ and by the properties of the release machinery. In turn, $[Ca^{2+}]_i$ changes might be affected by different factors, for example, by the action potential (AP) waveform and by the properties of the Ca^{2+} channels and by Ca^{2+} buffers. Therefore, in the following set of experiments we tested which quantal parameters undergo changes during PTP.

3.5.1 PTP is mediated by an increase in release probability

Based on the constant mEPSC amplitudes after 100 Hz induction trains (Fig. 3-1B, F), PTP was presynaptic in origin (an increase in the amount of quanta released), similar as at other synapses (Zucker and Regehr, 2002). Thus, an increase either in p_r or in N (or combination of both) might be involved. We next tested whether an increased size of the

readily releasable pool (RRP) of vesicles contributed to the presynaptic mechanism of PTP (Fig. 3-9).

Figure 3-9. The readily releasable pool of vesicles is not significantly increased during PTP. *A*, Top: EPSCs in response to the first 10 stimuli of the first (black) and the second (gray) 4 s 100Hz train, both for the first 4 s 100 Hz train applied 20 s later. The middle panel shows the corresponding plot of EPSC amplitudes for the first 25 stimuli of each 100 Hz train, and the bottom panel shows the plot of cumulative EPSC amplitudes, fitted with lines and back extrapolated to time 0 to obtain a measure for the RRP. Black and gray symbols are for the first and second 100 Hz trains, respectively. *B*, Low time resolution plot of EPSC amplitudes for the experiment illustrated in *A*, where the two 4 s 100 Hz trains indicated by arrows. Note that the first 100 Hz train induced PTP of ~170% of control, but the second 100 Hz train did not increase synaptic strength further. *C*, Plot of the relative pool size increase as a function of the PTP amplitude. The data points for cells measured in control extracellular solution and in the presence of 1mM KYN and 0.1mM CTZ are indicated. The dashed line indicates the unity slope line. The data in this figure were obtained in P4-P6 rats.

To do so, we used a method for measuring the size of the RRP, in which EPSC amplitude plots in response to 100 Hz trains are analyzed (Schneggenburger et al., 1999). The cumulative EPSC amplitude plots in response to 100 Hz trains were fitted with a line and

the back-extrapolated EPSC amplitude value at time 0 was taken as a measure of the pool size (Fig. 3-9A, lower panel).

In these experiments, PTP was induced by a 4 s 100Hz train, and the pool size for control conditions was estimated by analyzing the first 25 EPSCs of the first induction train (Fig. 3-9A, black trace and black symbols). The experiment shown in Fig. 3-9A was done in the presence of 1 mM KYN and 0.1 mM CTZ, to suppress AMPA receptor desensitization and saturation, which might compromise the pool size estimates (Neher and Sakaba, 2001). When PTP was maximal at ~20–30 s after the first 100 Hz train, a second 100 Hz train with 4 s duration was applied to test whether the pool size was increased (Fig. 3-9B, second arrow). At the peak of PTP, the pool size was increased to $107 \pm 2\%$ of its control value ($n = 6$ cells). This small increase in pool size can account only for a small fraction ($< 10\%$) of the overall amount of PTP, which was $221 \pm 13\%$ in these experiments ($n = 6$). This can also be seen in Figure 3-9C, which plots the relative increase of pool size as a function of the PTP for each cell. Note that the data points lie far below the unity line that is indicated by the dashed line. Some of these experiments ($n = 3$ cells) were also done in the absence of KYN and CTZ. However, similar results were obtained in the absence and presence of these drugs (Fig. 3-9C, open and filled symbols). We conclude that PTP induced by 100 Hz trains is mediated by an increased release probability (p_r) from an essentially unchanged pool of readily releasable vesicles.

As mentioned above, the release probability p_r depends on intrinsic Ca^{2+} sensitivity of the release machinery (Bollmann et al., 2000; Schneggenburger and Neher, 2000; Lou et al., 2005), as well as on local $[\text{Ca}^{2+}]_i$, that is reached transiently at the sites of vesicle fusion. The increased local $[\text{Ca}^{2+}]_i$ could, in turn, be changed by: a) an increase in Ca^{2+} influx (for example, because of a change in the action potential (AP) waveform or otherwise an increase in Ca^{2+} current) or b) a reduced intracellular Ca^{2+} buffering (Felmy et al., 2003). To verify whether there is a change in Ca^{2+} influx it would be useful to study PTP under paired pre- and postsynaptic recordings.

3.5.2 Whole-cell recordings of the presynaptic terminal suppress PTP

In the next experiments, we investigated posttetanic potentiation (PTP) under conditions of presynaptic whole-cell recordings (Fig. 3-10). We used K^+ -containing presynaptic pipette solutions and recorded the calyces under current-clamp conditions while simultaneously recording from the postsynaptic principal neuron.

Figure 3-10. Whole-cell recording of the presynaptic nerve terminal reversibly suppresses PTP and accelerates the decay of residual $[Ca^{2+}]_i$. *A*, Time plot of EPSC amplitudes in the experiment, the PTP induction protocol (4 s, 100 Hz train) was given twice under conditions of presynaptic whole-cell recording (wcr pre) and another two times after withdrawal of the presynaptic pipette. The traces on the left show EPSCs and presynaptic APs for control (black traces) and after the induction of PTP (gray traces). The traces on the right show EPSCs for control (black traces) and after the induction of PTP (gray traces), after the presynaptic pipette was removed. *B*, Average time course of relative EPSC amplitude before and after 100 Hz trains of 4 s duration. Filled symbols are under presynaptic whole-cell recording; open symbols are after withdrawal of the presynaptic pipette in the same recordings. *C*, Average residual $[Ca^{2+}]_i$ measured under conditions of presynaptic whole-cell recording (gray trace) and after pipette removal (black trace) for a subset of cells shown in *B*. $[Ca^{2+}]_i$ is shown as the increment over the baseline $[Ca^{2+}]_i$ recorded in each cell. The data in this figure were obtained from P8–P10 rats. Error bars represent SEM.

In the example of Figure 3-10A, a 4 s 100Hz induction train was applied twice under conditions of presynaptic whole-cell recording. In both cases, only a slowly recovering phase of synaptic depression was observed, but we found that PTP was absent. This can also be seen in the inset of Figure 3-10A, which shows presynaptic action potentials and EPSCs before (black traces) and immediately after (gray traces) the 100 Hz train. After a recording time of ~ 800 s, the presynaptic patch pipette was withdrawn, and the PTP protocol was repeated twice. In this recording, strong PTP was observed already ~ 2 min after the withdrawal of the presynaptic pipette, and the amount of PTP was stable for the remaining recording period. In other cells, PTP recovered more gradually after withdrawal of the presynaptic pipette. In Figure 3-10B, the average time course of the relative EPSC amplitude is shown for conditions of presynaptic whole-cell recordings (filled symbols) and after removal of the presynaptic patch pipette (open symbols; $n = 14$ cells; P8–P10). PTP observed after pipette withdrawal was similar to PTP observed in the absence of presynaptic recordings. Thus, PTP reached its peak ~ 20 – 30 s after the 100 Hz induction train, and the average PTP decayed with a time constant of 57 s (Fig. 3-10B, open symbols). At the peak of PTP, the average relative PTP was $183 \pm 10\%$ (Fig. 3-10B), similar as for PTP observed under control conditions with 4s 100 Hz trains at the same age (P8–P10; see Fig. 3-3B, gray bars). During presynaptic whole-cell recording, however, the relative EPSC amplitude was only $86 \pm 5\%$ of control at 20–30 s after the 100 Hz induction train. and thus, depression occurred instead of PTP. The difference between the two recording conditions was highly significant ($p < 0.01$; paired t-test).

The recovery of PTP observed after withdrawal of the presynaptic pipette (Fig. 3-10A, B) suggests that presynaptic whole-cell recording prevented the build-up of an intracellular signal necessary for PTP, rather than leading to an irreversible loss of intracellular messenger molecule(s). We therefore tested whether presynaptic whole-cell recording altered the presynaptic Ca^{2+} signaling. To do so, in a subset of the recordings, we imaged presynaptic $[\text{Ca}^{2+}]_i$ with 100 μM fura-4F during presynaptic whole-cell recording and after removal of the presynaptic pipette. The average residual $[\text{Ca}^{2+}]_i$ traces obtained for $n = 7$ cells are shown in Figure 3-10C, both under presynaptic whole-cell recording (gray trace) and after pipette withdrawal (black trace). The decay of residual $[\text{Ca}^{2+}]_i$ was significantly faster under conditions of whole-cell recording (time constant, 9 ± 2 s) than after withdrawal of the presynaptic pipette (28 ± 4 s; $n = 7$; $p = 0.007$; Wilcoxon two-sample test). Under whole-cell conditions, the average decay of residual $[\text{Ca}^{2+}]_i$ was so fast, that at the time of maximal PTP (20–30 s after the induction train), the

increment of residual $[Ca^{2+}]_i$ over baseline $[Ca^{2+}]_i$ had decayed to 25 ± 15 nM over baseline (Fig. 3-10C, gray trace). In contrast, after pipette removal, the increment in residual $[Ca^{2+}]_i$ over baseline $[Ca^{2+}]_i$ was 113 ± 65 nM (Fig. 3-10C, black trace). This suggested that the faster decay of residual $[Ca^{2+}]_i$ under conditions of whole-cell recordings contributes to the absence of PTP when presynaptic whole-cell recordings are made.

The absence of PTP, when the presynaptic cell is whole-cell patch-clamped, did not allow us to quantify whether changes in AP waveform, or a change in Ca^{2+} current during each AP contributed to PTP, since PTP was not observed under these conditions. Therefore, in the following experiments we tried to modify the presynaptic recording conditions to obtain PTP. First, we loaded calyces with intracellular solution, containing $300 \mu\text{M}$ L-glutamate, which according to the study of (Ishikawa et al., 2002) abolishes the “wash-out” of baseline synaptic transmission and even potentiated spontaneous and evoked release at the calyx of Held. However, even with $300 \mu\text{M}$ L-glutamate in the presynaptic pipette ($n=3$), we could not obtain PTP (data not shown).

The next trial was to use perforated patch-clamp technique, which was shown to be less invasive to the cell (see Methods).

3.5.3 Perforated presynaptic patch-clamp recordings

As was shown above, our presynaptic whole-cell recordings at the calyx of Held reversibly suppressed PTP. One of the reasons might be the observed acceleration of residual $[Ca^{2+}]_i$ (Fig.3-10C) that might be caused by a direct diffusion of Ca^{2+} into the recording patch pipette (Pusch and Neher, 1988). In addition, it is also possible that presynaptic whole-cell recording impaired the function of intracellular signaling pathways like PKC pathway, which might be involved in PTP (see below). Therefore, to achieve conditions as close as possible to the physiological ones, in the following experiments we applied perforated-patch technique to presynaptic cells, which better preserves the cytosolic cellular composition (see Methods section 2.1.4), using Amphotericin B as a pore-forming agent. In our initial experiments we performed only presynaptic recordings to, first, establish perforated patch clamp in the calyx and, second, to test whether presynaptic calcium current (I_{Ca}) undergoes changes after prolonged HFS in this condition. As described above, an increase in I_{Ca} is one possible mechanism for PTP. Once the seal was formed and the patch was perforated, cells were voltage-clamped

to -70 mV and continuously perfused with an extracellular ringer solution that contained TTX, TEA (see 2.1.2 section in Methods) to isolate presynaptic I_{Ca} . The PTP protocol was applied, but instead of afferent fiber stimulation with a bipolar electrode, short (0.5-1 ms) depolarizations from a holding potential -70 mV to $+28$ mV were used. I_{Ca} were recorded and online corrected by a P/4 protocol (Fig.3-11).

Analysis of I_{Ca} peak amplitude showed that after HFS I_{Ca} at the time point, where usually the peak of PTP was observed (~ 30 s after HFS), was in average $93 \pm 0.5\%$ ($n=3$; mean \pm SEM) of the control value (Fig.3-11, red circle). These experiments gave similar results to the work of Forsythe and colleagues (Forsythe et al., 1998), who showed that EPSC recovery from depression, observed after prolonged HFS in paired whole-cell pre- and postsynaptic recordings, was accompanied by slow recovery of presynaptic I_{Ca} from inactivation, which I_{Ca} undergo during HFS.

Figure 3-11. Presynaptic perforated patch-clamp recordings. PTP induction train was applied to the calyx of Held by using 1 ms depolarization pulses from the holding potential of -70 mV to $+28$ mV. The presynaptic Ca^{2+} current (I_{Ca}) was measured. The amplitude of the I_{Ca} was normalized to the control value, obtained by averaging of first five points before HFS (4s, 100 Hz). Black circles represent average time course ($n=3$) of relative I_{Ca} peak amplitude before and after HFS (an arrow shows time, at which HFS was applied). Inset shows superimposed $I_{Ca^{2+}}$ traces for control (black trace) and after PTP induction (red trace).

The results with presynaptic perforated patch recording suggest that the Ca^{2+} current was unchanged or even slightly decreased at the time when PTP is usually maximal (~ 20 - 30 s following the 100 Hz train). However, it would have been desirable to make

presynaptic perforated patch recordings, paired with simultaneous postsynaptic recordings to prove that under these conditions PTP is indeed expressed. We tried to do these experiments, but because they were technically very difficult and time-consuming, they could not be finished within the frame of this work. In the next set of experiments, we used a pharmacological approach to shed light on the PTP mechanism(s) at the calyx of Held.

3.5.4 Involvement of phospholipase-C/protein kinase-C in PTP

The previous experiments suggest that either the massive spatially averaged intracellular $[Ca^{2+}]_i$ rise during PTP induction train (~ 3 - $10 \mu M$), or the lower, but much longer-lasting residual $[Ca^{2+}]_i$ could induce PTP. Investigation of PTP mechanisms at various synapses revealed a wide range of molecular targets participating in PTP. Initial attention was focused on Ca^{2+} /calmodulin - dependent protein kinase type II (CaMKII), which was shown to be involved in PTP in squid giant terminal (Augustine et al., 1994; Zucker and Regehr, 2002). However, in CaMKII KO mice PTP and facilitation remain intact (Stevens et al., 1994). A recent study at hippocampal mossy fiber terminals pointed out a role of protein kinase C (PKC) in mediation of PTP (Brager et al., 2003). Based on experiments with PKC-selective inhibitors, the authors provided an evidence for an involvement of Ca^{2+} -dependent PKC in PTP expression at these central nervous system synapses.

We, therefore, used pharmacological tools to examine whether posttetanic potentiation at the calyx of Held synapse is mediated via PLC/PKC pathway. Pretreatment of the slices (incubation for ~ 30 min) with PKC inhibitor Ro-31-8220 ($3 \mu M$) significantly blocked PTP from the control level of $180 \pm 10 \%$ ($n=7$) down to $116 \pm 5 \%$ ($n=15$, $p < 0.001$, t -test; Fig.3-12A and Fig.3-15), without affecting the baseline transmission. In the Fig.3-12A the average time course of the relative EPSC amplitude is shown for control condition (filled black symbols, $n=7$) and a different group of cells obtained in slices that were preincubated for > 30 min in Ro-31-8220 (filled gray symbols; $n = 15$ cells; P8–P10).

Since the amplitude of PTP is inversely related to the control EPSC amplitude (Fig. 3-3C), to do not overestimate an effect of this inhibitor on PTP, we distributed data, presented in Fig.3-12A, for both control and Ro-318220 into two groups each: cells with large (> -6 nA) and small initial EPSC amplitude (< -6 nA). These data are presented in

Fig.3-12A as black (for control) and gray (for Ro-31-8220) traces and show the dynamic range of PTP in the control condition and after pretreatment with PKC inhibitor.

In Figure 3-12B, we plotted the amplitude of PTP in response to 4 s induction trains as a function of the control EPSC amplitude for both conditions. We noticed that almost half of the cells, preincubated in 3 μ M Ro-31-8220, had basal EPSC amplitude in average higher than in control cells (control, -5.1 ± 2.5 nA; Ro-31-8220, -6.7 ± 2.7 nA), although this difference was not significantly significant ($p > 0.1$, t -test).

Interestingly, Ro-31-8220 not only decreased PTP, but also delayed its peak by ~ 40 s (Fig.3-12A). These data show that Ro-31-8220, in addition to PTP suppression, might also interfere with recovery of evoked release from depression, caused by HFS.

Figure 3-12. Effect of Ro-31-8220 on PTP.

A, Averaged time course of EPSC amplitudes is shown for control cells (black symbols) conditions ($n=7$) and for cells incubated with Ro-31-8220 ($n=15$). Continuous black and gray traces show the dynamic range for PTP in both conditions, obtained by sorting the data into 2 groups based on their initial amplitude. The basal EPSC amplitude with the value of -6 nA was chosen as a threshold for separation. Error bars represent SEM. *B*, Scatter plot of PTP amplitude as a function of the control EPSC amplitude. The same color code was used for control and Ro-31-8220 data. PTP was significantly blocked by Ro-31-8220, despite slightly higher initial EPSC amplitude in the case of Ro-31-8220 application compared to control.

In order to examine the role of PKC in recovery from depression, we applied pairs of trains ($n=25$ stimuli, at 100 Hz) to the presynaptic terminal at different intervals (1; 4; 10 and 20 s) between trains and recorded EPSCs from the postsynaptic cell (Fig.3-13A). Synaptic responses displayed strong depression during HFS (control, Fig.3-13A, upper left panel).

Figure 3-13. Effect of Ro-31-8220 on the recovery from depression. *A*, The calyx of Held was simulated with short ($n=25$ stimuli) 100 Hz train and then identical second train was applied after interval of 1, 4, 10 and 20 s in the control conditions (upper panel, black color) and in presence Ro-31-8220 (lower panel, gray color). *B*, The amplitude of the 1st EPSC in the second train was normalized to the 1st EPSC in the first train, and ratio was plotted against the inter-stimulus interval. Black trace corresponds to the control case and gray to Ro-31-8220. Error bars represent SEM.

In the control conditions $36 \pm 2\%$ ($n=5$) of the response was recovered with an interval of 1s and complete recovery was already observed at 10s ISI (Fig.3-13A, upper panel, right). In the presence of Ro-31-8220, the depression during the train was not altered (Fig.3-13A, lower panel, left). However, the recovery of the response, despite its variation between the cells, was, on average, slower than in control conditions (Fig.3-13A, lower panel, right). For comparison, EPSC response with 10s ISI between trains recovered to $76 \pm 10\%$ ($n=3$), while in control already full recovery was observed. Ratios of the 1st response during the second over the first trains were plotted against the stimulation interval in Fig. 3-13B (control, $n=5$; Ro-31-8220, $n=3$). The difference in the recovery at 4 and 10 s between control and Ro-31-8220 was about 30%. These preliminary results

suggest that protein kinase C might be involved in recovery of evoked responses from depression under normal conditions.

It should be mentioned that Ro-31-8220 is an inhibitor, which blocks preferentially Ca^{2+} -independent (novel) PKCs. Therefore, to identify particular PKC isoform(s) that might be involved in PTP at the calyx of Held, we applied several other PKC antagonists. Their effect on the PTP amplitude is summarized in the Fig.3-15. First, we tested another broad-spectrum PKC inhibitor – Bisindolylmaleimide I (BIS; 10 μM). The application of BIS blocked PTP by more than 50 % (control, 169 ± 7 %; BIS, 128 ± 2 %, $p < 0.001$, mean \pm SEM; Fig.3-14 and 3-15). Similar to Ro-31-8220, BIS delayed PTP peak expression time for ~ 30 -40 s (Fig.3-14).

Figure 3-14. Effect of broad-spectrum PKC antagonist BIS on PTP. An averaged ($n=13$) time course of EPSC amplitudes is shown for control (black circles) and cells treated with BIS (red circles). Application of this inhibitor blocked PTP (* $p < 0.001$, paired t -test), induced with 4s 100 Hz train, and delayed its peak. Error bars represent SEM.

In the next experiments, we applied 10 μM Gö-6976, which specifically inhibits conventional (PKC_{α} , $\text{PKC}_{\beta 1}$). However, no effect was observed (Fig.3-15, control, 153 ± 10 %; Gö-6976, 186 ± 27 %, $p > 0.1$). A further increase of the concentration (up to 20 μM) or a longer incubation time led to same results.

Another blocker that we tried was Calphostin C (20 μM), the most potent and frequently used C1-domain antagonist. C1-domain is a cystein-rich region, which is present not only in all PKCs, but also in Munc-13-1 proteins where it mediates the effect of diacylglycerol (DAG) and phorbol esters (Betz et al., 1998). The application of Calphostin C had no effect on the PTP amplitude ($217 \pm 30\%$ for control; $226 \pm 25\%$ for

Calphostin C; Fig.3-15). However, it should be mentioned that preincubation of the slices with this blocker led to a significant decrease in their quality, so that it was hard to perform these experiments. The absence of Calphostin C effect, therefore, should not indicate that PKC or Munc-13 are not involved in PTP, because the more selective PKC inhibitors Ro-31-8220 and BIS did have an effect (see above).

As was mentioned above, Ca^{2+} /calmodulin-dependent protein kinase type II (CaMKII), was shown to be involved in PTP in squid giant terminal (Augustine et al., 1994; Zucker and Regehr, 2002). We tested this possibility for the PTP at the calyx of Held, by application of 20 μM Calmidazolium, the calmodulin blocker. But, it also failed to suppress PTP. The averaged PTP amplitude during application of Calmidazolium was $184 \pm 10\%$ and did not differ significantly ($p > 0.1$, paired *t*-test) from the control values of $168 \pm 11\%$ (Fig.3-15).

Figure 3-15. Involvement of PLC/PKC pathway in posttetanic potentiation. Bar diagram shows the degree of EPSC potentiation at the calyx of Held in the absence (control, gray bars) and presence (open bars) of various drugs. Slices were preincubated (30 to 60 min) and then continuously perfused with different PKC inhibitors. PTP protocol was applied at 100 Hz for 4 s. PTP amplitudes were measured and compared between untreated and preincubated slices. Among applied inhibitors only Ro-31-8220 and BIS were able to decrease PTP (* $p < 0.001$, paired *t*-test). Gö-6976, Calmidazolium and Calphostin C were ineffective in blocking potentiation.

To summarize, we found an involvement of PKC in PTP at the calyx of Held from our pharmacological experiments. However, we could not draw a conclusion about the specific PKC isoforms that might be involved in PTP. The fact that Gö-6976 (the

inhibitor of conventional PKCs) and Calphostin C (that blocks DAG binding to PKCs and Munc-13-1) did not work, could either mean that we had problems with drug specificity at the calyx of Held or (in the case of Gö-6976) that a “novel” PKC isoforms might be involved. Indeed, the expression of the novel PKC_ε isoform, for example, was previously shown at the calyx of Held in (Saitoh et al., 2001).

4 Discussion

In the present work, we aimed to answer the question whether activity-dependent long-term forms of synaptic plasticity exist at the calyx of Held, which could play role in its formation and/or maturation?

Our hypothesis was based on recent knowledge about synapse development, obtained from the studies in other brain regions. It was shown that initial connections are formed largely through molecular mechanisms that depend on intrinsic developmental programs (Kandler and Friauf, 1993; Russell and Moore, 1995; Cohen-Cory, 2002; Crowley and Katz, 2002). For example, in Munc-18 knockout mice neurotransmitter release is completely abolished, but the loss of Munc-18 does not influence the initial synapse formation in the mouse embryo (Verhage et al., 2000). At the same time, it has become clear that electrical activity is essential for the development of neuronal circuits too. Both spontaneous and experience-driven activities exert critical influence on synaptic maturation and refinement of neuronal circuits (Friauf and Lohmann, 1999; Zhang and Poo, 2001; Cohen-Cory, 2002; Ene et al., 2003). The immature synapse may be pre- or postsynaptically “silent” unless sufficient depolarization is provided. For example, studies in cortex and hippocampus showed that newly formed glutamatergic synapses are mediated by NMDA receptors and more synapses acquire AMPA receptors as the neuron matures (Cohen-Cory, 2002). The depolarization may result in the recruitment of AMPA receptors to the synapse in a manner similar to that found in the induction of long-term potentiation (LTP) (Liao et al., 1995; Wu et al., 1996; Isaac et al., 1997). On the other hand, in the mossy fiber pathway region LTP has been found to depend on Ca^{2+} influx into the presynaptic cell after HFS and NMDA receptors have only a minor role in synaptic plasticity (Tsien and Malinow, 1990).

To test our hypothesis we applied HFS of varying length to the calyx of Held synapse and probed long-term plasticity of synaptic responses. We observed posttetanic potentiation of EPSCs, but longer (> 2 min) lasting LTP-like potentiation was absent. But, if postsynaptic NMDA receptors would play a role, it remains possible that postsynaptically induced form of LTP is also present at the calyx, since our recordings were done under postsynaptic voltage-clamp recordings, which blocks current flow through NMDA-receptor channels. Indeed, young calyces express high density of NMDA

receptors (Takahashi, 2005), whose number decreases when synapse matures. This possibility can be investigated in the future studies.

Instead, HFS induced robust posttetanic potentiation (PTP) at the calyx of Held, which shared properties with short-term enhancement in other central synapses. Because this form of synaptic plasticity was previously overlooked at the calyx of Held (but see (Habets and Borst, 2005)), we decided to study PTP in more detail and learn about its underlying mechanisms by using different experimental approaches. We found that a residual (~ 40 - 120 nM) $[Ca^{2+}]_i$ signal in the presynaptic terminal with a surprisingly small amplitude decays in parallel with PTP, and that whole-cell recording of the presynaptic nerve terminal abolishes PTP. These findings suggest that additional intracellular signaling components, besides a simple accumulation of residual free $[Ca^{2+}]_i$, might contribute to the generation of PTP at the calyx of Held. Indeed, we found that inhibition of protein kinase C (PKC) suppresses PTP. Thus, during periods of high-frequency activity, residual Ca^{2+} builds-up and associated intracellular messengers like PKC are activated.

4.1 Identification and developmental regulation of PTP at the calyx of Held

Brief 100 Hz trains of up to a few seconds duration caused robust PTP of synaptic strength at the calyx of Held (Fig.3-1). The unchanged mEPSC amplitudes during PTP and the finding that PTP was suppressed by presynaptic whole-cell recording indicate that this potentiation of synaptic strength was presynaptic in origin, similar to PTP at other synapses (Zucker and Regehr, 2002).

The decay time constant of PTP depended on the length of the induction train, with time constants in the range of 20–60 s (Fig. 3-2). This distinguishes this form of synaptic enhancement from augmentation, which decays with a shorter decay time constant (~ 8 s), independent of the strength of the induction train (Magleby and Zengel, 1976). Recently, it was shown (Habets and Borst, 2005) that prolonged 20 Hz trains induce a longer-lasting form of PTP at the calyx of Held, with decay time constant of ~ 9 min. This form of PTP was associated with an $\sim 30\%$ increase in the size of the readily released pool (RRP), whereas in our study, the RRP was increased by $\sim 10\%$ (Fig. 3-9). Both studies show that PTP at the calyx of Held is mediated by an increased release probability without strongly increased RRP, similar to augmentation in hippocampal synapses (Stevens and Wesseling, 1999). It seems possible, though, that during longer-lasting

forms of PTP the pool size is increased more substantially (~30%) (Habets and Borst, 2005) compared with the shorter forms of PTP studied here.

We showed that PTP was induced more easily in calyces of Held of young rats (P4–P6) compared with two older age groups studied right before and after the onset of hearing at around P12 in rodents (P8–P10 and P12–P14) (Fig. 3-3). This adds PTP to a series of functional developmental changes at the calyx of Held, which include the presynaptic AP width, the kinetics of AMPA-receptor-mediated EPSCs, and the amount of synaptic depression (Taschenberger and von Gersdorff, 2000; Iwasaki and Takahashi, 2001; Joshi and Wang, 2002). These developmental changes are thought to help the calyx of Held to reliably transmit trains of high-frequency action potentials. Given the role of presynaptic Ca^{2+} in PTP, it is likely that the developmental regulation of PTP is caused by an increased Ca^{2+} buffering and Ca^{2+} extrusion at the calyx of Held (Chuhma and Ohmori, 2001). Indeed, the shift of PTP induction toward longer 100 Hz trains during development (Fig. 3-3B) was analogous to the effect of EGTA-AM application in young calyces of Held. EGTA-AM blocked PTP induced by weak induction more readily than PTP induced by a stronger induction protocol (1 vs. 4 s 100 Hz trains) (Fig. 3-4E, F). It is thus tempting to speculate that an increase in the expression of an endogenous Ca^{2+} buffer with slow binding kinetics, such as parvalbumin (Lee et al., 2000), might contribute to the developmental regulation of PTP. Parvalbumin is expressed at the calyx of Held (Felmy and Schneggenburger, 2004), and its onset of expression at around P8 in rats (Lohmann and Friauf, 1996) (Felmy and Schneggenburger, 2004) coincides well with the down-regulation of PTP observed here.

Thus, these results show that PTP, an additional form of synaptic plasticity, which was found at the calyx of Held, is developmentally regulated and could be expressed in two different time-scales, depending on the stimulation protocol: fast decaying, within ~1 min (induced by 1-4 s 100 Hz stimulation in our study); and longer decaying, within ~9 min (induced by 20 Hz stimulation for 5 min, (Habets and Borst, 2005)).

The question arises what could be the physiological role of PTP in the developing calyces of Held? It was shown from *in vivo* recordings that globular bushy cells in the aVCN, which give rise to calyces of Held, have spontaneous firing rates in the range of 1 - 100 Hz, and sound stimulation further increases their firing rates up to a few hundred Hz (Friauf and Ostwald, 1988; Spirou et al., 1990; Smith et al., 1991; Kopp-Scheinflug et al., 2003). The activity patterns of aVCN neurons in developing rodents before the onset of airborne hearing at around P12 (Jewett and Romano, 1972; Blatchley et al., 1987)

have, to our knowledge, not been recorded yet. However, rhythmic patterned activity, maybe driven by spontaneous electrical activity of inner hair cells (Beutner and Moser, 2001) has been reported in other species. Such a pre-sensory rhythmic activity in the auditory system might contribute to the maintenance, and refinement of synaptic connections in the auditory pathway. It is possible that induction of PTP and the associated activation of intracellular signalling pathways, like the protein kinase-C pathway, reflect a non-associative mechanism of functional re-enforcement of synapses, which precedes longer-lasting functional and morphological changes of excitatory synapses during postnatal development.

On the other hand, PTP, as one of the forms of short-term enhancement (STE), will also contribute to shape the information-processing characteristics at the calyx of Held in certain cases, but are not related to the development of this synapse.

4.2 Presynaptic Ca^{2+} -dependence of PTP

Various lines of evidence suggest that PTP is driven by elevations of presynaptic $[\text{Ca}^{2+}]_i$ in the low nanomolar range (~40–120 nM) (Fig. 3-7C). First, PTP and the slowest decay phase of a residual $[\text{Ca}^{2+}]_i$ signal decayed in parallel with similar time constants (Fig. 3-6C, 3-7A), in agreement with previous Ca^{2+} -imaging studies (Delaney et al., 1989; Regehr et al., 1994). Second, PTP was suppressed by the membrane-permeable Ca^{2+} chelator EGTA-AM, although EGTA-AM also reduced the baseline synaptic strength, in agreement with previous studies in young (< P10) rats (Borst and Sakmann, 1996) (Fedchyshyn and Wang, 2005)(Fig. 3-4). These experiments show that the prolonged presence of residual $[\text{Ca}^{2+}]_i$ with an increment of ~80 nM over baseline $[\text{Ca}^{2+}]_i$ is necessary for PTP. Recently, another work appeared, supporting the idea that small but prolonged intraterminal Ca^{2+} elevations can enhance transmitter release up to 2-fold (Awatramani et al., 2005). The authors manipulated the resting potential of the calyx terminal by depolarizing the terminal from a holding potential of -80 mV to -60 or 65 mV for several seconds. Such depolarization of the membrane potential led to an activation of P/Q-type Ca^{2+} channels, a gradual rise in the background level of Ca^{2+} (~50-100 nM), and caused a 2-fold increase in the amplitude of the glutamatergic EPSC. Neither the depolarization nor this small change in Ca^{2+} altered the spike-evoked Ca^{2+} influx; however, they were sufficient to increase significantly the probability of glutamate release, with no effect on the readily releasable pool of vesicles. Thus, similar

requirements (~100 nM) of residual $[Ca^{2+}]_i$ for PTP induction and for a short-term depolarization-induced enhancement (STDE), observed by (Awatramani et al., 2005), suggest that PTP and STDE might share common mechanism(s).

In addition, an importance of intracellular presynaptic Ca^{2+} elevations for PTP induction can be seen from our experiments, where presynaptic whole-cell recordings were done in combination with postsynaptic voltage-clamp (Fig.3-10). Presynaptic whole-cell recordings suppressed PTP, which was probably caused by the accelerated decay of residual $[Ca^{2+}]_i$ (Fig. 3-10C), and not primarily by a “wash out” of an intracellular signalling molecule into the patch pipette. This is because PTP readily recovered after removal of the presynaptic pipette (Fig. 3-10), opposite to what would be expected for an irreversible loss of a diffusible signalling molecule from the cytoplasm. Presynaptic whole-cell recording likely caused a diffusion of Ca^{2+} , and possibly also Na^+ , into the recording patch pipette (Pusch and Neher, 1988) and thereby accelerated the decay of residual $[Ca^{2+}]_i$. Na^+ accumulation during trains of presynaptic action potentials (APs) contributes to the residual $[Ca^{2+}]_i$ signal by compromising the function of Na^+ -dependent Ca^{2+} -clearance mechanisms (Zhong et al., 2001). It is possible that diffusion of Na^+ into the measuring patch pipette suppressed the accumulation of Na^+ , thereby leading to the observed faster decay of residual Ca^{2+} . Thus, the accelerated decay of the residual $[Ca^{2+}]_i$ signal most likely underlies the suppression of PTP during presynaptic whole-cell recording, although it remains possible that presynaptic whole-cell recording also impaired the function of intracellular signalling pathways, such as the protein-kinase C pathway, which might be involved in PTP. Indeed, we show that PKC blockers suppress PTP (Fig. 3-12 - 15; see below for discussion).

While studying the Ca^{2+} -dependence of PTP, we observed an additional involvement of residual $[Ca^{2+}]_i$ in the mechanisms of short-term depression, which is observed during HFS at the calyx of Held (Borst et al., 1995; von Gersdorff et al., 1997; Forsythe et al., 1998; Schneggenburger et al., 1999). This progressive decline in the size of synchronous release (phasic) during HFS, which has been attributed primarily to the depletion of a pool of readily releasable vesicles, was accompanied by a “standing” current, which probably represented both asynchronous (mEPSC-like) release and a glutamate spillover current. Interestingly, application of EGTA-AM blocked the “standing current” during HFS (Fig.3-5), which points towards the possibility that the observed “standing” current is primarily a consequence of asynchronous release. Analysis of EPSC depression, measured during PTP induction trains (100 Hz, 4s), showed that

bath application of EGTA-AM blocked the 1st EPSC by ~44 %. Surprisingly, the phasic EPSC during the steady-state of depression was increased (Fig.3-5). Such a different sensitivity of phasic and asynchronous release to EGTA-AM was described previously in other studies (Lu and Trussell, 2000; Hagler and Goda, 2001; Otsu et al., 2004). It was proposed that asynchronous release is triggered by a relatively low $[Ca^{2+}]_i$ (than phasic that can be maintained during the interval between repeated APs. Phasic release, which requires high $[Ca^{2+}]_i$ associated with microdomains, would be expected to occur briefly (< 1ms) in association with each AP (Bollmann et al., 2000; Schneggenburger and Neher, 2000). It is possible, as suggested in (Otsu et al., 2004), that if Ca^{2+} build-up increases the rate of asynchronous release, relatively few recovered RRP vesicles would be able to accumulate for phasic release during the brief time between successive stimuli in a train, leading to decrease in phasic release. This counterplay between synchronous and asynchronous release might represent an important mechanism, by which synapses are able to maintain synaptic transmission when driven with high frequencies. The slow Ca^{2+} EGTA will reduce the spatially averaged $[Ca^{2+}]_i$ rise more strongly than the microdomain $[Ca^{2+}]_i$, and thereby shift the release from asynchronous to phasic mode. Interestingly, endogenous Ca^{2+} buffers with slow Ca^{2+} binding kinetics, like parvalbumin, might play a similar role. Parvalbumin is expressed at calyceal terminals from postnatal day six (P6) onwards and its up-regulation with development might increase the presynaptic Ca^{2+} buffering strength (Felmy and Schneggenburger, 2004). This could be especially relevant for such high fidelity synapses like the calyx of Held, which is “designed” to reliably localize high-frequency sounds.

4.3 Probing the PTP mechanisms at the calyx of Held

Given the evidence that PTP is caused by small elevations of presynaptic $[Ca^{2+}]_i$ by ~80 nM, how do such small $[Ca^{2+}]_i$ elevations increase the transmitter release probability? Considering the estimates of the local $[Ca^{2+}]_i$ reached transiently at the Ca^{2+} sensor for vesicle fusion (~10–20 μ M) (Bollmann et al., 2000; Schneggenburger and Neher, 2000), it is seen that only a negligible fraction of the overall release potentiation is explained by summation of residual $[Ca^{2+}]_i$ with the local $[Ca^{2+}]_i$ signal. We would expect a PTP of only 104% of control for a residual $[Ca^{2+}]_i$ of 100 nM, assuming a peak local $[Ca^{2+}]_i$ of 10 μ M and a fourth power relationship between transmitter release and $[Ca^{2+}]_i$. It is also unlikely that the increased release probability underlying PTP is caused by the same

mechanism that causes Ca^{2+} -dependent short-term facilitation. It has been shown that brief (~ 20 ms) $[\text{Ca}^{2+}]_i$ elevations by ~ 500 – 600 nM cause an approximately twofold enhancement of transmitter release during short-term facilitation at the calyx of Held (Fig. 7B in (Felmy et al., 2003)). Thus, the $[\text{Ca}^{2+}]_i$ increment needed to cause a given enhancement is ~ 5 – 10 times higher for facilitation compared with PTP, making it likely that the two forms of short-term plasticity are mediated by different Ca^{2+} -dependent mechanisms (Zucker and Regehr, 2002). Short-term facilitation at the calyx of Held has been proposed to result from a mechanism of Ca^{2+} summation, aided by supralinearities caused by (partial) saturation of a fast endogenous Ca^{2+} buffer (Felmy et al., 2003). However, a mechanism of Ca^{2+} -buffer saturation is unlikely to cause significant amounts of PTP, because the small elevation of $[\text{Ca}^{2+}]_i$ during PTP (~ 120 nM at most) should not significantly saturate endogenous Ca^{2+} buffers.

Therefore, in the next experiments, we performed direct presynaptic recordings to identify which of above discussed Ca^{2+} -dependent mechanisms might be relevant for PTP at the calyx of Held.

4.3.1 Role of changes in presynaptic calcium currents

Calyceal calcium currents facilitate calcium-dependently (Borst and Sakmann, 1998; Cuttle et al., 1998). They could activate more rapidly in the presence of residual calcium. Therefore, to quantify the possible contribution of facilitation and inactivation of calcium currents, direct measurements of calcium currents and calcium influx during an AP after the establishment of PTP are necessary. However, as it was already mentioned above, it was not possible to test these mechanisms in whole-cell recordings, because presynaptic whole-cell recordings suppressed PTP completely (Fig. 3-10). Therefore, we used perforated-patch clamp at the calyx of Held, which could better preserve intracellular signalling pathways. The channels, formed by Amphotericin B (the antibiotic used here for perforation), are permeable to the monovalent cations and Cl^- , but not to divalent ions such as Ca^{2+} , which is an important signaling molecule in the cell. In these experiments, we applied HFS, which normally induced PTP, and measured presynaptic I_{Ca} . However, no increase in I_{Ca} peak amplitude was observed (Fig. 3-11). Instead, I_{Ca} strongly inactivated during the train and was not yet fully recovered at the time when the peak of PTP was usually observed (~ 20 – 30 s following HFS train). Such inactivation of presynaptic calcium currents was also observed during our whole-cell recordings (not

shown) and was previously described by (Forsythe et al., 1998), who studied the role of I_{Ca} inactivation in short-term depression at the calyx of Held. Thus, it seems that even under the more “physiological” conditions of perforated patch clamp recordings, I_{Ca} undergoes inactivation, and slow recovery from inactivation following HFS. Therefore, PTP is probably not mediated by a modulation of presynaptic Ca^{2+} currents (which could, for example, occur after the activation of PKC). Nevertheless, it remains possible that changes in AP waveform occur during PTP that then lead to an increased I_{Ca} . To test this, it would be desirable to perform presynaptic perforated patch recordings under current-clamp, and simultaneous postsynaptic recordings to measure PTP. However, because these experiments were technically very challenging, we were not able to obtain conclusive results within the frame of this work.

Concerning the role of AP waveform in modulation of Ca-influx, we did not observe changes in AP waveform during presynaptic whole-cell recordings (Fig. 3-10A). This, however, does not necessarily argue against AP broadening, because PTP was absent under this experimental condition. Indeed, evidence for a change in presynaptic AP waveform during a longer-lasting form of PTP has been observed recently by (Habets and Borst, 2005).

4.3.2 Involvement of second messengers

Another mechanism by which changes in synaptic strength could occur at the presynaptic terminal involves intracellular second messenger-dependent regulation of protein interactions within the release machinery. Various protein kinases have been implicated in the regulation of transmitter release (Greengard et al., 1993; Vaughan et al., 1998). Cyclic AMP-dependent protein kinase (PKA), protein kinase C (PKC) and Ca^{2+} - and calmodulin-dependent protein kinase II (CaMKII) stimulate neurotransmitter release in various neuronal preparations. In our study, the involvement of PKC was investigated, because it was shown to be important for PTP in other brain regions (Alle et al., 2001; Brager et al., 2003).

PKC is a Ca^{2+} and phospholipid-dependent kinase. To date, eleven mammalian isoforms of PKC have been identified and divided into three subclasses: conventional, novel and atypical, based on their structure and properties (Newton, 2001; Rhee, 2001). PKC is highly expressed in brain and distributes differentially in neurons in an isoform-specific manner. Although all of the PKC subtypes exhibit broad substrate specificity and

most likely regulate many aspects of cell function, they differ dramatically in their ability to be regulated by cellular levels of Ca^{2+} and various phospholipids. Some subtypes, like conventional ones, are highly sensitive to Ca^{2+} , whereas others are relatively insensitive. Several regulatory domains have been identified within the PKC molecule: 1) a C1 domain, which is a cystein-rich region that is present in all PKC isoforms and mediates the effect of diacylglycerol (DAG) and phorbol esters; 2) a C2 domain, which mediates the Ca^{2+} -binding property of PKC. In conventional and novel PKCs, C1 is present in a tandem repeat, named C1A and C1B. The C2 domain in conventional PKCs binds membranes in a Ca^{2+} -dependent manner, however, novel C2 domains do not bind Ca^{2+} .

Phorbol esters, which activate all known PKC isoforms, induced a profound enhancement of transmitter release from a wide variety of neuronal preparations and also at the calyx of Held synapse (Hilfiker and Augustine, 1999; Hori et al., 1999; Lou et al., 2005). Phorbol esters have been a valuable tool in PKC research. However, recently it was shown that phorbol esters can potentiate transmitter release also via Munc-13, a brain-specific protein essential for neurotransmitter release and specifically localized to presynaptic terminals. It contains a DAG/phorbol ester binding domain (C1) and two C2 domains homologous those of PKCs (Augustin et al., 1999; Rosenmund et al., 2002). Munc-13-1 interacts with syntaxin 1 and with DOC2, a C2-domain-containing protein of the putative regulator of neurotransmitter release (Orita et al., 1997). Based on various lines of evidences, it was suggested that Munc-13-1 plays an essential role in the priming step after vesicle docking (Augustin et al., 1999) and Munc-13-1 is involved in phorbol ester-induced potentiation of glutamate release in addition to the PKC-pathway (Rhee et al., 2002).

It is likely that during PTP at the calyx of Held, Ca^{2+} either acts at a high-affinity site relatively tightly associated with the release machinery, but distinct from the low- to intermediate-affinity site that drives vesicle fusion, and causes an increase in the effective Ca^{2+} sensitivity of vesicle fusion, in agreement with previous ideas about the action of residual Ca^{2+} (Zucker and Regehr, 2002). Such a high-affinity site could be formed by Ca^{2+} /calmodulin interacting with the presynaptic vesicle priming factor Munc-13 (Junge et al., 2004). However, because PTP was not accompanied by a pool size increase (Fig.3-9), one would have to postulate a post-priming role for Munc-13 activated by Ca^{2+} /calmodulin. To test the role of PKC, we used a pharmacological approach and treated slices with different PKC inhibitors (Fig.3-12 - 15). The broad-spectrum PKC inhibitor BIS was able to block PTP by ~50% (Fig. 3-14, 3-15). However, the most

prominent effect was observed with Ro-31-8220, which suppressed PTP by ~70% (Fig.3-12, 3-15). In addition, the peak of the residual potentiation was delayed after Ro-31-8220 (Fig.3-12) and BIS treatment (Fig.3-14), which points towards a possible role of PKC not only in potentiation, but also in acceleration of the recovery rate of EPSCs from depression after a high frequency. The recovery process was tested in the presence of the PKC inhibitor Ro-31-8220 by analyzing EPSC responses at different interstimulus intervals. We found that Ro-31-8220 slowed down the recovery from depression (Fig.3-15), which proposes an involvement of PKC in the recovery from depression. PKC might regulate this process via phosphorylation-dephosphorylation events of certain substrate proteins. However, the slowing of recovery from short-term depression can also be due to the inhibition of PTP itself because, as was suggested by John Wesseling (personal communication), the recovery from depression might be speeded up by short-term enhancement, like augmentation (or, in our case, PTP) of transmitter release.

To test what can be the possible mechanism(s) of PKC activation and which particular PKC isoforms are involved in PTP, we performed additional pharmacological experiments. For example, to answer the question whether it is the C1 or the C2 domain (or, may be both), which might be modulated during PTP, we first used Calphostin C, an antagonist which competes with DAG and phorbol esters for the binding to the C1 domain of PKCs. Acute application or incubation of the slices with Calphostin C had no effect on PTP (Fig.3-15). However, we could not draw a conclusion from these experiments, because preincubation with this blocker was also accompanied by the degradation of the slices. Therefore, the Calphostin C effect could be overlooked, because of the cytotoxicity of this antagonist, or another reason might be that it could not reach the intracellular space of the terminal from extracellular medium.

It is known that calmodulin can mediate various actions of Ca^{2+} in the cells, for example, such as activation of Ca^{2+} -dependent adenylate cyclases 1 and 8 (AC1 and AC8), PLC $_{\delta}$, CaMKII or CaM-binding site on Munc-13. To test whether increase in intracellular Ca^{2+} concentration during PTP might promote calmodulin activation, we applied Calmidazolium (calmodulin blocker). However, no effect on PTP was observed (Fig.3-15). These results either suggest that calmodulin-mediated pathway does not play a significant role in PTP.

In another line of pharmacological experiments, we tried to verify, which PKC isoforms might be involved in PTP induction. Application of Gö-6976, a specific inhibitor of conventional PKCs (PKC $_{\alpha}$, PKC $_{\beta I}$) had no effect on PTP (Fig.3-15). These

results suggest that Ca^{2+} -independent (novel) PKC isoforms might play role in PTP at the calyx of Held. Indeed, it was shown that novel PKC_ε isoform is expressed in this synapse and that activation of PKC_ε by phorbol esters might cause its translocation toward the synaptic side of the terminal (Saitoh et al., 2001). However additional pharmacological investigations together with immunocytochemistry are necessary to investigate this question further.

Concerning the role of the PKC pathway in PTP, it is interesting to know how PKC can exert its action to increase the transmitter release. What could be the potential molecular targets? It seems that mechanisms of PKC-dependent regulation of release are different among different preparations. For example, the activation of PKC by phorbol esters increase the readily-released pool (RRP) in hippocampal neurons (Stevens and Sullivan, 1998), whereas it increases the Ca^{2+} sensitivity of secretion rather than RRP size in chick ciliary ganglion (Yawo, 1999). At the calyx of Held, application of phorbol esters, which can potentially target both PKC and Munc-13 (see above), increases the Ca^{2+} sensitivity of vesicle fusion (Wu and Wu, 2001; Lou et al., 2005) and, in addition, slightly increases the presynaptic Ca^{2+} current (Lou et al., 2005).

Figure 4-1. Schematic representation of possible PTP mechanisms at the calyx of Held. Accumulation of presynaptic residual $[\text{Ca}^{2+}]_i$ is very important for PTP induction. It can trigger a series of different processes. Activation of the protein kinase C (PKC)-pathway might be one of them. PKC can modulate either Ca^{2+} influx, for example by phosphorylation of Ca^{2+} channels, or the Ca^{2+} -sensitivity of the release machinery. A possible involvement of phospholipase-C (PLC), one of the products of which is diacylglycerol (DAG) that could activate both PKC and Munc-13, still has to be tested.

Thus, based on our study and on the current knowledge about Ca^{2+} -dependent intracellular signalling during various forms of synaptic plasticity, we can discuss the mechanisms that might increase the amount of transmitter release during PTP at the calyx

of Held (Fig.4-1). From one hand, elevated residual presynaptic $[Ca^{2+}]_i$ could activate PKC via direct Ca^{2+} binding to its C2 domain. Alternatively, PKC might be also regulated by DAG, which could be activated during PTP by certain mechanisms, for example, by activation of phospholipase C (PLC). There are four distinct PLC subfamilies, such as PLC_β , PLC_γ , PLC_δ and PLC_ϵ , which have been identified in mammals. All of these PLC isozymes require Ca^{2+} for the catalytic function of the hydrolysis of phosphatidylinositol 4,5-bisphosphate [PtdIns(4,5)P2] to inositol 1,4,5-trisphosphate and diacylglycerol in response to the activation of more than 100 different cell surface receptors (Rhee, 2001). The presence of distinct regulatory domains in PLC isoforms renders them susceptible to different modes of activation (Rhee, 2001): (i) for example, PLC_δ is most sensitive to Ca^{2+} among other isoforms; (ii) the activation of PLC_β can be promoted by the activation of G-protein-coupled receptors; (iii) mobilization of PLC_γ is influenced by different neurotrophins via activation of receptor protein tyrosine kinases; (iiii) PLC_ϵ activation might be influenced by cyclic AMP level in the cell, which is regulated by Ca^{2+} -dependent adenylyl cyclases of type 1 and 8 (Cooper, Mons and Karpen, 1995). As one can see, there is a big “net” of protein-protein interactions that could activate different intracellular signalling pathway, in particular the PKC pathway.

In turn, PKC activation could either increase the Ca^{2+} influx into the cell by direct phosphorylation of Ca^{2+} channels or enhance the Ca^{2+} -sensitivity of vesicle fusion. Recently, Lou and coworkers (2005) proposed that the Ca^{2+} -sensitivity might change via an increase in the “willingness” of vesicle to fuse, without a change in the Ca^{2+} -binding properties of the Ca^{2+} sensor. Increased fusion willingness might be caused by lowering the energy barrier for fusion, a mechanism which was implicated in augmentation and in Ca^{2+} -independent, hypertonicity-evoked transmitter release (Stevens and Wesseling, 1999). Lou and coworkers (2005) suggested that SNAREs and synaptotagmins, proteins representing the release machinery, might be such a Ca^{2+} sensor, which might be modulated by PKC phosphorylation. Indeed, the PKC phosphorylation site in SNAP-25 has been mapped to serine (Ser¹⁸⁷) (Shimazaki et al., 1996; Genoud et al., 1999; Nagy et al., 2002; Rhee et al., 2002), which is located within the negatively charged C-terminal and between the cleavage sites for botulinum toxins A and E. This region has been shown to be of critical importance for Ca^{2+} -triggered exocytosis. Another Ca^{2+} sensor candidate might be synaptotagmin I or II. It was shown that point mutation in synaptotagmin I caused a twofold decrease in Ca^{2+} sensitivity of neurotransmitter, but didn't alter

spontaneous release or the size of the readily releasable pool (Fernandez-Chacon et al., 2001).

On the other hand, Munc-13s were also shown to be capable to activate SNARE complex formation by unfolding syntaxin (Brose et al., 1995; Augustin et al., 1999) Munc-13s have a DAG binding site like PKC and binding of DAG to Munc-13 is thought to mediate augmentation of release in hippocampal neurons (Brose and Rosenmund, 2002). Although we found no significant increase in the readily-releasable pool (RRP) during PTP, the main mechanism by which Munc-13s exert its action to potentiate transmitter release, we do not exclude this possibility, especially for the longer-lasting form of PTP observed at the calyx of Held by (Habets and Borst, 2005). It is also possible that DAG (or phorbol ester) binding to Munc-13 lead to an increased “willingness” of fusion, may be if Munc-13 remains bound to SNARE proteins after vesicle priming.

However, future work needs to establish the exact mechanism of the release probability increase and the modulatory Ca^{2+} -binding site(s) involved in the action of Ca^{2+} during PTP.

4.4 Outlook and future experiments

In this work posttetanic potentiation was identified at the calyx of Held, which was previously not described at this synapse. Possible mechanisms were investigated using different experimental approaches. Ca^{2+} -imaging revealed that the transient increase of glutamate release during PTP was caused by elevations of intracellular Ca^{2+} in the presynaptic terminal. In addition, an involvement of the PKC pathway was shown by pharmacological experiments using different PKC antagonists.

The next step would be to examine which PKC isoform(s) might be involved in PTP and what are the molecular targets of their action. For example, immunocytochemistry can be applied to verify the expression of particular PKC isoform(s) at the calyx of Held. From another side, more pharmacological experiments could be done using antagonists specific for different PKCs inhibitors. A possible involvement of PLC also could be tested in the same way.

In another line of research an occlusion experiments could be performed, pursuing the question whether potentiation of transmitter release caused by phorbol esters (Lou et al., 2005), shares the same mechanisms with PTP. In order to explore this possibility, the degree of PTP needs to be tested during phorbol ester application. Perforated presynaptic

patch-clamp in combination with postsynaptic whole-cell recordings could be performed to test whether PTP can be observed by this approach, and if yes, then one would have a possibility to examine presynaptic PTP mechanisms more directly.

Summary

In this work, a hitherto overlooked form of short-term plasticity was identified at the calyx of Held, a glutamatergic excitatory synapse in the auditory brainstem pathway.

Brief trains of high frequency stimulation (100 Hz for 1-8 s), which were applied to the afferent fibers that give rise to the calyces of Held, induced robust potentiation of excitatory postsynaptic currents (EPSCs), following the well-known depression of synaptic transmission during high frequency trains. This transient overshoot of synaptic transmission at the calyx of Held shared many properties with posttetanic potentiation (PTP) at other synapses. At the peak of PTP, synaptic strength was increased about two-fold and the decay of PTP lasted over 10s of seconds to more than 1 minute, depending on the length of the induction train. The unchanged mEPSC amplitudes during PTP and the finding that PTP was suppressed by whole-cell recording of the nerve terminal indicate its presynaptic origin.

PTP was induced more easily in synapses from young rats (postnatal days, P4 - P7) as compared to an older age group (P8 - P14), suggesting that PTP is developmentally regulated, and might play a role during the formation and/or maturation of the calyx of Held.

We next investigated the possible mechanisms underlying PTP. First, we found that PTP is mediated primarily via an increase in the release probability of the vesicles in the readily releasable pool (RRP), without a significant change in the size of RRP. Second, surprisingly low (~ 80 nM at the peak of PTP), but prolonged elevations of residual $[Ca^{2+}]_i$ in the presynaptic terminal were responsible for the induction of PTP. This high efficacy of a small residual $[Ca^{2+}]_i$ signal during PTP, and the sensitivity of PTP to presynaptic whole-cell recording, which was accompanied by accelerated residual $[Ca^{2+}]_i$ decay, suggested that other presynaptic intracellular messengers besides Ca^{2+} might also be involved in PTP. Therefore, we tested the protein kinase C / Munc-13 pathway. And indeed, different pharmacological experiments identified a role of protein kinase C in the induction of PTP at the calyx of Held.

Thus, the calyx of Held represents a highly plastic synapse, which displays several forms of short-term plasticity that are very similar to those observed in other synapses of the central nervous system. The accessibility of this synapse to presynaptic recordings will allow understanding the mechanisms of short-term enhancement in the near future.

Acknowledgements

First, I would like to thank my supervisor Prof. Dr. Ralf Schneggenburger for giving me a great opportunity to work in his laboratory and for his constant support, patience, constructive criticism and guidance during the whole PhD project. Sincere thanks to my PhD thesis committee members the head of the department Prof. Dr. Erwin Neher and Prof. Markus Missler for their critical suggestions and friendly support during the course of the project.

I am thankful to the founders and coordination team of the Neuroscience Program for their help, perfect organization of the study process and other activities, which gives a nice opportunity for international students to study and have interesting life in Göttingen.

Many thanks to all current and former members of the Laboratory of Synaptic Mechanisms (or Synaptic Dynamics and Modulation, the former name of this group in Göttingen): Marcus Wölfel, Felix Felmy, Martin Müller, Xue-Lin Lou, Ralf Schneggenburger, Sigrid Schmidt, Le Xiao, Yun-Yun Han, Zhizhong Dong, Sarah Magnin. The people from this wonderful group were always around to help, supported me and made my life in the laboratory unforgettable. Special thanks to Dr. Xue-Lin Lou and Dr. Takeshi Sakaba for the great discussions, help and teaching me of special practical “tricks” to get wonderful electrophysiological recordings. I would also like to thank Martin Müller for his help in the lab, patience in sharing the set-up and critical volunteered reading of the Methods part of this manuscript. Many thanks to our beautiful part of the group: Le Xiao and Yun-Yun for their enormous support during daily life and especially during the movement of our lab to Lausanne. I would like to thank Sigrid Schmidt, Frank Würriehausen and Frank Köhne for their kind technical assistance.

Many thanks to the people from the group of Microscopy of Synaptic Transmission: Martin Wienisch, Edward Lemke, Veronica Müller, Maria Krikunova, Jürgen Klingauf, Natalya Glyvuk, Yaroslav Tsytsyura, Peter Vanden Berghe for having a great time in the lab and outside. Big thanks to all my friends, especially to Zinayida Shevtsova for the great friendship, support and nice time in daily life.

My biggest gratitude goes to my dear parents, Natalia and Sergey Korogod, and my sister Tatiana Korogod for their endless love, care and enormous support, which make me happy throughout the life. Very special thanks to my farther. The scientific discussions with him brought my interest in such wonderful field of science as Neuroscience. And, I am endlessly grateful to my husband, Alexey Kochubey, for his great help and essential support in all aspects of my life.

Curriculum Vitae

Personal data:

Full name: Natalya Sergiivna Korogod

Born: 08.08.1979 in Dniepropetrovsk, Ukraine

Parents: Natalya Petrivna and Sergiy Mikhailovich Korogod

Citizenship: Ukraine

Martial status: married, no children. Husband, Kochubey Olexiy Olexandrovich

September 1986 – July 1993	Elementary and secondary school N174, Dniepropetrovsk, Ukraine
September 1993 – July 1996	Studying at the Lyceum of Informational Technologies, Dniepropetrovsk, Ukraine
September 1996 – July 2001	Studying at the Physical Faculty, Department of Experimental Physics, Dniepropetrovsk National University, Ukraine. B.Sc. degree in July 2000.
July 2001	Thesis defence for M.Sc. degree in “Biomedical and technical apparatus and systems”
October 2001 – August 2002	Master’s course in the International MSc/PhD Study Program “Neurosciences”, Georg-August-University, Göttingen, Germany
August 2002	Master’s examination in “Neurosciences” Program, admission to the PhD part of the Program
Since October 2002	PhD project within the “Neurosciences” Program, in the group of Synaptic Dynamics and Modulation (Prof. Dr. Ralf Schneggenburger), Department of Membrane Biophysics (Prof. Dr. Neher), Max-Planck Institute for biophysical Chemistry, Gottingen, Germany. Thesis advisor – Prof. Ralf Schneggenburger
