

Role of alternative splicing in the biological properties of the voltage-gated potassium channel $K_v10.1$

Dissertation

for the award of the degree
“Doctor rerum naturalium”

Division of Mathematics and Natural Sciences
of the Georg-August-Universität Göttingen

within the doctoral program CMPB
of the Georg-August University School of Science (GAUSS)

submitted by

Vincenzo Romaniello

from Aversa, Italy.

Göttingen, April 2014

Thesis committee members

Prof. Dr. Walter Stühmer (Referee), dept. of Molecular Biology of Neuronal Signals, Max Planck Institute of Experimental Medicine, Göttingen.

Prof. Dr. Michael Hörner (2nd Referee), dept. of Cellular Neurobiology, Johann-Friedrich-Blumenbach-Institute for Zoology and Anthropology, Göttingen.

Prof. Dr. Tobias Moser, dept. of Otolaryngology, University Medical School, Göttingen.

Prof. Dr. Luis A. Pardo, dept. of Molecular Biology of Neuronal Signals, Max-Planck Institute of Experimental Medicine, Göttingen.

Extended committee members

Prof. Dr. Blanche Schwappach, dept. of Molecular Biology, University Medical School, Göttingen.

Dr. Manuela Schmidt, Somatosensory Signaling Group, Max-Planck Institute of Experimental Medicine, Göttingen.

Date of oral examination **20th May 2014**

Declaration

I hereby declare that this thesis has been written independently and with no other aids or sources than quoted.

Vincenzo Romaniello

Göttingen, 8th April 2014.

Abbreviations

Units

σ^2	Variance
A	Absorbance
bp, kb	Base pair, kilobase
C_{fast} , C_{slow}	Fast capacitance, slow capacitance
Ci, μ Ci	Curie, Microcurie
Cp	Crossing point
cpm	Counts per minute
kDa	Kilodalton
G, G_{max}	Conductance, maximal conductance
g	Acceleration (relative centrifugal force)
i	Single channel current
I	Macroscopic (total) current
k	Slope factor
min	Minute
mOsm	Milliosmole
MW	Molecular weight
ON	Overnight
N	Total number of channels
nt	Nucleotide
P_o	Open probability
R	Resistance
rpm	Rotations per minute
R_s	Series resistance

RT	Room temperature
U	Unit
V_{Half}	Voltage for half-maximal activation
vol	Volume
w/v	Weight for volume

Cell lines, Organisms, Genes and Proteins

AChR	Acetylcholine receptor
AS	Alternative splicing
BBS	Bungarotoxin-binding site
cNBD	Cyclic nucleotide binding domain
CHO	Chinese hamster ovary
DNA, cDNA	Deoxyribonucleic acid, complementary DNA
HEK	Human embryonic kidney
<i>E. coli</i>	<i>Escherichia coli</i>
ER	Endoplasmic reticulum
ESEs/ISEs	Exonic splicing enhancers/intronic splicing enhancers
ESSs/ISSs	Exonic splicing silencers/intronic splicing silencers
hnRNPs	Heterogeneous nuclear ribonucleoproteins
IgG	Immunoglobulin G
NLS	Nuclear localization signal
PAS/PAC	Per-Arnt-Sim/PAS associated C-terminal
PTB	Polypyrimidine tract binding protein
RNA, cRNA, mRNA	Ribonucleic acid, capped RNA, messenger RNA
SR	Serine-rich
TCC	Tetramerizing coiled coil

WT Wild-type

Methods and Chemicals

ABTS	2,2'-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid)
Ar	Argon
ATP,CTP,GTP,UTP	Adenosine-, Cytidine-, Guanosine-, Uridine- triphosphate
BN-PAGE	Blue native-Polyacrylamide gel electrophoresis
BP	Band pass
BSA	Bovine serum albumin
BTX	α -Bungarotoxin
CaM	Calmodulin
CO ₂	Carbon dioxide
DAPI	4',6-diamidino-2-phenylindole
dH ₂ O	Distilled water
DDM	<i>n</i> -Dodecyl β -D-Maltopyranoside
DEPC	Diethyl pyrocarbonate
DMEM	Dulbecco's modified eagle medium
DMSO	Dimethyl sulfoxide
DNase	Deoxyribonuclease
dNTP	Deoxyribonucleoside triphosphate
DTT	1,4-Dithio-DL-threitol
ECL	Enhanced chemiluminescence
EDTA	Ethylenediamine tetraacetic acid
EGTA	Ethylene glycol tetraacetic acid
ELISA	Enzyme-linked immunosorbent assay
Endo H	Endoglycosidase H

FCS	Fetal calf serum
Fiji	Fiji is just ImageJ
GFP	Green fluorescent protein
HEPES	(4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid)
HRP	Horseradish peroxidase
IP	Immunoprecipitation
IPTG	Isopropyl β -D-1-thiogalactopyranoside
JACoP	Just another colocalization plugin
LB	Luria Bertani broth
LP	Long pass
MEM	Minimum essential medium
NFR	Normal frog ringer
NMDG	N-methyl- <i>D</i> -glucamine
PBS	Phosphate buffered saline
PCR	Polymerase chain reaction
Pi	Propidium iodide
PI	Protease inhibitor
PKA	Protein kinase A
PKC	Protein kinase C
PNGase F	Peptide N-Glycosidase F
PVDF	Polyvinylidene difluoride
RNAi, siRNA	RNA interference; small interfering RNA
RNase	Ribonuclease
RPA	Ribonuclease protection assay
RPMI	Roswell Park Memorial Institute
SDS	Sodium dodecyl sulphate

SDS-PAGE	SDS Polyacrylamide gel electrophoresis
SEM	Standard deviation of the mean
TBE	Tris-Borate-EDTA
TBS	Tris-buffered saline
TEA	Tetraethylammonium acetate
TEMED	N'N'N'N Tetramethylethyldiamine
TEVC	Two-electrode voltage clamp
X-Gal	5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside

1. Introduction

1.1 Ion channels

The flow of ions across the cell membrane is a crucial process for life: it provides nutrients, generates electrical signals, regulates cell volume, secretes electrolytes across epithelial layers (Hille, 2001). Ion channels, together with transporters and pumps are the main players to accomplish these physiological functions. Ion channels are proteins equipped with a hydrophilic pore traversing the entire lipid bilayer of the membrane of all prokaryotic and eukaryotic cells. They allow the transit through the membrane of different inorganic ions, like Na^+ , K^+ , Ca^{2+} and Cl^- , with a very high flow rate: up to 100 million ions/s can flow through a single channel (Kandel, 2000). Two main factors distinguish ion channels from simple aqueous pores. The first is the ion selectivity, meaning that ion channels allow the passage exclusively (or with very high selectivity) of one ion rather than another. This is thought to be mediated by the selectivity filter region of the channel that preferentially interacts with and mediates the passage of the proper ion. The second important distinction is that the former are not always in open state. Events of opening and closure (or "gating") are continuously occurring and, depending on a specific stimulus, strictly regulated.

The first insights into the structure and function of ion channels had been derived from molecular and structural biology studies as well as pioneering electrophysiological investigations. The first milestone in the latter field was achieved by Hodgkin and Huxley who in 1952, based on evidence provided by voltage clamp experiments, elaborated a series of mathematical models describing how ionic current generated by ion channels give rise to action potential in neurons (Hodgkin and Huxley, 1952). Later on, towards end of the 1970s, the field of electrophysiology was revolutionized by the invention of the patch-clamp technique, a powerful method that allows real time analysis of current flowing at the level of single channel molecule (Neher et al., 1978). About thirty years ago the first ion channel was cloned (Noda et al., 1983), and to date genes for most of the major classes of ion channels have been cloned and sequenced.

Moreover, after the first structure of a bacterial potassium channel obtained by X-ray crystallography (Doyle et al., 1998), several different channel structures are now available. Ion channels subunit sequences have also been extensively engineered through manipulation of their DNA sequence, providing hints about the function associated with the mutated DNA region.

Based on data from various fields, we know that ion channels are generally macromolecular (oligomeric) complexes formed by assembly of several subunits. The majority of channels have three, four, or five homologous or identical α subunits arranged in circular symmetry, forming a single aqueous pore at their axial intersection (Fig. 1 A). In certain types of channels, additional accessory subunits are coupled to the ion conducting (α) subunits (Fig. 1 B). Ion channels possess many features typical of membrane proteins: they are synthesized and inserted into the membrane of the endoplasmic reticulum (ER), glycosylated in the Golgi, and transported and inserted into target membranes by membrane fusion processes (see section 1.2).

The wide variety of ion channel structures is correlated with a large diversity regarding the main type of stimulus causing their opening: change in the voltage across the membrane (*voltage-gated channels*), mechanical stress (*mechanically gated channels*), or the binding of a ligand (*ligand-gated channels*). The ligand can be either an extracellular mediator, a neurotransmitter (*transmitter-gated channels*) or an intracellular mediator, such as an ion (*ion-gated channels*), or a nucleotide (*nucleotide-gated channels*) (Alberts et al., 2002). The activity of many ion channels can be moreover modulated by post-translational modification like phosphorylation, dephosphorylation, ubiquitinylation, SUMOylation, palmitoylation and N-linked-glycosylation. Mechanisms of alternative splicing (as will be described in section 1.5.2) as well as interaction of the α subunits of the channels with auxiliary (β or γ) subunits play a critical role expanding ion channel diversity and in the modulation of their function (Fig. 1 B) (Li and Um; 2006).

Figure 1 Ion channels multisubunit architecture. (A) Ion channels can be formed by heterooligomers from distinct subunits (left), as homooligomers from a single type of subunit (middle), or from a single polypeptide chain organized into repeating motifs, where each motif behaves like one subunit (right). (B) Some channels contain auxiliary subunits (β or γ), which modulate the gating characteristics of the central core (figure modified from Kandel, 2001).

To date, more than one hundred genes coding for several hundreds of different ion channels have been identified (Gabashvili et al., 2007). The need for classification of this plethora of molecules led to the elaboration of a numbering system for mammalian voltage-gated potassium channel (Chandy, 1991), then for voltage-gated calcium channels (Ertel et al., 2000) and for voltage-gated sodium channels (Goldin, 2002). However, a classification system widely accepted nowadays is based on the IUPHAR (International Union of basic and clinical Pharmacology) classification (<http://www.iuphar-db.org>), in which the products of gene families and superfamilies are named based on the chemical symbol of the main permeating ion (Na, K, or Ca) and with the principal physiological regulator depicted subscript (for example, a voltage activated potassium channel will be depicted with K_v) followed by a number indicating the gene subfamily and a decimal that separates the number assigned to specific channel isoforms. This classification system will be used wherever appropriate in this thesis.

Overall, in recent years improved electrophysiological methods coupled with advanced molecular and structural biology techniques have provided a much more comprehensive knowledge about the once ‘black box’ of ion channels.

1.1.1 The superfamily of voltage-gated channels

As the name already suggests, voltage-gated channels are opened by changes in membrane potential. They all consist of four homologous motifs, each of them formed by six transmembrane segments (S1 to S6) containing a voltage sensor domain and a pore-forming domain (Fig. 2). The four pore-forming α domains converge to form the single central pore, whereas the four voltage sensors are placed laterally within the membrane lipid bilayer. The opening and establishment of ionic conductance requires that voltage-gated channels are provided with charges that would respond to voltage changes, as already postulated by Hodgkin and Huxley in 1952. Subsequently, the existence of the voltage sensor was demonstrated: it consists of a region within the S4 transmembrane segment of each domain composed of repeated motifs of one positively charged residue followed by two hydrophobic residues, potentially creating a helical arrangement of positive charges through the membrane (Noda et al., 1984). Neutralization of the four positively charged residues in the S4 segment of domain I of the sodium channel by site-directed mutagenesis has major effects on the voltage dependence of activation (Stühmer et al., 1989). The movement of the voltage-sensor charged by changes of electric field across the membrane therefore alters the equilibrium between the closed and open states of the channel, thus controlling the ion flow. The passage of ions occurs through the pore region, situated between S5 and S6 transmembrane segment of each domain. Voltage-gated channels show different ion selectivities for monovalent cations and are therefore classified as Na_v , K_v , and Ca_v channels.

Apart from the similar backbone structure previously mentioned, the final structure of the voltage-gated channels show relevant differences between different families: in Na_v channels, the four homologous α domains, (each of them formed by six transmembrane segments) are derived by a single, linear sequence connected by intracellular loops and associated with one or more auxiliary β -subunits, the latter required for normal kinetics and voltage dependence of gating (Catterall, 2000a). In the case of Ca_v , the pore-forming α_1 linear sequence is assembled together with a transmembrane, disulfide-linked complex of α_2 and δ subunits and an intracellular β subunit. In some cases, a transmembrane γ subunit is also found. Mutations in these subunits have a tremendous impact on expression level, voltage dependence and gating properties of the channels

(Catterall, 2000b). With forty known genes, voltage-gated potassium channels represent the largest superfamily of ion channels. Unlike voltage-gated calcium and sodium channels, the voltage-gated potassium channels encode in their primary sequence only a single α domain. The assembly of four α domains is primarily mediated by a region located within the intracellular hydrophilic amino-terminus (K_V1) or carboxy-terminus, (as the case of K_V7 , K_V10 , K_V11 and K_V12 channels)(Jenke et al., 2003). This region is known as the tetramerization domain (Li et al., 1992). Homo- or heterotetramers (formed by different subunits within the same family) of α subunits form the functional voltage-gated potassium channel. β subunits can also interact with these types of channels, modulating their function (Catterall, 1995). In this regard, the tetramerization domain may also serve as a scaffold to bind accessory β subunits (Tombola et al., 2006).

Figure 2 General architecture of a voltage-gated channel. *Top* shows the basic subunit (or domain in the case of Na^+ and Ca^{2+} channels). The gray background represents the lipid bilayer. The cylinders represent transmembrane segments. The region between S5 and S6 forms the pore. The voltage sensor part of the channel consists of the segments from S1 to S4. The + or - signs indicate charges involved in voltage sensing. In the bottom part, a schematic view of the channel from the outside showing the assembled four subunits or domains is seen. Figure from (Bezanilla, 2005).

1.2 Trafficking of ion channels

The intracellular trafficking of membrane proteins such as ion channels is a complex and highly regulated process. It involves both forward (towards the plasma membrane) and backward (internalization from the plasma membrane) transport. The journey starts when the nascent protein chain moves from the ER membrane bound ribosome into the ER lumen. Here the processes of folding and assembly occur, in a co-translational manner (Kosolapov and Deutsch, 2003). In most of the voltage-gated potassium channels (including $K_V10.1$ channels) the ‘newborn’ protein may additionally undergo core-glycosylation at this phase (Napp et al., 2005, Steele et al., 2007). A pre-synthesized oligosaccharide (Glc3MangGlcNAc2) is transferred to an asparagine (Asn) residue in the nascent peptide chain by the enzyme oligosaccharyltransferase (Kaplan et al., 1987). Core glycosylation generally occurs at the Asn residues in the sequon Asn-X-Ser/Thr, (X is any amino acid except proline) (Kaplan et al., 1987). N-Linked glycosylation represents a common form of membrane protein processing that can profoundly affect protein expression, structure, and function. Defects in glycosylation may result in the generation of misfolded, aggregated proteins failing to reach a functional state.

Quality control mechanisms at the ER, such as heat shock protein (Hsp) 70 and 90, and calnexin (Zerangue et al., 1999; Ficker et al., 2003; Steele et al., 2007; Staudacher et al., 2010) ensure that only correctly folded, assembled channel proteins are exported from the ER to Golgi (Ellgaard and Helenius, 2001) whereas misfolded proteins are retained in the ER (aggregating with other misfolded proteins) and eventually targeted for degradation (Zerangue et al., 1999). In the Golgi, further processing of the channel protein like complex glycosylation occurs; the oligosaccharides gain complexity as proteins progress through the Golgi apparatus, resulting in complex, high-mannose, or hybrid oligosaccharides. From the Golgi network the complex glycosylated proteins are directed to the plasma membrane to be finally inserted within the lipid bilayer. Remarkably, ion channels do not simply traffic to any random area in the plasma membrane, but rather localize to specific cell surface domains (Steele et al., 2007). Membrane insertion process occurs by means of SNARE-mediated fusion of vesicles containing the ion channel protein with the plasmalemma. SNAREs are thought to

deform membranes, affecting the hydrophobic–hydrophilic boundary and directly inducing fusion (Jahn and Scheller, 2006). In order to ensure adequate cellular plasticity and homeostasis, ion channels expression at level of the cell surface is finely regulated. Channels undergo internalization and can either be recycled or degraded in proteasomes or lysosomes (Steele et al., 2007).

1.3 Physiological and pathophysiological roles of ion channels

Ion channels play important roles in diverse processes such as nerve and muscle excitation, hormone secretion, cell proliferation, sensory transduction, learning and memory, regulation of blood pressure, salt and water balance, fertilization and cell death (Ashcroft, 2006). In particular, voltage-gated potassium channels control cell excitability and set the resting potential, contributing to the origin and propagation of the action potential in neurons and other excitable cells.

Ion channel dysfunctions can result in a large variety of diseases; to date, mutations in over 60 ion channel genes have been associated with human pathologies. The dysregulation of certain types of voltage-gated channels causing hyperexcitability may result in different pathologic phenotypes: epilepsy, occurring in central neurons; myotonia (prolonged muscle contraction) in skeletal muscle, arrhythmia when in the heart. Other example of pathologic phenotypes associated with ion channels are cystic fibrosis, hypertension, diabetes, and gastrointestinal disorders (Ashcroft, 2006). Increasing evidences suggest an involvement of ion channels in cell proliferation and cancer (see section 1.3.1). Given the important role of ion channels in many pathophysiological events, together with their structural heterogeneity and convenient transmembrane localization, these molecules represent an attractive target for pharmacologic therapies. Indeed, it is not surprising that currently more than 13% of all available pharmacologic therapies utilizes drugs having ion channels as their primary therapeutic target (Overington et al., 2006).

1.3.1 Role of ion channels in cell proliferation and cancer

An emerging physiological and pathophysiological role of ion channels expression is their implication with cell proliferation (Wonderlin and Strobl, 1996; Pardo, 2004; Kunzelmann, 2005). Oscillation of membrane potential exerted by ion channels is required for progression of the cell cycle: the membrane potential in early G1 phase is depolarized and the transition from G1 to S phase during mitosis is accompanied by hyperpolarization of the membrane potential (Wonderlin et al., 1995). In this context, potassium channels expression, while inducing a shift of the membrane potential towards negative values, would provide the driving force required for calcium to enter the cell. Calcium is an important mediator of intracellular signals, implicated in the control of proliferation among other crucial processes in cell physiology (Lee et al., 1993). Beside the calcium-mediated effect, another hypothesis about ion channel impact on proliferation relies on the regulation in cell volume mediated by chloride channels: changes in cell size would either favor the progression along the cell cycle, or commit the cell to undergo apoptosis (Lang et al., 2000). Moreover, inhibition of K⁺ channels may affect regulation of cytosolic pH and reduce proliferation by causing cellular acidification (Kunzelmann, 2005). The proliferative stimulus related to expression of potassium channels (K_{Ca}3.1 and K_V1.3) is also crucial for lymphocyte B and T maturation and proliferation. These channels have been proposed as novel therapeutic targets for autoimmune disorders (Beeton et al., 2005). More interestingly, dysregulation of Ca²⁺-channels (in particular transient receptor potential - TRP - channels), K⁺ channels (like K_{Ca}1.1, K_{Ca}3.1, K_V1.3, K_V10.1 and K_V11.1) and Na⁺ channels (like Na_V1.5 and Na_V1.7) all contribute to cancer progression, acting through a series of mechanisms, ranging from cell cycle and cell metabolism regulation, influencing the cell motility and capacity of invasion of tumor cells (Pedersen and Stock, 2013; Pardo and Stühmer, 2014; Urrego et al., 2014).

1.4 K_V10.1 channels

K_V10.1 (also named Eag1) is a member of the *ether-à-go-go* (eag) family of voltage activated potassium channels. The name *eag* was assigned to a mutant showing leg-shaking in response to ether anesthesia in the fruit fly *Drosophila melanogaster* (Kaplan and Trout, 1969). Subsequent cloning of the gene revealed that K_V10.1 encodes a voltage-gated potassium channel (Brüggemann et al., 1993). The human ortholog of *Drosophila eag* gene (K_V10.1) was cloned in 1998: the gene is located at position 32.1–32.3 of the long arm of human chromosome 1; it encodes eleven exons (Occhiodoro et al., 1998; Pardo et al., 1999) and it is translated into a protein of apparent molecular weight of ~130 kDa (Napp et al., 2005). To date, the *eag* family includes eight members: beside K_V10.1, the closely related K_V10.2 (eag2), the K_V12 (elk) subfamily (elk1, elk2, elk3) and the K_V11 (erg) proteins (erg1, erg2, erg3) have been identified. Similarly to the other K_V superfamily members, K_V10.1 shows the characteristic six transmembrane domains with long intracellular amino- and carboxyl- terminal regions, bearing several recognizable motifs. In the N-terminal domain, a Per-Arnt-Sim (PAS)/PAS associated C-terminal (PAC) domain and a binding site for calmodulin. Two binding sites for calmodulin, a cyclic nucleotide binding domain (cNBD), a nuclear localization signal (NLS) and a tetramerizing coiled-coil (TCC) domain in the carboxyl-terminus (Fig. 3). The binding sites for calmodulin modulate channel function (see below). The TCC domain is crucial for assembly in the tetrameric conformation typical of functional channels (Jenke et al., 2003; Ludwig et al., 1997). The functional roles of K_V10.1 PAS/PAC (frequently named *eag* domain) and cNBD domains are still undisclosed. However, recent crystal structure analyses show that PAS/PAC and cNBD domains extensively interact; disruption of this interaction induced by mutations alters the gating properties of K_V10.1 channels (Haitin et al., 2013). K_V10.1 channels also undergo post-translational modifications: glycosylation sites are present on asparagine residues at positions 388 and 406 of the extracellular loop between S5 and S6 transmembrane domains. Asn-388 seems to undergo only core glycosylation; additionally complex sugars are bound to Asn-406. Correct glycosylation is critical for the proper trafficking of the channel to the membrane, as well as for its correct function once the channel reached already the membrane (Napp et al., 2005). Regarding the channel trafficking, K_V10.1 undergoes very rapid surface turnover (a given set of

membrane channels is getting internalized once during ~100 min), which controls the subcellular distribution and life cycle of the channel (Kohl et al., 2011). $K_V10.1$ channels are partitioned in different subdomains along the plasma membrane, and their activity varies depending on their distribution (Jiménez-Garduño et al., 2013). This could provide a functional correlate to the finding that endogenous $K_V10.1$ channels diffuse within the plasmatic membrane of hippocampal neurons (Gómez-Varela et al., 2010).

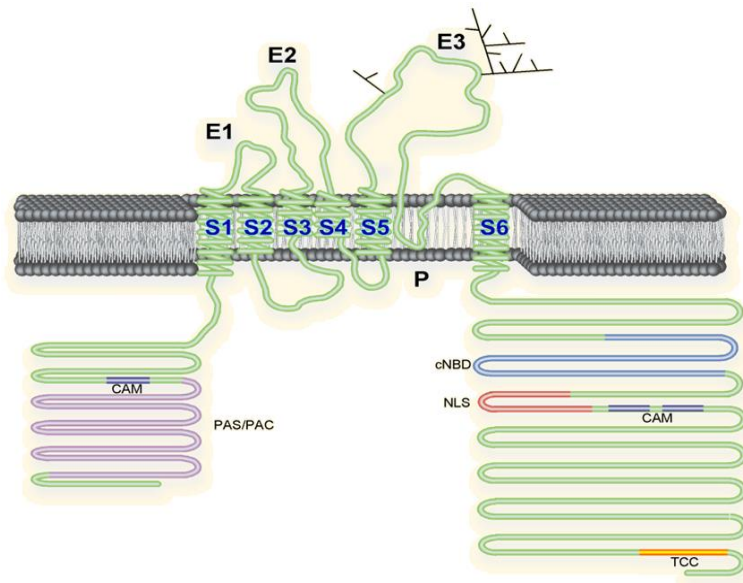

Figure 3 Putative structure of a subunit of the voltage-gated potassium channel $K_V10.1$. Each subunit is formed by six transmembrane domains; the voltage sensor is located between S1 and S4, and the pore between S5 and S6. The branches along the third extracellular loop (E3) represent glycosylation sites. Two long intracytoplasmic regions containing several binding motifs are also highlighted.

A second $K_V10.1$ transcript (called $K_V10.1b$, to distinguish it from the originally cloned, $K_V10.1a$) has been cloned from mouse and human brain, and bovine retina. $K_V10.1b$ has an insertion of 27 amino acids in the extracellular linker between transmembrane segments S3 and S4 (Warmke and Ganetzky, 1994; Frings et al., 1998; Pardo et al., 1999). As far as determined, $K_V10.1a$ and $K_V10.1b$ share expression pattern and electrophysiological properties. Additional $K_V10.1$ transcripts derived from events of alternative splicing have been recently detected in human brain and cancer cell lines (see section 1.5.3).

In a physiological context, $K_V10.1$ expression pattern is limited to adult brain and myoblasts, and virtually absent in peripheral tissues (Occhiodoro et al., 1998). In myoblasts, $K_V10.1$ contributes to the hyperpolarization required for the differentiation of these cells in post-mitotic, fusion-competent myotubes (Bijlenga et al., 1998). In brain, $K_V10.1$ channels have preferential presynaptic localization, and contribute to short-term synaptic plasticity. Parallel fiber/Purkinje cell synapses of $K_V10.1$ knockout mice show increased short-term facilitation (Mortensen PhD thesis, 2012). $K_V10.1$ -deficient mice show no detectable alterations during embryogenesis and develop normally to adulthood. No major behavioral effects were detected, apart from a mild hyperactivity and longer lasting haloperidol-induced catalepsy (Ufartes et al., 2013).

However, despite the only partially characterized role of $K_V10.1$ in physiology, this channel subfamily has been extensively studied because of their involvement in oncogenesis (see section 1.4.2).

1.4.1 Electrophysiological properties of $K_V10.1$

$K_V10.1$ is a voltage-gated potassium channel producing slow activating, outward rectifying currents, which do not inactivate. A slight inward rectification is observed with strong depolarizations, compatible with block by intracellular sodium (Pardo et al., 1998). The best known $K_V10.1$ blockers are astemizole, imipramine (García-Ferreiro et al., 2004) and dofetilide (Ficker et al., 2001). However, none of these compounds is specific for $K_V10.1$, since they also block K_V11 channels. Additionally, $K_V10.1$ is relatively insensitive to the commonly used potassium channel blockers tetraethylammonium acetate (TEA) and 4-aminopyridine (Brüggemann et al., 1993).

K_V10 -elicited currents have a defining electrophysiological feature, making them easily distinguishable from other ion channels. This consists in a marked dependence of the activation kinetics on the potential prior to the stimulus: $K_V10.1$ activates faster the more depolarized the potential was before the stimulus (see Fig. 4). This phenomenon is reminiscent of the shift described by Cole and Moore (Cole, 1978), although orders of magnitude more pronounced. The Cole-Moore shift is augmented by extracellular magnesium and protons in a dose-dependent manner (Terlau et al., 1996). $K_V10.1$

channels function is inhibited by intracellular Ca^{2+} /calmodulin (CaM), through the Ca^{2+} /CaM binding domains on both N- and C- termini (Schönherr et al., 2000; Ziechner et al., 2006; Gonçalves and Stühmer, 2010).

Figure 4 Cole-Moore shift effect. $\text{K}_{\text{V}10.1}$ activation kinetics are strongly influenced by the pre-pulse potentials. Pre-pulse conditioning time interval is highlighted with a red dotted line. The black line is associated with the depolarization time. Figure modified from (Ludwig et al., 1994).

Interestingly, another factor modulating $\text{K}_{\text{V}10.1}$ channels current is the phase of the cell cycle: macroscopic current derived from injection of rat $\text{K}_{\text{V}10.1}$ channels into *Xenopus laevis* oocytes was regulated during cell cycle, since maturation in oocytes triggered by mitosis-promoting factor altered the current properties. Current amplitude was reduced, and this effect was accompanied by a strong inward rectification (Brüggemann et al., 1997). Currents compatible with $\text{K}_{\text{V}10.1}$ profile have been detected in several cancer cell lines. In this context, $\text{K}_{\text{V}10.1}$ current is also dependent on the cell cycle, as human neuroblastoma cells synchronized in G0/G1 phase show reduced amount of Eag1 current (Meyer and Heinemann, 1998). Using a heterologous expression system, Camacho and co-workers report that $\text{K}_{\text{V}10.1}$ current amplitude is consistently down-regulated at the M-phase of the cell cycle. The observed electrophysiological changes could be due to reorganization of the cytoskeleton occurring during the G2/M transition (Camacho et al., 2000).

1.4.2 K_v10.1 and cancer

The discovery of a relation between cell cycle and K_v10.1 function made this potassium channel attractive for cancer research. Soon it was shown that K_v10.1 channels possess oncogenic properties. Cell lines transfected with K_v10.1 acquire features typical of cancerous cells, showing faster growth rate, losing cell contact inhibition, being able to keep growing in very low serum concentrations and inducing formation of aggressive tumors when injected into immune-depressed mice (Pardo et al., 1999). Expression of currents compatible with K_v10.1 was initially described in neuroblastoma (Meyer and Heinemann, 1998), and breast cancer cell lines (Ouadid-Ahidouch et al., 2001). Subsequently, a larger screening of K_v10.1 expression levels (in terms of mRNA transcript and protein) was performed. Here it was confirmed that K_v10.1 was not (or only scantily) expressed in healthy non-neural tissue while it was aberrantly expressed in numerous cancer cell lines, and in over 70% of the tested human cancer tissues from diverse origin (Hemmerlein et al., 2006; Mello de Queiroz et al., 2006). Based on their restricted expression pattern in normal tissue, combined with their high expression in cancer, K_v10.1 channels have been proposed as potential candidate as early cancer biomarker (Farias et al., 2004; Pardo and Stühmer, 2008; Rodríguez-Rasgado et al., 2012).

K_v10.1 pharmacological blockade with astemizole and imipramine decreases tumor cell proliferation *in vitro* (Ouadid-Ahidouch et al., 2001; Gavrilova-Ruch et al., 2002) and, in the case of astemizole, also *in vivo*: in mouse models, oral doses of astemizole (far below the toxicity range of the compound) reduce the progression of subcutaneous tumors (melanoma, pancreas and mammary carcinomas) and the frequency of metastasis in lung carcinoma models, with a potency comparable to the maximal tolerable dose of cyclophosphamide, an established chemotherapeutic compound (Downie et al., 2008). Additional strategies, more specific than the available pharmacological tools, for the inhibition of the expression and/or function of K_v10.1 have also been successfully developed. Interfering-RNA against K_v10.1 transcript leads to a reduction in proliferation in cell lines expressing this channel (Weber et al., 2006). Moreover, a monoclonal antibody specifically targeting the pore region of the channel and blocking its function, inhibits tumor cell growth both *in vitro* and *in vivo* (Gómez-

Varela et al., 2007). Another promising approach aiming treatment of K_V10.1-positive tumors combines the specificity of a single chain antibody targeting K_V10.1 with the potency of TRAIL (tumor necrosis factor-related apoptosis-inducing ligand), an apoptosis-inducing molecule. This fusion protein successfully induced apoptosis selectively to tumor cells, leaving alive the surrounding non-cancer cells (Hartung et al., 2011).

The contribution of K_V10.1 channels to tumorigenesis is not completely dependent on its function as ion channel. Engineered K_V10.1 channels bearing a mutation in the pore region that cancels ion permeation are still capable of increasing cell proliferation and tumor growth in immune-deficient mice, emphasizing a non-canonical function for these channels. Recent reports provide additional evidence for K_V10.1 non-canonical function in cancer. Conformational changes of the voltage sensor of the channel may activate of p38 MAPK kinases signaling, a critical pathway modulating cell proliferation (Hegle et al., 2006). K_V10.1 expression in mammalian cells results in increased secretion of VEGF (vascular endothelial growth factor), providing an increased vascularization to the K_V10.1-positive tumor microenvironment. Moreover, an increased HIF-1 (hypoxia-inducible factor 1) transcription factor activity, activating many genes promoting cell survival under hypoxic conditions has been detected in K_V10.1 expressing cells (Downie et al., 2008). K_V10.1 channels are also expressed at the inner nuclear membrane, where their amino- and carboxyl- terminal region exposed to the nucleoplasm could interact with heterochromatin, modulating accordingly gene expression (Chen et al., 2011).

1.5 Alternative splicing

pre-mRNA splicing represents a crucial step in mRNA maturation: introns are removed and exons are joined together, leading to a single gene product for each transcriptional unit in a process called constitutive splicing. Proteomes are however much more complex than genomes. The human genome contains 20,000–25,000 protein-coding genes, only four times those found in the yeast *Saccharomyces cerevisiae*. The genome

of *Drosophila melanogaster* contains fewer protein-coding genes (~14,000) than the apparently simpler organism *Caenorhabditis elegans* (~19,000)(International Human Genome Sequencing Consortium, 2005). A way to expand proteomic complexity without increasing the number of genes consists of generating two or more different proteins from a single gene by alternative splicing (AS) (Hui, 2009). The multiple mRNAs originated by AS from a single gene often encode structurally and functionally different proteins with specific enzymatic activity, ligand binding properties, cellular localization, protein stability and/or post-translational modifications. AS is a very common biological event, with up to 95% human multiexon genes exhibiting it (Barash et al., 2010).

The splicing reaction is catalyzed by a set of multicomponent ribonucleoprotein complexes that form the spliceosome, which recognizes the intron-exon boundaries along the pre-mRNA and catalyzes the reactions that removes introns and joins exons. Exon recognition by the spliceosome machinery is achieved through the identification of conserved intronic dinucleotides: GU at the 5' (donor) and AG at the 3' (acceptor) ends. Constitutive splicing occurs at strong splice sites, which are always recognized by the spliceosome. The exact sequence around the splicing site determines the affinities of cognate splicing factors, eventually affecting their recognition by the splicing machinery (Kornblihtt et al., 2013). Weaker sites, where the pre-mRNA sequence diverges from the consensus can promote the occurrence of alternative splicing.

The use of weak sites is regulated by RNA binding, *trans*-acting proteins (repressors and activators) and *cis*-acting regulatory sites (silencers and enhancers) on the pre-mRNA. Exonic and intronic splicing enhancers (ESEs/ISEs) promote exon recognition, while exonic and intronic splicing silencers (ESSs/ISSs) reduce the probability that a neighbouring site is used as a splice junction (Matlin et al., 2005). The majority of splicing repressors are heterogeneous nuclear ribonucleoproteins (hnRNPs) and polypyrimidine tract binding protein (PTB). Most of the activator proteins that bind to ESEs are members of the SR protein family. Such proteins contain RNA recognition motifs and arginine and serine-rich (SR) domains. Although commonly considered as repressors, individual hnRNPs can also promote the usage of alternative splice sites, mainly through ISEs (Matlin et al., 2005). Moreover, additional RNA binding proteins can function as splicing regulators by binding ISSs or ISEs (Lewin et al., 2011). The

coordinated expression and/or activity of splicing *trans*-acting proteins determines the composition of the pool of protein isoforms in a given cell type, developmental stage etc. Adding further complexity to this system, the effects of regulatory factors are sometimes position-dependent. For example, a splicing factor can be an activator when bound to an intronic enhancer element, and a repressor when bound to an exon (Lim et al., 2011). Alternative exon usage is also modulated by secondary structure of the pre-mRNA (Warf and Berglund, 2010), transcriptional rates of RNA polymerase II, chromatin structure and modifications (Kornblihtt et al., 2013).

The relative positions of weak and strong sites may give rise to different modes of alternative splicing, as summarized in Fig. 5. One or more exons can be either included or excluded from the final transcript (exon skipping); an alternative 3' and 5' splice sites can favor the lengthening or shortening of a particular exon; a portion of an intron can be included in the final transcript (intron retention). Exon skipping is the most common mechanism of AS, accounting for ~40% of the entire alternative splicing events (Keren et al., 2010).

Figure 5 Mechanisms of alternative splicing. Schematic representation of different strategies of AS. Grey boxes represent exons; the black lines joining them are introns. The blue lines indicate the splicing sites. Figure from Liu and Cheng, 2013.

1.5.1 Impact of pre-mRNA splicing in disease

Due to the complexity of the alternative splicing mechanism, mutation may occur at different levels along the splicing reaction and modify the splicing pattern. Mutations involving *cis*-acting regulatory sites along the pre-mRNA sequence can disrupt the normal splicing patterns or activate alternative splice patterns in an inappropriate tissue or developmental stage, as is the case of familial isolated growth hormone deficiency type II, where an increased alternative splicing of the growth hormone gene results in short stature (Binder et al., 1996). Mutations in components of the spliceosome or in their auxiliary factors cause retinitis pigmentosa (loss of rod photoreceptors)(Faustino and Cooper, 2003), or spinal muscular atrophy (loss of spinal cord motorneurons resulting in skeletal muscle denervation) (Kolb et al., 2007). Changes in alternative splicing patterns are also associated with neoplasia and metastasis (Philips and Cooper, 2000), as is the case of CD44 in pancreatic ductal carcinoma (Günthert et al., 1991), NF1 in neurofibromatosis (Ars et al., 2000), BRCA1 and BRCA2 in ovary and breast cancer (Claes et al., 2003), or the oncogene MDM2 (Bartel et al., 2002).

Manipulation of alternative splicing may open new therapeutic avenues. Isoform-specific antisense oligonucleotides and interference RNAs have been developed and tested for the treatment of several diseases, ranging from certain types of thalassemia and dystrophies, to cystic fibrosis, cancer, and pain (Forte et al., 2005; Sazani and Kole, 2003). Bifunctional oligonucleotides that bind specific regions of pre-mRNAs and then modify splicing mechanism via an antisense-targeting domain can enhance the inclusion of exon 7 in the SMN2 transcript and reduce the severity of spinal muscular atrophy (Owen et al., 2011). Additional approaches use compounds that affect phosphorylation of splicing factors (Pilch et al., 2001), stabilize putative pre-mRNA secondary structures (Varani et al., 2000), or directly interact with spliceosome components. Two natural compounds interfering with the spliceosome (Spliceostatin A and Pladienolide) display antitumor activity *in vitro* and *in vivo* (Kaida et al., 2007; Kotake et al., 2007).

1.5.2 Impact of AS on ion channels physiology and pathophysiology

Alternative splicing modulates features of several ion channels, affecting their physiology and pathophysiology. AS modulation may result in changes in electrophysiological properties, surface expression, intracellular localization and pharmacological profile of ion channels. For example, $Ca_v1.2$ have a cardiac-specific splice isoform showing less sensitivity to diltiazem, a potent vasodilator (Zhang et al., 2010). It is also known that alternative splicing in this particular channel is regulated by the PTB protein (a *trans*-acting splicing regulator protein), mediating a switch between two mutually exclusive exons. Mutations in either of these two exons underly the Timothy syndrome (a systemic disorder, resulting in a severe pleiotropic disease phenotype) (Tang et al., 2011). Alternative splicing in the C-terminus of $Ca_v1.3$ modulates its electrophysiological properties, and $Ca_v1.4$ channels express 19 splice isoforms, some of them with characteristic electrophysiological behavior (Tan et al., 2011).

A naturally occurring variant of $Na_v1.1$ recovers more rapidly from inactivation. This is thought to modify the seizure likelihood and response to anti-epileptic drugs (Fletcher, et al., 2011). The cardiac $Na_v1.5$ channels have at least nine splice variants, which can have either unchanged electrophysiological properties, altered kinetics or produce non-functional channels. The distribution of the variants involves species-dependent, tissue-specific, and developmental factors (Schroeter et al., 2010).

$K_{Ca}1.1$ channels represent a typical example of extensive AS in potassium channels. These are encoded by a large gene consisting of 35 exons; here AS leads to the production of channels with distinct properties, including differences in calcium/voltage sensitivity (Chen et al., 2005), subcellular targeting (Zarei et al., 2004) and regulation by cellular signaling pathways (Erxleben et al., 2002; McCartney et al., 2005; Tian et al., 2001). Remarkably, one of the short isoforms is not functionally expressed at the cell surface and acts as a dominant negative of cell surface expression by trapping other $K_{Ca}1.1$ channel α -subunits in the endoplasmic reticulum and perinuclear compartments (Chen et al., 2005). Similarly, in a breast cancer cell line a functionally inactive variant of $K_{ir}3.1$ exerts a dominant negative effect on the full-length channel (Wagner, Stadelmayer et al., 2010). The same applies in a physiological context for $K_{2P}2.1$

channels in the brain (Veale et al., 2010) or to $K_{Ca3.1}$ in human lymphoid tissues (Ohya et al., 2011). Two spliced isoforms of $K_V11.1$ expressed almost exclusively in tumors form heterotetramers with the full length channels, down-regulating the current and blocking cell differentiation and inducing escape from apoptotic death (Guasti, Crociani et al., 2008).

1.5.3 $K_V10.1$ splice isoforms

The human $K_V10.1$ channel gene has eleven exons: the long N-terminal cytoplasmic region is encoded by exons one to five; exons six and seven encode the transmembrane domains, and exons eight to eleven generate the long C-terminal cytoplasmic region of the channel. As mentioned previously, a second $K_V10.1$ splice variant ($K_V10.1b$) was cloned in 1994, where exon 6 is spliced 81 base pairs downstream the site for the short variant (via alternative 5' splicing site), forming exon 6b. $K_V10.1a$ and $K_V10.1b$ show the same expression pattern and similar electrophysiological features.

Sun and colleagues (2009) reported the expression of a *Drosophila* $K_V10.1$ splice variant, in COS cells transfected with a full length D- $K_V10.1$ cDNA. Such protein (that they called Eag80) contains both N- and C-terminal sequences of the full-length channel but lacks all channel-forming transmembrane domains. Eag80 production is stimulated by either PKA or PKC, and by calcium influx. Eag80 can activate a MAPK kinase signaling pathway affecting the cell morphology (Sun et al., 2009).

More recently two short isoforms derived from exon skipping events have been described in the human $K_V10.1$ channel. They were named E65 and E70 after the predicted molecular weight of 65 and 70 kDa, respectively. E65 lacks exons from 4 to 9, while E70 is missing exon 4 to 7 (see Fig. 6). Both E65 and E70 mRNA are devoid of transmembrane domains. Therefore, they do not form a functional ion channel. E65 was cloned from tumor cell lines (Ramos Gomes PhD thesis) and E70 from human brain (Pardo LA, unpublished data).

Figure 6 Exon organization of the full-length channel transcripts $K_v10.1a$, $K_v10.1b$, and of the truncated isoforms **E65** and **E70**. Boxes represent exon sequences, the black line connecting them are intron sequences. More in details, orange boxes represent exons coding N-terminal region of the channel protein; brown exons encode the transmembrane domain, blue exons the C-terminal region. The green and red lines depicted on the $K_v10.1b$ sequence represent the splicing sites determining E65 and E70 expression.

Finally, it has been found that E65 modifies the electrophysiological properties of the full-length channel when both are co-expressed in *Xenopus laevis* oocytes. The modified current resembles the one recorded from mature oocytes. This is due to a direct activation of the maturation of the oocyte by E65, suggesting a role in cell cycle regulation for this splicing isoform (Ramos Gomes Ph.D. thesis, 2010).

2. Aims of the work

2.1 General Aim

To study the impact of alternative splicing on K_V10.1 biological properties

2.2 Specific Aims

To confirm the expression of K_V10.1 short isoforms in native system

To check for interaction between K_V10.1 and its short isoforms

To investigate the impact of E65 and E70 expression on the electrophysiological properties of K_V10.1

To study the mechanisms by which E65 and E70 modulate K_V10.1 electrophysiological properties

3. Materials and Methods

3.1 Cell cultures

3.1.1 Mammalian cell lines and media composition

Cell lines DU 145 (ACC 261), HEK 293 (ACC 305), HeLa (ACC 57), IPC 298 (ACC 251), IGR 39 (ACC 239), IMR 32 (ACC 165), and SH-SY5Y (ACC 209) were purchased from DSMZ (Braunschweig, Germany). MDA-MB 435S (HTB 129) were from ATCC (Manassas, VA, USA), PNT 2 (ECACC95012613) were obtained from ECACC (Salisbury, UK). GL15 cells were kindly provided by Dr. Fioretti (University of Perugia, Italy). Each cell line was propagated and maintained according to the provider's instructions: HEK 293 cells were maintained in Dulbecco's MEM/F12 1:1 (Gibco) supplemented with 10% FCS (PAA); DU 145, PNT 2 and GL 15 in Dulbecco's MEM (Gibco) with 10% FCS; HeLa, IPC 298, MDA-MB 435S and SH-SY5Y in RPMI 1640 (Gibco) with 10% FCS. IMR 32 cells were cultured in RPMI 1640 complemented with non-essential amino acids (Gibco) and 20% FCS; IGR 39 in Dulbecco's MEM with 15% FCS. The culture medium of the stably transfected HEK-pTRACER-K_v10.1 cells was complemented with the antibiotic Zeocin (Invivogen) at a concentration of 3 µg/ml.

3.1.2 Cell cultures: routine handling

Cells were routinely grown in T25 or T75 flask (Sarstedt) and incubated in a Heracell 240 CO₂ incubator (Thermo Scientific) at 37 °C and 5% CO₂. As cells reached ~90% confluence, the culture medium was removed, and cells were firstly washed once with 10 ml Phosphate Buffered Saline (PBS, Gibco), then 2 ml Trypsin/EDTA solution (0.05%/0.2% (w/v) in PBS without Ca²⁺/Mg²⁺, Biochrom) were added. Cells were then maintained for 4 min in the incubator, subsequently resuspended in 5 ml culture medium and placed in a sterile centrifuge tube (Greiner Bio One) and finally centrifuged 2 min at 1,200 x g at room temperature (RT). The supernatant was carefully

removed and cell pellets were thoroughly resuspended in a suitable amount of fresh culture medium (usually 3-5 ml), according to the desired dilution, and seeded in new vessels. When needed, cells were counted using a Neubauer chamber: 10 μ l of cells resuspension were added to 30 μ l Trypan Blue solution (0.4% in PBS, Sigma). Unstained (viable) cells in each of four large squares of the chamber were counted. The total number of live cells for each ml medium is represented by the number of counted cells multiplied by 1×10^4 . When needed, cells were frozen according to the following procedure: the pellet derived from $\sim 1 \times 10^6$ trypsinized cells was resuspended in 500 μ l culture medium and added to a cryovial (Greiner Bio One) containing 500 μ l of freezing medium (50% DMEM/F12; 25% FCS; 25% DMSO (Sigma)), which was immediately placed in a freezing container (Nalgene) and stored for 24 hours at -80 °C. Cells were then stored indefinitely in liquid nitrogen. To start a culture from frozen cells, cryovials were incubated 5 min at 37 °C; their content was added to a centrifuge tube containing 10 ml of pre-warmed growth medium and centrifuged at $1,000 \times g$ for 3 min. The obtained cell pellet was resuspended and placed in a new vessel. The medium was replaced after 24 hours in order to eliminate any eventual DMSO residue.

3.1.3 Transfections

For all the experiments of this work two transfection modalities were employed: liposome-based (Lipofectamine 2000, Invitrogen) and electroporation technology (Nucleofector, Lonza). 80-90% confluent cells cultivated in T25 flasks were generally used for Lipofectamine transfections. Briefly, tube A (containing 12.5 μ l Lipofectamine in 250 μ l Opti-MEM (Gibco)) and tube B (containing 5 μ g DNA in 250 μ l Opti-MEM) were incubated 5 min at RT. Afterwards the content of A was added to tube B, followed by another 20 min RT incubation. In the meanwhile cells were washed in PBS and the growth medium was replaced with 3.5 ml Opti-MEM medium. To the cells were finally added 520 μ l of the mixture Lipofectamine-DNA (proportion 2.5:1) in Opti-MEM and they were incubated for 5 hours. After this time the flask content was replaced with 4 ml of growth medium. Regarding electroporation-based transfections, cells at 80-90% confluence and grown on T25 or T75 flasks were trypsinized, washed once in PBS, counted and centrifuged. For each transfection 100 μ l nucleofection solution (solution

V, proprietary composition) and 4 µg plasmidic DNA were added to 1-2 x10⁶ cells, and a current pulse (program A-23 for HEK cells, G-04 for SH-SY5Y cells) was applied to the mixture cells-DNA. Cells were finally plated at a suitable density in the chosen vessel. Transfection efficiency ranged between 30% and 90% depending on the cell type, transfection method, and sequence of plasmidic DNA. Transfected cells were used for further experiments 24-72 hours after transfections.

3.1.4 *Xenopus laevis* oocyte preparations

Oocytes were obtained by survival surgical laparotomy from anesthetized (tricaine 0.2%) *Xenopus laevis* frogs (purchased from Nasco). They were defolliculated under collagenase digestion: oocytes were incubated for two hours with shaking motion at 18 °C in a solution containing 1.4 mg/ml collagenase (SERVA) diluted in calcium-free Barth's medium (88 mM NaCl; 1 mM KCl; 2.4 mM NaHCO₃; 0.82 mM MgSO₄; 7.5 mM Tris-HCl, pH 7.5). The oocytes were rinsed several times with calcium-free Barth's medium, then washed with Barth's medium including calcium (Barth-medium calcium-free complemented with 0.33 mM Ca(NO₃)₂, 0.41 mM CaCl₂ and 0.1 mM gentamicin (Roth)). Oocytes were finally kept in ND96 medium (96mM NaCl; 2 mM KCl; 0.2 mM CaCl₂; 2 mM MgCl₂; 5 mM HEPES; 0.5 mM teophylline (Sigma), 0.1 mM gentamicin, pH 7.5) and incubated at 18 °C (Memmert incubator). Stage VI oocytes were sorted and used for downstream applications within 24 hours after the preparation. 50 nl cRNA solutions (corresponding to 0.025 – 1 ng cRNA) were injected into each oocyte using a Nanoject and 3.5 inches long glass pipettes (both from Drummond); after this process, only oocytes with homogenous pigmentation and normal turgor were collected. All the experiments were performed between 24 and 72 hours after injections.

3.2 Molecular biology

3.2.1 Total RNA isolation.

Cells in culture were trypsinized and counted as previously described. Aliquots of $\leq 5 \times 10^6$ cells were centrifuged at $1,200 \times g$ for 2 min RT; supernatant was removed and the pellets were washed with 5 ml PBS and centrifuged again at $1,200 \times g$ for 2 min RT. Pellets derived from this process were immediately placed on ice and stored at -80°C or directly processed to extract total RNA. In the latter case cells were lysed with 350 μl RLT buffer (Qiagen) complemented with 143 mM of β -mercaptoethanol (Sigma). The lysates were passed several times through a 25-gauge needle. To homogenize and eliminate insoluble debris from the lysates, these were placed in QIAshredder spin columns (Qiagen) and centrifuged 2 min at top speed ($16,100 \times g$; all the centrifugations of this protocol were performed in a benchtop microcentrifuge at RT). Homogenized lysates were mixed with 1 volume of 70% ethanol in DEPC-treated water, loaded onto RNeasy Mini spin columns (Qiagen) and centrifuged 30s at $11,000 \times g$. The flow-through was discarded and the RNA binding the silica-gel membrane of the column was washed with 350 μl of RW1 buffer and centrifuged 30s at $11,000 \times g$. RNA samples were then treated with RNase free DNase (Qiagen) in order to eliminate genomic DNA. For each sample a solution containing 20 μl (54 Kunitz units) of DNase and 140 μl RDD buffer (supplied with the RNase-Free DNase Set) was prepared. 160 μl of this solution were pipetted into the columns and incubated 30 min RT. Then 350 μl of RW1 were added and, after further 5 min incubation, the samples were centrifuged 30s at $11,000 \times g$. Then, 500 μl RPE buffer were added to the columns and centrifuged 30s at $11,000 \times g$; a second wash with 500 μl RPE buffer was followed by 6 min centrifugation at top speed in order to dry the columns. These were incubated with 30 μl DEPC-treated water for 6 min at RT and finally centrifuged again 6 min at top speed in order to elute RNA. The RNA amount and quality were assessed by spectrophotometric measurements (Nanophotometer, Implen): only RNA samples having A_{260}/A_{280} and $A_{260}/A_{230} \geq 1.9$ were used for downstream applications.

3.2.2 mRNA isolation

For isolation of mRNA, the Micro-FastTrack 2.0 Kit (Invitrogen) was used. Up to 500 µg of total RNA per sample were precipitated adding 1/10 vol sodium acetate 5 M and 2.5 vol ice-cold Ethanol 100%. The samples were stored 60 min at -20 °C, then centrifuged 15 min at 4 °C top speed (16,100 × g). RNA pellets were washed once with 70% ethanol, and resuspended in 10 µl Elution Buffer (10 mM Tris-HCl, pH 7.5 in DEPC-treated water). The solution was added to 1 ml Binding Buffer (500 mM NaCl, 10 mM Tris-HCl, pH 7.5 in DEPC-treated water), heated up to 65 °C for 5 min and placed immediately on ice for 1 min. The solution containing RNA was pipetted onto a vial of oligo(dT) cellulose. The tube was tightly sealed, allowing the oligo(dT) cellulose to swell for 2 min. After that, it was incubated under rocking at room temperature for 20 min. The oligo(dT) cellulose was then centrifuged at 4,000 × g in a microcentrifuge for 5 min at RT. The supernatant was carefully removed from the resin bed. The oligo(dT) cellulose was resuspended in 1.3 ml Binding Buffer (500 mM NaCl, 10 mM Tris-HCl, pH 7.5 in DEPC-H₂O) and centrifuged again at 4,000 × g for 5 min at RT. This washing step was repeated four more times, until the buffer appeared no longer cloudy. The resin was subsequently resuspended in 300 µl Binding Buffer, transferred to a spin column and centrifuged at 4,000 × g for 30s at RT. The latter resuspension/centrifugation step was repeated four more times. The resin was finally resuspended in 200 µl Low Salt Wash Buffer (250 mM NaCl, 10 mM Tris-HCl, pH 7.5 in DEPC-treated water) and centrifuged at 4,000 × g for 30s at RT. This last step was repeated once. The spin column was then placed into a new RNase-free microcentrifuge tube and 100 µl Elution Buffer (10 mM Tris-HCl, pH 7.5 in DEPC-treated water) was mixed into the cellulose bed and centrifuged at 4,000 × g for 30s at RT. A second aliquot of 100 µl Elution Buffer was added to the column, mixed into the cellulose, and centrifuged again 30s at RT. In order to collect any remaining eluate, a centrifugation at 4,000 × g for 1 min at RT was performed. The eluted mRNA was precipitated with 10 µl of 2 mg/ml glycogen carrier, 30 µl of 2 M sodium acetate, and 600 µl of 100% ethanol. The samples were placed on dry ice for 20 min, then centrifuged at maximum speed for 15 min at 4 °C. The supernatant was carefully removed and discarded. The pellet was washed with 70% ethanol. The ethanol was removed, and the pellet was air-dried for 5–10 min. the mRNA pellet was finally resuspended in 10 µl Elution Buffer (10 mM Tris-HCl, pH 7.5

in DEPC-treated water). mRNA amount and purity were assessed by means of spectrophotometric measurements.

3.2.3 Capped RNA (cRNA) synthesis

This was obtained performing *in vitro* transcription using the T7 mMessage mMachine Kit (Ambion). pSGEM vector containing the gene of interest was linearized with SfiI (as described in 3.2.6.1). The digestion was terminated by adding 1/20 vol 0.5 M EDTA, 1/10 vol 3 M sodium acetate and 2 vol of 100% ethanol. The samples were mixed thoroughly and chilled at $-20\text{ }^{\circ}\text{C}$ for one hour. DNA was then precipitated at $16,100 \times g$ for 15 min at $4\text{ }^{\circ}\text{C}$. The supernatant was removed, the tubes were re-centrifuged for a few seconds, and the residual supernatant was disposed. Pellets were air-dried for 7 min and resuspended in a volume of TE buffer adequate to obtain a final DNA concentration of $0.5\text{--}1\text{ }\mu\text{g}/\mu\text{l}$. The reaction of *in vitro* transcription was assembled at RT, adding the following components in a sterile microcentrifuge tube: DEPC-water (to $20\text{ }\mu\text{l}$ final volume), $10\text{ }\mu\text{l}$ 2X NTP/CAP, $2\text{ }\mu\text{l}$ 10X Reaction Buffer, $1\text{ }\mu\text{g}$ linear template DNA, $2\text{ }\mu\text{l}$ T7 Enzyme Mix. The samples were incubated for 2 hours at $37\text{ }^{\circ}\text{C}$. cRNA was then recovered by lithium chloride precipitation: $30\text{ }\mu\text{l}$ DEPC- H_2O and $30\text{ }\mu\text{l}$ LiCl Precipitation Solution (7.5 M lithium chloride, 50 mM EDTA) were added to the samples, mixed thoroughly and chilled for one hour at $-20\text{ }^{\circ}\text{C}$. The tubes were microcentrifuged at $16,100 \times g$ for 20 min at $4\text{ }^{\circ}\text{C}$ to pellet the RNA and the supernatant was carefully removed. RNA pellets were washed with $\sim 500\text{ }\mu\text{l}$ 70% ethanol, RNA pellet were air-dried for 7 min before being resuspended in $\sim 30\text{ }\mu\text{l}$ DEPC- H_2O . After determined the RNA concentration and purity, the samples were frozen at $-80\text{ }^{\circ}\text{C}$.

3.2.4 cDNA synthesis

SuperScript First-Strand Synthesis system (Invitrogen) was used for cDNA production. $5\text{ }\mu\text{g}$ total RNA were added to $0.5\text{ }\mu\text{g}$ OligodT_{12-18mer} and DEPC-water, till $12\text{ }\mu\text{l}$ total volume. The mixture was incubated 10 min at $70\text{ }^{\circ}\text{C}$, then placed for 1 min on ice. After that, $7\text{ }\mu\text{l}$ of reaction buffer composed by RT Buffer (57 mM Tris-HCl, 143 mM KCl,

pH 8.4), 7 mM MgCl₂, 29 mM DTT (DL-Dithiothreitol; Clelands reagent), 1.4 mM dNTP mix were added to the tubes, which were incubated 5 min at 42 °C. Afterwards, 200 U SuperScript II reverse transcriptase was added to each sample, and 1 µl of DEPC-treated water was used in the –RT control samples. All the samples were then incubated 50 min at 42 °C, followed by 15 min at 70 °C. 2 U RNase H were also used for each tube, which were incubated for 20 min at 37 °C. 29 µl of DEPC-water were added, in order to obtain 50 µl cDNA having concentration of 0.1 µg/µl.

3.2.5 Polymerase Chain Reaction (PCR)

PCR reactions were performed using 10 ng template plasmidic DNA (or 100 ng first strand cDNA), 2.5 µl 10X reaction buffer (containing 20 mM Tris-HCl, 10 mM (NH₄)₂SO₄, 10 mM KCl, 2 mM MgSO₄, 0.1% Triton X-100, pH 8.8; from New England Biolabs), 200 µM dNTP mix (New England Biolabs), 0.2 µM of each specific primers (synthesized by Sigma), 1.2 U of Taq DNA polymerase (New England Biolabs) and sterile H₂O, up to 25 µl final volume. The thermocycler (Mastercycler, Eppendorf) was set up using the following amplification program: 20 cycles of amplification including, after an initial denaturation step of 3 min at 95 °C, 95 °C for 30s, 59 °C (or different temperature, depending on the T_m of the primers) for 30s, 72 °C for 3 min. Nested PCR reactions were performed using 150 ng first strand cDNA, 2.5 µl 10X reaction buffer (containing 20 mM Tris-HCl, 10 mM (NH₄)₂SO₄, 10 mM KCl, 2 mM MgSO₄, 0.1% Triton X-100, pH 8.8), 200 µM dNTP mix, 0.2 µM of each specific primers, 1.2 U of Taq DNA polymerase and sterile H₂O, up to 25 µl final volume. The thermocycler settings were as follows: 20 cycles of amplification including, after an initial denaturation step of 3 min at 95 °C, 95 °C for 30s, 59 °C for 2 min and 30s, 72 °C for 3 min. After this, 1 µl of the product of this reaction was used as template for the second round PCR. The reaction consisted now of 35 cycles: after an initial denaturation step of 3 min at 95 °C, 95 °C for 30s, 59 °C for 2 min and 30s, 72 °C for 2 min). The amplification products were loaded on a 1.2% agarose gel containing 5 µl (for each 100 ml gel volume) Serva DNA stain G (SERVA). Electrophoresis was performed at 100 V for ~40 min; the electrophoretic mobility was visualized with UV light, and the relevant DNA amplicons were purified, cloned and sequenced.

Primer name	Sequence (5'-3')
E70 Forward	ATT GAA AAA GTG CGG CAA AC
E70 Reverse	GGC ACC TGG TAG AGC TTC AG
K_v10.1 External Forward	TGT TCG GCG GTC CAA TGA TAC TAA
K_v10.1 External Reverse	TCC CGG CCC CCT CTC TCA
K_v10.1 Internal Forward	TTG GGG AAT GCT CAG ATA GTG G
K_v10.1 Internal Reverse	GGC CTC ATT CTT TCG TTT CAT

Table 1 List of the primers used for PCR and nested PCR amplification.

Real-time PCR experiments were also performed. For this purpose a LightCycler 480 (Roche) thermocycler and the TaqMan probes system were used. Each PCR reaction consisted of 200 ng first strand cDNA sample, 5 µl hot-start-PCR-mix (containing FastStart Taq DNA polymerase, reaction buffer, MgCl₂ and dNTP mix, from Roche), 0.5 U Uracil-DNA-glycosylase (New England Biolabs), 1 µl primer mix (containing 900 nM forward and reverse primers, plus 250 nM TaqMan probe) and DEPC-water, up to 10 µl final volume. The oligonucleotides used are listed in table 2. PCR amplification protocol was set as follows: initial denaturation steps (2 min at 50 °C and 10 min at 95 °C) were followed by 50 cycles made by 10s at 95 °C; 15s at 56 °C; 1 min at 60 °C. The program ended at 40 °C for 30s. The resulting amplification data for each target gene were standardized to the amount of the housekeeping gene, the human transferrin receptor type 1.

Name	Taqman probe (5'-3')	Primer Forward (5'-3')	Primer Reverse (5'-3')
hEag1	(6-Fam-) AACGTGGTTGAGGGCAT CAGCAGCCT(-6-Tamra)	TCTGTCCTGTTTGCCAT ATGATGT	CGGAGCAGCCGGACAA

Table 2 List of the TaqMan probes and primers used for real-time PCR. The human transferrin receptor was used to control for RNA integrity.

3.2.6 Cloning

DNA derived from nested PCR experiment possess A-overhanging ends which, after purification, can be easily cloned into pGEM-T vector (Promega), having T-overhanging ends and provided in linearized state by the manufacturer. In the other cases the cloning procedure implies digestion using one or more restriction enzymes (NEB) and purification of the products before performing the ligation.

3.2.6.1 Restriction enzyme digestion

All the digestions were performed using restriction enzymes and reaction buffers provided by New England Biolabs. 8 µg DNA from vector and insert plasmids were digested with 1-2 µl restriction enzyme(s), together with the appropriate buffer. The following component were added to a sterile tube placed on ice: 8 µg DNA template to digest, 1-2 µl enzyme(s), 3 µl buffer; dH₂O up to a final volume of 30 µl. Time and temperature of incubation were depending on the type of enzymes used.

3.2.6.2 Dephosphorylation

It was necessary to perform dephosphorylation in order to avoid recircularization of the plasmid if the enzymes would generate compatible ends after digestion. For this, the tubes were heated to 65 °C for 20 min in order to inactivate the enzymes after the digestion; subsequently 3.45 µl of 10X Antarctic Phosphatase Buffer and 1 µl Antarctic phosphatase enzyme (New England Biolabs) were added. Finally the tubes were incubated 20 min at 37 °C (60 min if the restriction enzyme leaved 3' extensions) and heat-inactivated 5 min at 70 °C. All the digestion products were run on a 0.8% agarose gel containing Serva DNA stain G for ~40 min at 100 V, excised using a clean scalpel under UV light, and collected in a sterile tube for the purification.

3.2.6.3 DNA purification

The fragment of agarose gel containing the amplified DNA of interest or the digested DNA was weighted, and either stored at +4 °C or processed immediately for DNA purification. For this purpose, the NucleoSpin Extract II kit (Macherey Nagel) was employed. To start, 200 µl of NTI binding buffer provided with the kit was added for each 100 mg gel containing the DNA. The mixture was incubated 10 min at 50 °C and vortexed at intervals of two minutes in order to facilitate the agarose melting. The content of the tube was pipetted into a NucleoSpin column and centrifuged 30s at 11,000 x g (all the centrifugations of this protocol were performed at RT). Subsequently, 700 µl of buffer NT3 were added to the column and centrifuged again; this washing/centrifugation step was repeated one more time before performing a final centrifugation 3 min at 16,100 x g in order to dry the silica membrane. The NucleoSpin column was then placed in a sterile microcentrifuge tube. Depending on the expected amount of DNA recovered, 20-30 µl NE buffer (5 mM Tris-HCl, pH 8.5) were added to the silica membrane; the columns were incubated for 3 min and afterwards centrifuged 3 min at 16,100 x g to elute DNA. The quality and amount of the purified DNA were estimated loading 1 µl of the eluted in a 1% agarose gel and performing densitometry analysis: after electrophoretic run performed for ~40 min at 100 V, gel was exposed under UV illumination and, using the software Quantity One (Bio-Rad), the amount of

signal derived from the purified DNA was compared to the one from DNA band at 3 kb (containing 125 ng DNA) of the 1 kb ladder (New England Biolabs).

3.2.6.4 Ligation

A mass ratio 1/3 between vector DNA and insert DNA was generally used for ligation. The enzyme used was T4 ligase (New England Biolabs). As an example, in a sterile microcentrifuge tube were added 1 µl of 10X T4 DNA Ligase buffer (50 mM Tris-HCl, 10 mM MgCl₂, 10 mM Dithiothreitol, 1 mM ATP, pH 7.5), 0.05 pmol pGEM-T vector DNA having 3 kb length, 0.15 pmol of a purified DNA fragment 1 kb long and autoclaved water, reaching 10 µl final volume. The reaction was carried out incubating samples at 16 °C overnight.

3.2.6.5 Transformation

Competent DH5α *E. coli* (Life technology) were thawed on ice and 5 µl DNA from ligation samples was added to them. Cells were incubated on ice for 30 min, heat-shocked for exactly 45s at 42 °C, then placed back on ice for additional 2 min. After this, 200 µl LB medium (Luria Bertani broth: 1% Peptone 140; 0.5% Yeast extract; 1% NaCl; from Invitrogen) were added to the tubes, which were subsequently incubated at 300 rpm at 37 °C for one hour. The transformed bacteria were spread on pre-warmed LB-agar plates containing ampicillin (100 µg/ml) or kanamycin (50 µg/ml) and eventually containing X-Gal 20 mg/ml and IPTG 100 mM for the blue/white selection of the colonies. The plates were incubated overnight at 37 °C.

3.2.7 Small scale plasmid DNA preparation (Mini-prep)

NucleoSpin Plasmid QuickPure kit (Macherey Nagel) was used in order to isolate small scale plasmid DNA from transformed competent bacteria. A single transformed colony was added to a tube containing 5 ml LB medium complemented with ampicillin (100 µg/ml) or kanamycin (50 µg/ml) and incubated overnight in an orbital shaker at 200 rpm 37 °C. The tube was then centrifuged at 5,000 x g for 10 min at 4 °C. The supernatant was discarded and the pellet was resuspended in 250 µl resuspension buffer provided

with the kit (A1) and transferred to a microcentrifuge tube. Subsequently 250 µl buffer lysis buffer (A2) were added and the content of the tube was gently mixed by inverting it 8 times. After 5 min incubation RT, 300 µl neutralization buffer (A3) were further added, the tube was inverted again 8 times and then centrifuged at 11,000 x *g* for 5 min at RT. The supernatant was placed in a NucleoSpin Plasmid QuickPure column previously mounted on a collection tube and centrifuged for 1 min at 11,000 x *g* RT. The flow-through was discarded and 450 µl wash buffer (AQ) were added; a centrifuge of 3 min at 11,000 x *g* RT was performed in order to wash and dry the column, which was then placed on top of a sterile microcentrifuge tube. 30 µl elution buffer (AE, 5 mM Tris-HCl, pH 8.5) were added, and then finally the tube was incubated for 2 min at RT and centrifuged at 11,000 x *g* for 2 min at RT. Amount and purity of the eluted DNA was assessed by spectrophotometric analysis.

3.2.8 Endotoxin-free plasmid DNA preparation

Endotoxin-free plasmidic DNA for transfection of mammalian cells was obtained using NucleoBond Xtra Midi EF kit (Macherey Nagel). A single transformed colony was added to a tube containing 5 ml LB medium complemented with ampicillin (100 µg/ml) or kanamycin (50 µg/ml) and incubated 6-8 hours in an orbital shaker at 200 rpm 37 °C. This starter culture was subsequently diluted in a flask containing 100 ml LB medium complemented with the appropriate antibiotic and incubated overnight in an orbital shaker at 220 rpm 37 °C. Each culture was subdivided in 2 x 50 ml tubes, which were centrifuged at 5,000 x *g* for 10 min at 4 °C. Pellets were resuspended in 8 ml resuspension buffer (RES-EF), lysed by adding 8 ml lysis buffer (LYS-EF) and gently mixed by inverting the tubes six times. The mixture was incubated for 5 min at RT; in the meanwhile a filter was inserted into a NucleoBond Xtra column aiming to avoid to clog the column with insoluble cell debris. The columns was equilibrated using 15 ml equilibration buffer EQU-EF. After the 5 min incubation, 8 ml neutralization buffer (NEU-EF) was applied to the suspension, the tubes were gently mixed by inverting 12 times and incubated 5 min on ice before loading the whole content into the equilibrated NucleoBond Xtra Column Filter. The first wash was performed using 5 ml washing buffer (FIL-EF), the filter was then carefully removed from the column, which was now

washed first with 35 ml washing buffer (ENDO-EF) and afterwards with 15 ml washing buffer (WASH-EF). The column was allowed to empty by gravity flow and then loaded with 5 ml elution buffer (ELU-EF): the plasmidic DNA was eluted in a sterile 15 ml tube, precipitated using 3.5 ml isopropanol and centrifuged at 15,000 x g for 30 min at 4 °C. The supernatant was carefully discarded and pellet was washed with 2 ml 70% ethanol and centrifuged at 15,000 x g for 5 min at 4 °C. The ethanol was carefully removed from the tube and the DNA was dried for 10 min at RT before being reconstituted using a suitable amount of TE-EF buffer (100-300 µl, depending on the pellet size, in order to obtain a final DNA concentration of 2 µg/µl). Amount and purity of the eluted DNA were assessed by spectrophotometric analysis.

3.2.9 Site-directed mutagenesis

In order to obtain the desired point mutation (leucine was replaced with tyrosine in the TCC of K_V10.1 channels), the QuikChange II XL Site-Directed Mutagenesis Kit (Agilent technologies) was used. The plasmidic DNA to be mutated was first diluted to a concentration of 5 ng/µl. The reaction assembled in a sterile microcentrifuge tube placed on ice consisted of 10 ng plasmidic DNA, 125 ng of each primer L20Y F (5'-AGGAGGACATCAAGGCCTACAACGCCAAAATGACCAATA-3') and L20Y R (5'-TATTGGTCATTTTGGCGTTGTAGGCCTTGATGTCCTCCT-3'), 2.5 µl 10X reaction buffer, 1.5 µl QuikSolution reagent (to improve amplification efficiency), 1 µl (200 µM) dNTP mix, 15.9 µl dH₂O and finally 1.25 U *Pfu* Ultra HF DNA polymerase. The samples were thermocycled according to the following settings: initial denaturation step of 1 min at 95 °C, 18 cycles of amplification at 95 °C for 50s., 60 °C for 50s, 68 °C for 8 min 30s and a final extension step at 68 °C for 7 min. 3 µl of the amplified sample were loaded on a 0.8% agarose gel to check whether the amplification was successful. The remaining amplified DNA was incubated 60 min at 37 °C with 10 U of the restriction enzyme *DpnI* which digested the parental (methylated) dsDNA. 3 µl of the digested DNA were used to transform an aliquot of DH5α cells, as described in paragraph 3.2.6.5. In order to confirm the success of the mutagenesis, the resulting purified DNA was sequenced.

3.2.10 Probe preparation for RNase protection assays and *in vitro* transcription

The ~200 bp region spanning the area between exon 3 and exon 8 of K_v10.1 was used as E70 probe (Fig. 7). This sequence was amplified by PCR using pcDNA3-E70Venus as DNA template and the E70 specific primers listed in table 1. The amplified E70 probe DNA was then cloned into pGEM-T and linearized using the restriction enzyme *SacI* HF overnight at 37 °C. These procedures are described in paragraphs 3.2.6 and 3.2.6.1. Linearized DNA was precipitated and purified as follows: 10 µl 0.5 M EDTA, 20 µl 5M ammonium acetate and 130 µl ethanol were added to a sterile tube, mixed thoroughly, and chilled one hour at -20 °C. Samples were then centrifuged at 16,100 x *g* for 15 min at 4 °C. DNA pellet was washed in 70% ethanol, centrifuged at 16,100 x *g* for 2 min at 4 °C. Pellet was allowed to air-dry 10 min and finally resuspended with 10 µl sterile, nuclease-free H₂O.

The reaction of *in vitro* transcription was carried out using the MAXIscript kit (Ambion). In parallel with the E70 probe, in each experiment a sample containing mouse actin sequence (validated probe provided by the kit supplier) was also used, as well as RNA ladder (from Ambion) to estimate the size of the probes. The *in vitro* transcription reaction was assembled at RT in sterile microcentrifuge tubes, consisting of 1 µg template DNA (or 0.5 µg RNA ladder), 2 µl 10X transcription buffer; 500 µM each of ATP, CTP and GTP solutions; 50 µCi α-[³²P] UTP (15 µCi α-[³²P] UTP for RNA ladder), providing a final concentration of ~3.125 µM radiolabeled-UTP (~0.94 µM for RNA ladder). 30 U T7 Enzyme Mix and nuclease-free water to 20 µl were finally added. The components were mixed and, after a brief centrifugation, incubated for one hour at 37 °C.

In order to digest the remaining DNA eventually present in the tubes, 2 U TURBO DNase (included in the kit) were added to the reactions, followed by incubation 15 min at 37 °C. 1 µl of 0.5 M EDTA solution was then added to stop the reaction. 0.5 µl solution were taken from each tube and the amount of radiolabel incorporated was measured at a scintillation counter (Beckman LS 6000). One million counts-per-minute (cpm) was the threshold value indicating a satisfactory [³²P]UTP incorporation. Radiolabeled probes having a radioactivity level below this value were not used for downstream procedures.

Figure 7 Nucleotide sequence of the RNA antisense probe targeting E70 transcripts. The antisense RNA sequence length is 292 nt, while the E70 probe length is 197 nt). **1-51**: T7 promoter start region and multi cloning site; **52-175**: exon 8 antisense part; **176-248**: exon 3 antisense part; **249-292**: final part of the probe, ending with SacI-HF restriction site.

Before proceeding with ribonuclease protection assay, the freshly produced RNA probes were gel purified in order to exclude prematurely terminated transcription products, as well as unincorporated nucleotides. For this purpose, a denaturing 5% polyacrylamide gel was prepared. In a sterile vial were added 7.2 g urea, 1.5 ml 10X TBE solution, 1.9 ml 40% Acrylamide and dH₂O to 15 ml final volume. The mixture was stirred at RT to completely dissolved the urea, then 120 µl 10% ammonium persulfate and 16 µl TEMED were added, and immediately the gel was poured in a suitable gel cassette. After the polymerization (usually 30 min) the gel was placed into an electrophoresis cell filled with TBE buffer. At the end of gel preparation, 15 µl gel loading buffer II (95% Formamide, 0.025% xylene cyanol, 0.025% bromophenol blue, 18 mM EDTA, 0.025% SDS) were added to the samples (5 µl of loading buffer to 5 µl the RNA ladder aliquot), heated for 3 min at 95 °C, briefly centrifuged and finally loaded and run at 150 V for ~45 min. After this time, the gel was extracted from the cassette, covered with transparent plastic wrap, pasted into a X-ray cassette and exposed for 30s to a X-ray film (Fujifilm). The film was finally developed using a Curix 60 device (Agfa healthcare). The expected full-length probe sizes were 304 nucleotides (nt) for pTRI-Actin-Mouse and 292 nt for pGEM-T E70 probe (Fig. 8 A). The areas of the gel containing full-length transcripts were excised with a scalpel, transferred to a RNase-free microfuge tube, submerged in 350 µl of Probe Elution buffer (500 mM ammonium acetate/1 mM EDTA/ 0.2% SDS) and incubated overnight at 37 °C. Another X-ray film was exposed to the gel to ensure that the whole amount of full-length probes had been recovered (Fig. 8 B).

Figure 8 Gel purification of RNA probes for RNase protection assay. X-ray plate before (A) and after (B) excision of the full-length RNA probes.

Purification from unincorporated radionucleotides was performed also in RNA ladder samples, using IllustraMicroSpin G-50 columns (GE Healthcare). Briefly, the columns were prepared for the experiment as suggested by the manufacturer, subsequently 15 μ l of the freshly synthesized ladder were applied to the column placed upon a fresh sterile microcentrifuge tube. Purified RNA ladder was eluted by centrifugation at 735 x g for 2 min at RT. The amount of radioactive label of the eluted RNA antisense probes and RNA ladder was assessed by scintillation counting of 1 μ l of each solution. The detected values were in the range between 50,000-100,000 cpm/ μ l for the probes and about 250,000-300,000 cpm/ μ l for the RNA ladder.

3.2.11 RNase Protection Assay (RPA)

RPA experiments were performed using the RPA III kit (Ambion). Each experiment was carried out including both positive and negative controls provided by the manufacturer, constituted respectively by an actin probe-hybridizing mouse liver RNA and yeast RNA, to eventually reveal any unspecific background signal.

To start the experiment, 3 μ g mRNA (equivalent to and 200,000 cpm purified RNA antisense probes were placed in sterile, RNase-free microcentrifuge tubes. 1/10 vol of 5 M ammonium acetate and 2.5 vol of ethanol were subsequently added; tubes were mixed thoroughly and stored at -20 $^{\circ}$ C for one hour, allowing RNA to precipitate. The samples were then centrifuged at 16,100 x g for 20 min at 4 $^{\circ}$ C. The supernatant was

discarded and RNA pellets were washed with 70% ethanol, briefly centrifuged and air-dried for ~5 min.

Each pellet was resuspended in 10 μ l hybridization III buffer provided with the kit, heated for 4 min at 93 °C to denature RNA, and then incubated overnight at 42 °C to allow probes to hybridize.

Unprotected RNA was digested after incubation using enzyme mix RNase A/RNase T1 Mix diluted 1/100 in RNase digestion III buffer; 150 μ l of this solution were added to each sample. Additionally, 150 μ l of digestion III buffer were added to the no-RNase control tube(s), as a control for probe integrity. The RNA digestion was performed for 30 min at 37 °C, and was followed by addition of 230 μ l RNase Inactivation/Precipitation III solution.

The samples were mixed thoroughly, chilled at -20 °C for one hour and centrifuged at 16,100 x g for 20 min at 4 °C. In the meantime a 5% polyacrylamide gel was prepared, as described in paragraph 3.2.10. After centrifugation the supernatant was removed and RNA pellets were washed with 70% ethanol, briefly centrifuged and air-dried for ~5 min. RNA pellets were resuspended in 10 μ l gel loading buffer II (95% Formamide, 0.025% xylene cyanol, 0.025% bromophenol blue, 18 mM EDTA, 0.025% SDS), vigorously vortexed and heated for 4 min at 93 °C before being loaded into the gel. The amount of RNA ladder loaded was 40,000 cpm (corresponding to ~1.5 μ l of a 1/10 dilution of a 300,000 cpm/ μ l column-purified solution), complemented with 5 μ l gel Loading Buffer II. Only 20% of the No-RNase tube content was loaded, since a higher radioactivity level is expected compared to the other samples. Electrophoretic separation was carried out at 150 V for ~45 min. After this time, the gel was placed on Whatman paper, wrapped into a plastic foil, pasted into a X-ray cassette and exposed to a X-ray film at -80 °C for a time ranging between overnight to four days, depending on the amount of hybridized probe on target RNA. The film was finally developed using a Curix 60 device (Agfa). The expected sizes of the protected probes were 245 nt for pTRI-Actin-Mouse and 197 nt for pGEM-T E70 probe.

3.3 Biochemistry

3.3.1 Western blotting (WB)

3.3.1.1 Cells lysis for SDS-PAGE

80-90% confluent cells cultivated in T75 flasks were washed twice in PBS, scraped off the flasks using 3 ml PBS, and centrifuged at 800 x *g* for 3 min at RT. Pellets were resuspended in 400 µl ice-cold lysis buffer (50 mM Tris-HCl pH 7.4; 300 mM NaCl; 5 mM EDTA; 1% Triton X-100; a tablet of cOmplete protease inhibitor (PI) cocktail (Roche) was used for each 10 ml solution) and passed several times through a 25-gauge needle, incubated 20 min on ice and finally centrifuged at top speed for 20 min at 4 °C. The supernatant was carefully removed, placed in fresh tubes and either stored at -20 °C or directly used for downstream application.

3.3.1.2 Oocyte lysis for SDS-PAGE

For each experimental group, fifteen *Xenopus laevis* oocytes were resuspended in 300 µl (20 µl each cell) oocyte lysis buffer (150 mM NaCl, 20 mM Tris-HCl, 5 mM MgCl₂, 5 mM EDTA, 1% Triton X-100; a PI cocktail tablet was used for each 10 ml solution) and incubated 15 min on ice. Lysates were then centrifuged at 11,000 x *g* for 5 min at 4 °C. The supernatant was carefully removed with a fine tip and placed in a fresh microcentrifuge tube. Samples were again incubated 15 min on ice and centrifuged at 11,000 x *g* for 5 min at 4 °C. The supernatant was carefully removed, placed in fresh tubes and either stored at -20 °C or directly used for downstream application.

3.3.1.3 Cells lysis for protein analysis under native conditions

80-90% confluent cells cultured in T25 flasks were washed twice in PBS, scraped off the flasks using in 1 ml PBS solution containing PI cocktail and 200 ng/µl PefaBlock solution (a serine protease inhibitor, from Sigma), and transferred to microcentrifuge tubes. The samples were centrifuged at 1,500 x *g* for 3 min at 4 °C. After supernatant was removed, the pellet was resuspended in 800 µl ice-cold hypotonic buffer (10 mM Tris-HCl, 2 mM EDTA, PI and 200 ng/µl PefaBlock in H₂O), passed through a 26-

gauge needle ten times and incubated 20 min on ice. The homogenate was subsequently centrifuged at 400 x g for 10 min at 4 °C, to precipitate nuclei. Supernatant was placed in a ultracentrifuge tubes and centrifuged at 50,000 x g for 30 min at 4 °C in a TL-100 ultracentrifuge equipped with a rotor TLA 100.3 (Beckman Coulter). Supernatant was carefully removed and pellet were either frozen at -80 °C, or directly processed for the native PAGE analysis.

3.3.1.4 Protein quantitation

Protein amount was quantified using the Pierce BCA protein assay kit (Thermo Scientific), 7 µl of each sample derived from the previous procedure were added to 28 µl autoclaved H₂O and 10 µl of this mixture were loaded in triplicates on a 96 well plate, together with triplicates of 10 µl diluted BSA (bovine serum albumin) standard, as listed in table 3.

BSA dilution sample label	dH₂O µl	BSA µl	Final BSA concentration (µg/ µl)
A	0	35	2
B	17,5	52,5	1,5
C	35	35	1
D	30	30 from sample B	0,75
E	35	35 from sample C	0,50
F	35	35 from sample E	0,25
G	30	30 from sample F	0,125
H	32	8 from sample G	0,0025
I	60	0	0

Table 3 BSA dilution pattern used for protein quantization experiments.

Reagent B (4% cupric sulfate) was diluted 1/50 in Reagent A (sodium carbonate, sodium bicarbonate, bicinchoninic acid and sodium tartrate in 0.1 M sodium hydroxide) and mixed thoroughly. 200 µl of this mixture was added to each sample in the 96-well plate, which was then incubated 30 min at 37 °C. The absorbance of the samples at 562 nm was measured using a Wallac VICTOR² plate reader (Perkin Elmer). With these data we could draw a titration curve, which allowed us to estimate the protein amount relative to our samples.

3.3.1.5 SDS-PAGE and protein blotting on nitrocellulose membrane

NuPAGE Tris-Acetate SDS Buffer Kit (Invitrogen) was used for all SDS-PAGE experiments. Running buffer was prepared diluting 50 ml of 20X Tris-acetate Running buffer (containing 1 M Tricine, 1 M Tris Base, 70 mM SDS in H₂O, pH 8.25) in one liter distilled water; from this, 200 ml were placed into another vessel and complemented with 500 µl Antioxidant (containing N,N-Dimethylformamide and sodium bisulfate). A Pre-cast gel NuPAGE Novex 3–8 % Tris-acetate (Invitrogen) was loaded into a XCell SureLock electrophoresis cell (Invitrogen). 200 ml of freshly prepared buffer containing antioxidant were poured in the inner part of the chamber, with the running buffer placed the outer part. A maximal volume of 45 µl sample was loaded per well, along with 10 µl of pre-stained ladder (New England Biolabs), and electrophoresis was performed at 150 V for one hour. In the meantime, 1.2 liters of transfer buffer were prepared, consisting of 10 mM NaHCO₃, 3 mM Na₂CO₃, 20% methanol and 0.01% SDS solutions at pH 9.22. After the electrophoretic separation, proteins were transferred from gel to a nitrocellulose membrane (Amersham Hybond ECL - GE Healthcare) using a tank transfer method: both membrane and gel were incubated in transfer buffer and shaken for 10 min. The ‘sandwich’ for the transfer consisted on the gel containing the protein placed in tight contact with the membrane, surrounded by two pieces of Whatman paper and a sponge for each side of the sandwich. This complex was placed into the transfer tank Mini Trans-Blot Cell (Bio-Rad) within a gel holder cassette (Bio-Rad). The transfer protocol consisted of a voltage gradient from 10 to 40 V, increased by steps of 10 V every 10 min, and followed by a final step of 40 min at 50 V. The nitrocellulose membrane was removed from the sandwich and air-dried overnight at RT.

3.3.1.6 Blue Native PAGE (BN-PAGE) and protein blotting on PVDF membrane

BN-PAGE is a sensitive and high resolution tool for analysis of the molecular mass and oligomeric state of proteins in native conformation (Schägger and von Jagow, 1991). All the components (detergent, running buffers, protein ladder) used in BN-PAGE experiments were purchased from Invitrogen. Frozen pellets derived from cell lysates (procedure described in paragraph 3.3.1.3) were thawed on ice and resuspended in 200 μ l sample buffer (50 mM BisTris-propane, 750 mM 6-aminocaproic acid, pH 7 complemented with PI/10 ml solution). The protein concentration was measured as described in paragraph 3.3.1.4. In fresh microcentrifuge tubes, 250 ng of protein lysate were mixed with 12 μ l (6% final concentration) *n*-Dodecyl β -D-Maltopyranoside (DDM, a mild detergent) and diluted with sample buffer in order to achieve 14 μ l final volume. The mixture was incubated for 60 min on ice. After that, 6 μ l (1.5% final concentration) Coomassie G 250 were added and the samples were centrifuged at 16,100 x *g* for 10 min at 4 °C. Anionic dye Coomassie blue G 250 binds the negative charges of the amino acids, replacing SDS as charge-shift molecule, and maintaining in this case the protein structures in their native state. During the time of incubation with the detergent, a Native PAGE Novex 3-12% Bis-Tris pre-cast gel was loaded into a XCell SureLock electrophoresis cell, which was then filled in the outer part with NativePAGE Running Buffer (50 ml NativePAGE Running Buffer 20X containing 950 ml dH₂O) and internally with Dark Blue buffer (10 ml Cathode Additive, 10 ml Running Buffer, 180 ml dH₂O; final G-250 amount 0.02%). The wells were loaded with 10 μ l of sample supernatant and 7 μ l NativeMark protein ladder (Life technologies). Electrophoretic separation lasted for one hour at 150 V at 4 °C; after this time, the Dark Blue buffer was replaced with Light Blue buffer (1 ml Cathode Additive, 10 ml Running Buffer, 189 ml dH₂O; final G-250 amount 0.002%) and the samples were allowed to run for additional 3 hours at 250 V. After that, the proteins were transferred onto a PVDF membrane (Amersham Hybond-P; GE healthcare) using the Trans-Blot SD Semi-Dry Transfer Cell (Bio-Rad). Three Whatman paper pieces were placed on the transfer apparatus: the first pre-soaked in Buffer I (300 mM Tris-HCl, pH 10.4 and 10% methanol), and two pre-soaked in Buffer II (25 mM Tris-HCl, pH 10.4 and 10% methanol). The PVDF membrane (previously incubated in methanol for 1 min, then 3 min in dH₂O, finally in Buffer II immediately before loading), and the gel were then

added. Finally the last 3 pieces of Whatman pre-soaked in Buffer III (25 mM Tris-HCl pH 10.4; 40 mM aminocapronic acid; 20% methanol) were applied on top of the gel. The transfer time was 30 min at 2.5 mA/cm² of membrane. After blotting, the membrane was incubated in 8% acetic acid for 15 min and air-dried overnight at RT. The lane containing the unstained ladder was separated from the other samples, incubated 10 min in methanol, washed 5 times with dH₂O and incubated 30 min with Ponceau S (Merck Millipore) solution 0.1% in 1% acetic acid. The excess of staining was removed by several washes in dH₂O, until the ladder bands could be detected and promptly marked on the PVDF membrane containing the samples lanes.

3.3.1.7 Two-dimensional Blue Native PAGE (2D BN-PAGE)

The macromolecular composition of K_v10.1 complexes derived from BN-PAGE experiments was investigated using a SDS-PAGE approach as second dimension following a BN-PAGE (Schägger et al., 1993). The sample preparation and the BN-PAGE procedures were carried out as described in paragraph 3.3.1.3 and 3.3.1.6. After the electrophoresis, the lane containing the sample of interest was excised from the native gel with a scalpel and incubated in equilibrating solution (ES; made of 1% SDS in 0.125 mM Tris-HCl, pH 7.0) for 20 min, then in ES complemented with 100 mM Dithiothritol (DTT) for 25 min. After that, gel was incubated in ES with 60 mM Iodoacetamide for 25 min and finally pure ES for 10 min. The equilibrated lane was placed in the 2D well of a NuPAGE Novex-Tris Acetate 3-8 % SDS gel. 10 µl of prestained protein marker (Bio-Rad) were loaded in the ladder lane. The SDS-PAGE and protein blotting on nitrocellulose membrane were performed as described in 3.3.1.5.

3.3.1.8 Membrane blocking and protein signal detection

The dried nitrocellulose membrane was incubated in dH₂O (or in methanol for PVDF membranes, followed by 3x dH₂O washes) for 15 min. The Pierce Western Blot Signal (Thermo Scientific) Enhancer was used: solution A was applied to the membrane for 2 min then 5x washed with dH₂O. Then the solution B was added, incubated for 10 min and finally washed again 5x with dH₂O. To block unspecific binding sites of the antibody, the blotted membrane was incubated for 1 hour with 0.1% Casein (Roche) in TBS-T (TBS containing 0.1% Tween 20) solution. After that, a primary antibody

diluted in 0.1% casein TBS-T (see table 4) was applied for 90 min, followed by 7x washes with deionized H₂O and 5 min incubation in TBS-T. Subsequently the membrane was incubated for one hour with secondary ECL anti-rabbit (or anti-mouse, depending on the primary antibody species) IgG antibody horseradish peroxidase (HRP)-linked (GE Healthcare), diluted 1/7000 in 0.1% casein TBS-T. The membrane was washed again seven times with deionized H₂O and incubated in TBS-T for 5 min. For the detection of the protein signal, the membrane was incubated for 5 min with Immobilon Western Chemiluminescent HRP Substrate (Millipore) and luminescence was imaged using a Chemi-Doc XRS system (Bio-Rad).

3.3.2 Immunoprecipitation (IP)

An amount of 100 to 500 µg protein lysates (isolated and quantified as described in 3.3.1.1 and 3.3.1.4), together with respectively 15 to 25 µl of Protein G magnetic beads (New England Biolabs) was first incubated for 1 hour at 4 °C in order to pre-clear the crude cell extract, excluding from the experiment non-specific binding to the beads. A magnetic field was applied to the mixture for 30s and the beads were trapped in one side of the tube. The supernatant was then placed in a fresh tube, where 2 µg of a monoclonal antibody (see table 4) were also added. The tube content was mixed and incubated for one hour or ON (depending on the antibody) at 4 °C. 25 µl of magnetic beads were added to the suspension, vortexed and incubated for one hour at 4 °C. The beads were recovered in a magnetic field, washed 3 times with 400 µl protease-free wash solution (0.1% Triton X-100, 50 mM Tris-HCl, 300 mM NaCl, 5 mM EDTA, complemented with PI tablet for each 10 ml solution). Finally, an additional wash with 400 µl protease-free TBS (TRIS buffered saline: 50 mM TRIS, 150 mM NaCl, pH 7.6) was performed. The beads were resuspended in 16.25 µl TBS, 2.5 µl 10X Sample Reducing Agent (500 mM DTT, from Invitrogen) and 6.25 µl of 4X LDS sample buffer (40% glycerol, 6.8% Tris-Base, 6.6% Tris-HCl, 8% LDS, 0.06% EDTA, 0.75% Serva Blue G250, 0.25% Phenol Red, from Invitrogen), till reaching a final volume of 25 µl. For each sample, a no-IP (input) tube, containing 10% of the immunoprecipitated amount of protein, together with 1/4 vol LDS and 1/10 vol SRA was also prepared. All the samples were incubated for 10 min at 70 °C and then exposed to a magnetic field to

separate beads from supernatant. The IP supernatant, input and a protein ladder (New England Biolabs) were finally loaded on the appropriate polyacrylamide gel.

Label	Clonality, host	Target epitope	Dilution, final concentration	Experiment	Provider (or reference)
33	Monoclonal, mouse	C-terminus K _v 10.1	2 µg (IP); 2 µg/ml (ELISA)	Ip, ELISA	L.A. Pardo; (Hemmerlein et al, 2006).
49,56,62,66	Monoclonal, mouse	Pore region K _v 10.1	0.5 µg each	IP	L.A. Pardo; (Hemmerlein et al., 2006).
1218	Monoclonal, mouse	GFP (used for mVenus)	2 µg	IP	Abcam
6556	Polyclonal, mouse	GFP (used for mVenus)	1/1000	WB	Abcam
9391	Polyclonal, rabbit	C-terminus K _v 10.1	1/1500	WB	L.A. Pardo; (Napp et al., 2005).

Table 4 List of primary antibodies used in IP, ELISA and WB.

3.3.3 Glycosidase digestion

200 µg of protein lysate were immunoprecipitated, as described in 3.3.2. After the overnight antibody incubation and the addition of protein G magnetic beads, the magnetic beads were resuspended in 2 µl Beads Release solution (100 mM β-mercaptoethanol in 0.1% SDS), in order to release the proteins complexes bound to the beads. Samples were heated up to 99 °C for 10 min, briefly centrifuged, and exposed to a magnetic field in order to trap the beads at one side of the tube. At this point, the 21 µl supernatant from each sample were distributed in three microcentrifuge tubes, for treatment with Endo H, PNGase F (both from Sigma), and a control tube (CTL), containing immunoprecipitated samples not treated with enzyme (table 5).

	EndoH sample	PNGase F sample	CTL sample
100 µg protein lysate	7 µl	7 µl	7 µl
dH₂O	9,5 µl	Diluted with its own buffer	18 µl
Buffer	5 µl	12 µl	-
Denaturing solution	2,5 µl	2,5 µl	-
Samples denaturated at 100 °C for 5 min, then placed on ice 1 min and finally treated with:			
Detergent solution	-	2,5 µl	-
Enzyme	1 µl	1 µl	-

Table 5 Endo H and PNGase F digestions: list, and used amount of the components for each sample.

The tubes were incubated ON at 37 °C and then mixed with SRA and LDS buffers for SDS-PAGE, as described in paragraph 3.3.1.5.

3.3.4 K_V10.1 -BBS system for quantification of surface K_V10.1

3.3.4.1 Sample preparation

Insertion of a BBS at the extracellular part of K_V10.1 allows specific labeling of membranous K_V10.1-BBS in intact cells (Kohl et al., 2011). HEK-K_V10.1-BBS cells cultured on T75 flasks were washed once with 10 ml PBS. For each flask, 4 ml PBS containing α -Bungarotoxin (BTX)-Biotin (Invitrogen) at final concentration of 2.5 µg/ml were added, followed by incubation on ice for 10 min. The α -BTX-Biotin solution was removed and the flasks were washed twice with ice-cold PBS. Cells were scraped in 4 ml ice-cold PBS, centrifuged at 800 x g for 3 min. Cell pellets were resuspended with 400 µl lysis buffer (20 mM Tris-HCl, 150 mM NaCl, 5 mM MgCl₂,

1% Nonidet- P40, pH 7.4, containing a PI tablet each 10 ml solution). The lysates were passed several times through a 25-gauge needle and placed in microcentrifuge tubes, incubated for 20 min on ice and finally centrifuged at 16,100 x g for 15 min at 4 °C. Supernatants were placed in fresh tubes and the protein concentration was quantified as described in paragraph 3.3.1.4.

3.3.4.2 Enzyme-Linked ImmunoSorbent Assay (ELISA)

The entire procedure was performed on ice. 96-well streptavidin-coated plates (Thermo Scientific) were washed twice with PBS containing 0.05% Tween 20, 0.1% BSA and 0.1% Triton X-100. Each sample was placed in six wells of the 96-well plate (triplicates of 30 and 150 µg of protein) and incubated 30 min. The plates were washed twice and then incubated for 30 min with 100 µl NPE (150 mM NaCl, 5 mM EDTA, 50 mM Tris, 5mM KCl, 1% NP-40; pH 7.5) blocking solution containing 1% casein to remove unspecific binding sites of the antibody. 50 µl for each well of primary antibody anti-K_v10.1 diluted in NPE with 0.1% casein (final antibody concentration 2.5 µg/ml) were then added to the wells and incubated 90 min. The samples were washed 3 times with 100 µl NPE buffer containing 0.1% casein and incubated again with 100 µl NPE blocking solution (with 1% casein) for 30 min. At this point, 50 µl/well of secondary ECL HRP-linked anti-mouse IgG (GE Healthcare) (diluted 1/500 in NPE with 0.1% casein) were added to the wells and the mixture was incubated 90 min. After this, each well was washed 7 times with 100 µl NPE buffer containing 0.1% casein. Finally, 200 µl substrate 3-ethylbenzothiazoline-6-sulphonic acid (ABTS, from Invitrogen) were added for each well. The chromogenic peroxidase reaction was measured using a plate reader at 405 nm with a reference wavelength of 490 nm.

3.3.5 Cell fixation for fluorescent proteins imaging

Confluent CHO cells (~80-90%) were plated on poly-L-lysine coated 25 mm coverslips in 6-well plates and transfected as described in paragraph 3.1.3. About 24 hours after transfection, the medium was removed and wells were washed twice with 2 ml PBS. Cells were fixed in formalin solution (Sigma) for 10 min at 4 °C, then washed twice (5 min each) in PBS. Permeabilization of the membrane was performed incubating cells in

PBS with 0.5% Triton X-100 (Sigma) for 5 min RT. Samples were afterwards washed twice (5 min each) with PBS-T (PBS with 0.1% Tween-20 (Merck-Millipore)). ProLong Gold antifade reagent (Invitrogen) containing the membrane-impermeable nuclear staining DAPI was finally used to mount the coverslips on microscope slides Superfrost Plus (Thermo scientific). Mounted coverslips were air-dried for at least one hour at RT and finally stored overnight at 4 °C before analysis.

3.4 Electrophysiology

3.4.1 Two-electrode voltage clamp

Voltage clamp recordings of cRNA-injected *Xenopus laevis* oocytes (Stühmer, 1998) were performed 24-48 hours after injection, using a Turbo TEC-10CD amplifier (npi Electronics). Currents derived from cRNA-injected oocytes and DEPC-H₂O injected oocytes (negative control) were all recorded at RT. The intracellular electrodes having a resistance of 0.7-1.5 MΩ were filled with 2 M KCl. The external solution (Normal Frog Ringer, NFR) contained 115 mM NaCl, 2.5 mM KCl, 1.8 mM, CaCl₂, 10 mM Hepes, pH 7.2. Data were acquired with PULSE software (HEKA Electronics) and analyzed with IgorPro (Wavemetrics). For all protocols, the currents were filtered at 2 kHz and then sampled at a frequency of 10 kHz. The membrane potential was held at -80 mV. In order to characterize current-voltage relationships, an I-V protocol was used, generally consisting of 250 ms voltage pulses, ranging from +80 mV to -60 mV, with 20 mV decrements. To compare voltage-elicited current response between different groups of oocytes, the average steady state current from 80 to 95% time of the pulse was plotted against the voltage. As mentioned in section 1.4.1, the activation kinetics deceleration under hyperpolarized holding potentials is a hallmark of the K_V 10.1 channel (Terlau et al., 1996). This was determined using the following protocol: +40 mV pulses were applied for 500 ms after hyperpolarizing conditioning pulses (5000 ms) at -120 mV and -60 mV. The rise time of activation was established as the time required from 20% to 80% of the maximal current.

3.4.2 Whole cell patch clamp electrophysiology

HEK-K_v10.1 cells were transfected (as described in paragraph 3.1.3) and plated in 24-well plates, (~20,000 cells/ well) each containing a 12-mm coverslips coated with poly-L-lysine. Recordings were performed 24-72 hours after transfections. Only cells showing green signal (due to the transfection of the fluorescent protein mVenus) under epifluorescence illumination passing through a suitable dichromatic beamsplitter (Excitation BP 450-490 nm; Emission LP 515 nm) were analyzed. Macroscopic K_v10.1 currents were recorded in the whole-cell configuration of the patch-clamp technique (Hamill et al., 1981), using an EPC-9 amplifier and Patchmaster software (both from HEKA). Patch pipettes were pulled (with a List-Medical vertical puller) from WPI - PG10165-4 glass (World precision Instruments): the pipette resistance ranged between 2.5 and 3.5 MΩ. The intracellular solution contained 100 mM KCl, 1 mM MgCl₂, 5 mM BAPTA, 5 mM EGTA, 45 mM NMDG (N-methyl-D-glucamine), 10 mM HEPES; pH 7.4, osmolarity ~290 mOsm. Extracellular solution was made of 2.5 mM KCl, 160 mM NaCl, 2 mM CaCl₂, 1 mM MgCl₂, 8 mM Glucose, 10mM HEPES, pH 7.4, osmolarity ~300 mOsm. For all the experiments, the membrane potential was held at -80 mV. Fast capacity (C_{fast}), slow capacity (C_{slow}) and series resistance (R_S) compensations (at 70-90 %) were also applied. Signals were filtered at 4 kHz and sampled at 20 kHz. I-V protocol consisted of 250 ms (or 500 ms) voltage pulses, ranging from +80 mV to -60 mV, with 20 mV decrements. To compare voltage-elicited current response between different groups of cells, the current was first normalized to the cell size (as measured by C_{slow}). The resulting current density was averaged from 80 to 90% time of each pulse and plotted against the voltage. A high potassium-content extracellular solution was also used (60 mM KCl, 102.5 mM NaCl, 2 mM CaCl₂, 1 mM MgCl₂, 8 mM Glucose, 10 mM HEPES, pH 7.4, osmolarity ~320 mOsm) in order to check the voltage dependence of the conductance (*G versus V*), using a tail current protocol: each of 500 ms voltage pulses (ranging from +80 mV to -80 mV, with 20 mV decrements) was followed by 300 ms hyperpolarization at -120 mV. The exponential current-decay after the peak tail was fitted, and the extrapolated amplitude at time zero (i.e. at the beginning of hyperpolarization pulse) was considered as peak tail current. G/G_{max} values were obtained by normalizing the extrapolated peak tail current against +80 mV tail currents, and plotted *versus* voltage. Conductance–voltage curves were then fitted with a

Boltzmann sigmoidal function to describe the voltage dependence of $K_v10.1$ activation, according to Equation 1:

Equation 1:
$$G = \frac{G_{max}}{1 + e^{-(V - V_{Half})/k}}$$

Where G_{max} is the maximal conductance, V_{half} represents the voltage for half-maximal activation, and k is the slope factor.

3.4.3 Outside-out patch clamp recordings for noise analysis

Non-stationary noise analysis was carried out in the outside-out configuration on macropatches of *Xenopus* oocytes (Heinemann and Conti, 1992). Briefly, 24-72 hours after cRNA injections, the oocyte to be analyzed was immersed ~5 min in skinning solution (200 mM *L*-Aspartic acid, 20 mM KCl, 1 mM MgCl₂, 5 mM EGTA, 10 mM HEPES, pH 7.4), which provided the osmotic pressure to facilitate the removal of the vitelline membrane. This operation was performed under a strong illumination using a pair of fine tip forceps. The oocyte was then placed in a recording chamber containing NFR (external measuring solution), and allowed to attach to the bottom for 10-15 min before measurement. All the experiments were performed at RT, with oocytes from at least two different animals. Pulled patch pipettes (WPI - PG10165-4 glasses), having resistance 0.9 - 2 MΩ were filled with intracellular solution containing 100 mM KCl, 10 mM EGTA, 10 mM HEPES, pH 7.2. EPC9 amplifier and Patchmaster software were used for the measurements. Patches were held at a holding potential of -80 mV. Signals were filtered at 4 kHz and sampled at 20 kHz. After establishing the outside-out configuration, fast capacity was compensated. Non-stationary noise analysis data were acquired by applying short (50 ms) depolarization pulses to +40 mV for several hundred times. Variance was calculated with PulseTools software (HEKA). Number of channels N , and single channel currents i were determined from the variance σ^2 versus current amplitude I plot using the following equation 2:

Equation 2
$$\sigma^2 - \sigma_0^2 = i * I - I^2/N$$

Where σ_0^2 represents the baseline variance. The total current I flowing through an ion channel results from the combination of three parameters: the unitary current through a single channel i , the total number of available channels N , and the probability of a channel being open P_o (Equation 3).

Equation 3
$$I = i * N * P_o$$

3.5 Imaging

3.5.1 Epifluorescence microscopy

In order to estimate the cell transfection efficiency, fluorescence derived from transfected fluorophores was visualized with a Zeiss Axiovert 200M equipped with a Hg-arc lamp (HBO 100 W, Osram) using an appropriate dichromatic beamsplitter filter set:

- Excitation band pass (BP) 450-490; emission BP 515-565 nm for mVenus transfected cells, and
- Excitation BP 546/12; emission long pass (LP) 590 nm for mCherry transfected cells.

3.5.2 Confocal microscopy

Confocal images (from samples prepared as described in paragraph 3.3.5) were acquired with a Leica TCS SP2 system; the scan head is mounted on a Leica DMIRE2 inverted microscope. Images were taken using a 63X oil immersion objective having numerical aperture 1.4. The scanned stacks had $\sim 0.3 \mu\text{m}$ thickness. Laser line and filter range to detect the emission of each fluorophore were: DAPI (Laser line 405 nm, emission 418-477 nm); mVenus (laser line 514 nm; emission, 526-585 nm) and mCherry (laser line

594 nm; emission 607-655 nm). Acquired image stacks were converted to TIFF files and imported into Fiji (Fiji Is Just ImageJ) software (Schindelin et al., 2012). Quantitative colocalization analysis were performed with the plugin JACoP (Just Another Colocalization Plugin) (Bolte and Cordelières, 2006), based on Pearson's correlation coefficient (Adler and Parmryd, 2010).

3.5.3 Live imaging

IncuCyte Zoom (Essen BioScience) device was used for monitoring cell growth. After transfections (described in 3.1.3), the cells were plated on a suitable vessel at a confluence of 30-40%. The cells were loaded in the Incucyte Zoom placed into a cell incubator at 37 °C and 5% CO₂. Under these conditions, 16 images/well (using a 10X objective, Nikon) were acquired at intervals of 60 min, until confluence reached 100% (or for a maximal time of 100 hours after transfections). The growth curve was obtained using the IncuCyte ZOOM 2013A software (Essen BioScience): a confluency mask was used to track the cell growth, which was then plotted on a line graph against the incubation time.

3.6 Flow cytometry

To estimate the fraction of cells retained in different cell cycle phases, a kit based on DNA intercalating agent Propidium iodide (Pi) was used, the CycleTEST plus DNA from BD Biosciences. 48 hours post-transfections cells were trypsinized, centrifuged at 800 x g for 3 min at RT and counted. The pellets from ~1 x10⁶ cells were washed once in PBS, and centrifuged again at 800 x g for 3 min at RT. The samples were resuspended in 250 µl solution A (containing trypsin in a spermine tetrahydrochloride detergent buffer, to lysate the cell membranes and cytoskeletons), mixed and incubated for 10 min at RT. After that, 200 µl solution B (containing trypsin inhibitor and ribonuclease A, to inhibit the trypsin activity and to digest the RNA) were added, mixed and incubated for 10 min at RT. Finally 200 µl solution C cold (containing Pi, staining the DNA) were

applied to the samples, which were mixed and incubated 10' on ice in dark conditions. The samples were analyzed in a FACSAria flow cytometer (BD Biosciences) using an Ar 488 nm laser for excitation. The fluorescence emission was collected using 585/42 BP filters. Linear forward and side scatter gates were used to discriminate single cells from cell clumps and debris. After gating, a minimum of 1×10^4 events was recorded for each sample. FACS Diva software v5.0 (BD Biosciences) was used for data acquisition. The resulting fluorescence histograms were analyzed with FlowJo v7.5.5 software (Tree Star). The cell cycle statistics were obtained using the Watson algorithm (Watson et al., 1987).

3.7 Statistics

Statistical analysis was performed using the software Prism (GraphPad) and Igor (Wavemetrics). Sample values and current amplitudes were compared by two-tailed unpaired Student's t test. *P* values below 0.05 were considered statistically significant. Asterisks in the figures indicate *p*-values (* $p \leq 0.05$; ** $p \leq 0.01$; *** $p \leq 0.005$). Unless differently stated, data are represented as means \pm standard error of the mean (SEM).

4. Results

4.1 $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ splice isoforms expression in diverse cell lines

Recent findings in our laboratory revealed the existence of two $K_V10.1$ truncated isoforms in the human brain and in the melanoma cancer cell lines IGR 39 and IPC 298. These splice variants have been termed E65 and E70, based on their predicted molecular weight. Both the isoforms are derived from exon skipping events and are devoid of the whole transmembrane domains, therefore predictably non-channel proteins, lacking respectively exons four to nine and four to seven compared to the full-length $K_V10.1$ sequence (Ramos Gomes, 2010). In order to provide a more intuitive distinction between $K_V10.1$ full-length channel and its short isoforms in terms of nomenclature, in this section we will always refer at them as $K_V10.1$, $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$, respectively, based on their exon composition.

Here, nested PCR experiments were carried out in order to consolidate previous findings and to verify the expression of $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ in a panel of $K_V10.1$ -positive cell lines. Since $K_V10.1$ (full-length and $K_V10.1^{\Delta 4-7}$) is also expressed in brain under physiological conditions, human brain samples were also tested for short isoforms expression. For each nested PCR experiment, two sets of specific primers amplifying $K_V10.1$ (external and internal primers, whose sequences described in table 1 of materials and methods section) were used. The external primers anneal respectively to the boundary between exon 1 and 2 (forward), and exon 11 (reverse) of $K_V10.1$ sequence. The internal primers are located at exon 2 (forward) and exon 11 (reverse). Since all these primers target regions contained in both $K_V10.1$ and its short isoforms sequences, we expected to distinguish $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ expression from the full-length based on the differences in amplicon length.

PCR products were separated on agarose gel electrophoresis. A band compatible with $K_V10.1$, having electrophoretic mobility corresponding at about 1.9 kb, was present in all the tested cell lines. Additionally in certain samples amplified DNA having sizes of ~500 bp and ~900 bp were detected (Fig. 9).

Figure 9 $K_V10.1$ -expressing cells exhibit $K_V10.1^{\Delta 4-9}$ - and $K_V10.1^{\Delta 4-7}$ - compatible bands. Electrophoresis of DNA samples amplified with nested PCR. $K_V10.1$ was visualized in all the samples. Additional amplified products having length of ~500 and ~900 bp appeared in IGR 39, SH-SY5Y and IMR 32 cells. The ~900 bp fragment was also detected in total human brain. Blank sample contains H_2O instead of template cDNA.

Positive bands were excised from the gel, DNA was purified and cloned into pGEM-T for sequencing using vector-specific primers. Sequencing was carried out using the Sanger method, with a forward primer annealing to the T7 promoter region (5'-TGTAACACGACGGCCAGT-3') and a reverse primer for the SP6 promoter region (5'-AACAGCTATGACCATGATTACG-3'). Sequence analysis of the amplified fragments revealed that the shortest was a 488 bp fragment in which the end of exon 3 was joined with the beginning exon 10 of $K_V10.1$, thus representing $K_V10.1^{\Delta 4-9}$. The second additional amplicon was 933 bp long and represented the $K_V10.1^{\Delta 4-7}$ isoform, where the end of exon 3 was joined with the beginning exon 8 of $K_V10.1$. The results of all the nested PCR experiments are summarized in table 6: $K_V10.1^{\Delta 4-9}$ expression was observed in prostate cancer cells DU 145, but also in normal prostate epithelium cells PNT 2. Moreover $K_V10.1^{\Delta 4-9}$ was detected in melanoma cancer cells IGR 39 and IPC 298, and neuroblastoma SH-SY5Y cells. $K_V10.1^{\Delta 4-7}$ was detected in the neuroblastoma cancer cell lines SH-SY5Y and IMR 32 cells, and also human brain extracts.

Table 6 Summary of the results from nested PCR experiments followed by sequencing analysis. K_v10.1^{Δ4-9} expression has been found in DU 145, IGR 39, IPC 298, PNT 2 and SH-SY5Y cells. K_v10.1^{Δ4-7} was detected in SH-SY5Y, human total brain and IMR 32 cells.

Aiming to achieve a quantitative detection of K_v10.1^{Δ4-9} and K_v10.1^{Δ4-7} transcripts, which would not be feasible with nested PCR, TaqMan probes and primers for real-time PCR were designed and tested. With this system we could successfully amplify both short isoforms using as template K_v10.1^{Δ4-9} and K_v10.1^{Δ4-7} sequences embedded in plasmidic DNA, with a detection limit of ~0.1 femtograms (Fig. 10). These primers had also high specificity as not amplifying K_v10.1 full-length plasmid DNA (data not shown).

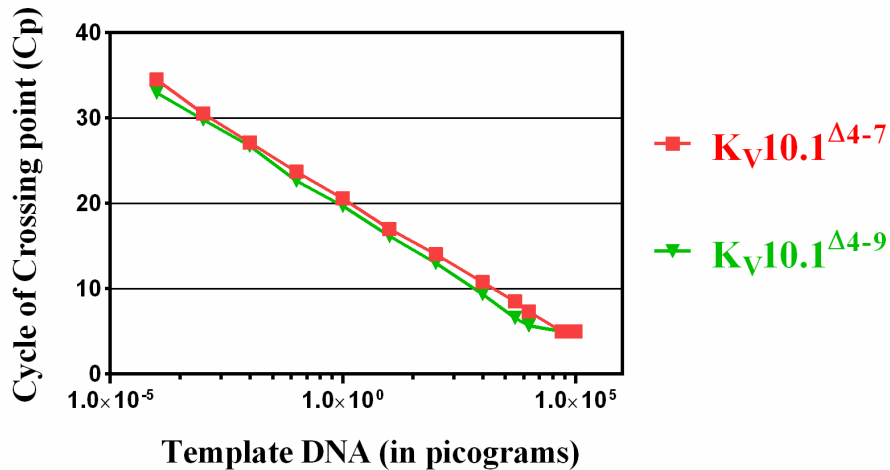

Figure 10 $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ TaqMan probes amplification efficiency. Real-time PCR with increasing dilutions plasmidic DNA. Both $K_V10.1^{\Delta 4-7}$ (squares) and $K_V10.1^{\Delta 4-9}$ (triangles) are successfully amplified starting from 0.1 femtograms DNA template. Cp (Crossing point) represents the cycle number where fluorescence emitted from the probe increases above the threshold.

Once the system was validated, real-time PCR experiments were performed using cell lines positive for $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ expression in the previous nested PCR experiments. Unfortunately, the resulting amplification rate of both splice isoforms was poor ($C_p \geq 35$) in all the cell lines and brain extract samples tested (data not shown), suggesting scarce expression for both $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$. The clear positive detection of $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ in nested PCR could be explained by the fact that real-time PCR is less sensitive (Guo et al., 2002).

In general, the methodology of PCR amplification is very sensitive, but on the other hand is also prone to give artifacts (Cocquet et al., 2006). For this reason, to unequivocally prove the existence of $K_V10.1$ short isoforms in native expression systems, we sought to determine $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ mRNA presence in a PCR-free system. Therefore, ribonuclease protection assays were performed. mRNAs isolated from diverse $K_V10.1$ -positive cancer cell lines were hybridized with radiolabeled antisense probes specifically targeting $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ transcripts (large amounts of human brain RNA necessary for RPA could not be obtained for obvious ethic issues). Single-stranded, unprotected mRNAs were digested and the result of the digestion was separated on a polyacrylamide gel. A 342 nt band, corresponding to length of the $K_V10.1^{\Delta 4-9}$ hybridized probe was detected in IGR 39

cells. $K_V10.1^{\Delta4-7}$ was detected in IMR 32 and SH-SY5Y cell extracts (Fig. 11). Findings derived from these experiments unequivocally demonstrated the expression of $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ transcripts in native expression systems, as previous results from nested PCR experiments already suggested.

Figure 11 $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ transcripts detected with RNase protection assay. Left panel: $K_V10.1^{\Delta4-9}$ transcript was detected in IGR 39 cell line. The protected probe size is 342 nt and undigested probe size 437 nt (experiment performed by Dr. Fernanda Ramos Gomes). Right panel: $K_V10.1^{\Delta4-7}$ transcript expressed in IMR 32 and SH-SY5Y cells. The protected probe size is 197 nt (undigested size 297 nt). The results of the RNase protection assay represent two independent experiments with identical outcome.

4.2 $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ interaction with full-length $K_V10.1$ channel

In a wide range of ion channels, splice variants may interact with the full-length channel, modulating its function (see for example Chiu, et al., 2010; Veale et al., 2010; Ohya et al., 2011; Tan et al., 2012). Here we asked whether also $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ would interact with $K_V10.1$ and we addressed this experimental question in a heterologous expression system, and with the use of biochemical and microscopy tools. First, co-immunoprecipitation (co-IP) experiments were performed. For this purpose, HEK cells stably transfected with $K_V10.1$ were transiently co-transfected with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ constructs tagged with the fluorescent protein mVenus (Ramos Gomes, PhD thesis 2010). The use of such a fusion protein allowed us to

overcome the lack of specific antibody available for $K_V10.1^{\Delta4-9}$ or $K_V10.1^{\Delta4-7}$, since an anti-GFP antibody could specifically target mVenus. Therefore, immunoprecipitation of $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ mVenus using an anti-GFP antibody was followed by blotting the membrane with an antibody against $K_V10.1$ (targeting C-terminus region of the channel and recognizing also the short isoforms epitopes). Anti- $K_V10.1$ immunoblot of GFP-immunoprecipitated extracts expressing $K_V10.1$ alone did not give rise to detectable bands. In contrast, in IP of extracts co-expressing $K_V10.1^{\Delta4-9}$ with full-length channel, signals compatible with $K_V10.1$ protein (~130 kDa) were detected. The same was true for extracts of cells expressing full-length together with $K_V10.1^{\Delta4-7}$, albeit quantitative and qualitative differences were present. First, the yield of full-length co-IP was much higher for $K_V10.1^{\Delta4-9}$ than for $K_V10.1^{\Delta4-7}$. Second, the bands compatible with $K_V10.1$ were also qualitatively different: $K_V10.1^{\Delta4-9}$ coprecipitated a diffuse band similar to the majoritarian form present in the inputs, while $K_V10.1^{\Delta4-7}$ pulled down two sharper bands of smaller size, indicative of non-mature forms of the channel (see Fig. 12 A, right panel). Input (not immunoprecipitated) samples were also used. Here, the ~75 kDa signal corresponding to the $K_V10.1^{\Delta4-9}$ -mVenus protein was less intense than the ~85 kDa one derived from the $K_V10.1^{\Delta4-7}$ -mVenus protein. This is probably due to a less efficient transfection rate for the DNA coding for $K_V10.1^{\Delta4-9}$ compared with the DNA coding for $K_V10.1^{\Delta4-7}$. Moreover, a band having size compatible with $K_V10.1^{\Delta4-7}$ was detected in the $K_V10.1 + K_V10.1^{\Delta4-9}$ sample: this is probably unspecific, since it also appears in the $K_V10.1$ sample (Fig. 12 A, left panel).

In vitro interaction between $K_V10.1$ and its short isoforms was confirmed by reverse co-IP using a monoclonal anti- $K_V10.1$ antibody directed against the pore region (that therefore does not bind to any of the shorter variants) and developing the immunoblot with anti-GFP antibody. Full-length $K_V10.1$ coprecipitated with both $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ (Fig. 12 B).

Figure 12 $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ coprecipitate with $K_V10.1$. Co-IP experiments: (A) Right panel: immunoprecipitation of mVenus co-precipitated $K_V10.1$ protein of ~130 kDa in $K_V10.1 + K_V10.1^{\Delta4-9}$ samples and $K_V10.1$ protein of ~110 kDa in $K_V10.1 + K_V10.1^{\Delta4-7}$. Left panel: input samples consisting of 10% (20 μ g) not immunoprecipitated cell extracts. (B) Immunoprecipitation of $K_V10.1$ with a transmembrane domain-targeting antibody coprecipitated $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$.

To further test for interaction occurring between $K_V10.1$ channel and its short isoforms $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$, confocal microscopy analyses were performed to check the existence (and eventually quantify the amount) of colocalization. For this purpose, CHO cells co-transfected with fluorescently tagged $K_V10.1$ and short isoforms ($K_V10.1$ -mCherry and $K_V10.1^{\Delta4-9}$ -mVenus) were used. Images of formalin-fixed cells were acquired using a laser scanning confocal microscope (Fig. 13 A). The same experiments were carried out on cells co-transfected $K_V10.1$ -mCherry and $K_V10.1^{\Delta4-7}$ -mVenus (Fig. 13 B). A plot profile of the two channels intensities drawn along the images already suggested the presence of a spatial overlap between the two fluorescent labels (Fig. 13 C and D). More precisely, the degree of colocalization between mVenus and mCherry channels was quantified using the Pearson's correlation, a statistical approach describing the correlation of the intensity distribution between channels: values between 0.5 and 1 are indicative of significant correlation (Adler and Parmryd, 2010). In our experiments values of 0.73 ± 0.09 were measured regarding interaction $K_V10.1^{\Delta4-9}$ - $K_V10.1$, while an average coefficient of 0.80 ± 0.08 was obtained for $K_V10.1^{\Delta4-7}$ - $K_V10.1$. These statistics are representative of at least 8 cells/group.

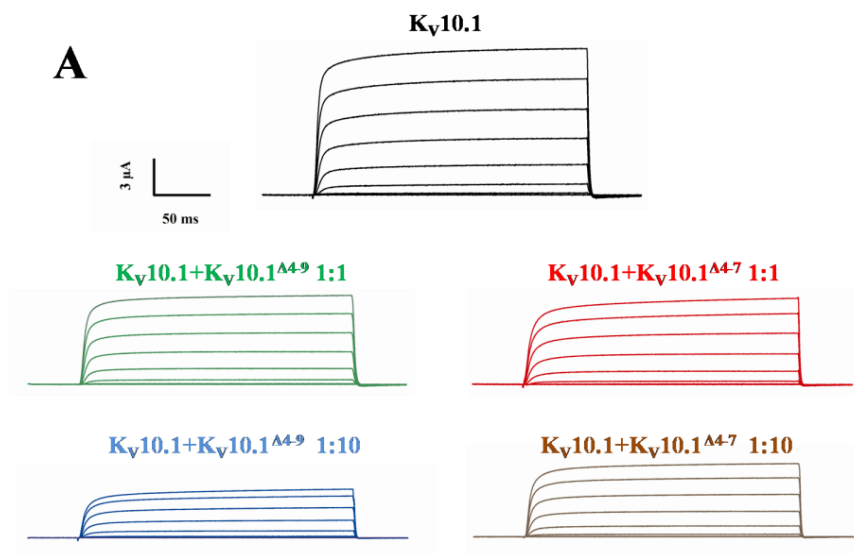

Figure 13 $\text{Kv10.1}^{\Delta 4-9}$ and $\text{Kv10.1}^{\Delta 4-7}$ colocalize with Kv10.1 . Confocal microscopy experiments: (A) Images of $\text{Kv10.1}^{\Delta 4-9}$ -mVenus and Kv10.1 -mCherry and the merge of the two channels. (B) Images of $\text{Kv10.1}^{\Delta 4-7}$ -mVenus, Kv10.1 -mCherry and the merge of the two channels. (C) Plot profile of $\text{Kv10.1}^{\Delta 4-9}$ and Kv10.1 channels derived from the yellow cursor in panel A. (D) Plot profile of $\text{Kv10.1}^{\Delta 4-7}$ and Kv10.1 channels derived from the yellow cursor in panel B.

4.3 Impact of $\text{Kv10.1}^{\Delta 4-9}$ and $\text{Kv10.1}^{\Delta 4-7}$ on Kv10.1 electrophysiological properties in the *Xenopus laevis* expression system

After having ascertained that $\text{Kv10.1}^{\Delta 4-9}$ and $\text{Kv10.1}^{\Delta 4-7}$ are interaction partners of full-length Kv10.1 channels, the next experimental task was to assess whether the short isoforms would affect the electrophysiological properties of the channel. In order to test this, *Xenopus laevis* oocytes were injected with RNA coding for Kv10.1 , or a mixture of RNA coding for Kv10.1 together with $\text{Kv10.1}^{\Delta 4-9}$ or $\text{Kv10.1}^{\Delta 4-7}$, at ratio 1:1 or 1:10 (Fig. 14 A). The macroscopic Kv10.1 current was measured using the two-electrode voltage clamp (TEVC) technique, using a protocol where the voltage was driven from -

60 mV to +80 mV, with voltage steps of 20 mV. In these experiments $K_V10.1$ current amplitude was significantly down-regulated by either co-injection with $K_V10.1^{\Delta4-9}$ or with $K_V10.1^{\Delta4-7}$ splice isoforms (Fig. 14 B). At 80 mV the average current reduction was $43.8 \pm 8.4\%$ ($p < 0.001$) and $36.1 \pm 9.5\%$ ($p = 0.005$), respectively. The $K_V10.1$ current reduction was even more pronounced at higher $K_V10.1^{\Delta4-9}$ or $K_V10.1^{\Delta4-7}$ concentration (1:10 ratio samples): $67.8 \pm 8.3\%$ ($p < 0.001$) and $65.5 \pm 7.4\%$ ($p < 0.001$) (Fig. 14 C), respectively. It is important to note that the current reduction detected in the cells under co-expression of $K_V10.1$ with $K_V10.1^{\Delta4-9}$ or $K_V10.1^{\Delta4-7}$ was not caused by the increased cRNA concentration or overloading of protein translation system since oocytes injected with higher quantity of $K_V10.1$ cRNA (up to $10 \text{ ng}/\mu\text{l}$), showed considerable increase in current magnitude (reaching up to $30 \text{ }\mu\text{A}$), already one day after injection (data not shown).

Figure 14 $K_V10.1$ current is down-regulated under co-expression with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ in a dose-dependent manner. Two-electrode voltage clamp recordings: (A) $K_V10.1$ macroscopic current traces recorded in $K_V10.1$, $K_V10.1$ with $K_V10.1^{\Delta4-9}$ or with $K_V10.1^{\Delta4-7}$ samples at 1:1 and 1:10 ratios. (B) I-V graph representing the macroscopic $K_V10.1$ current at each voltage step. (C) Bar graph resuming the macroscopic $K_V10.1$ current values at +80 mV.

A defining electrophysiological feature of $K_V10.1$ channel consists in a progressive deceleration of activation kinetics at increasing hyperpolarizing pre-pulses, reminiscent of Cole-Moore shift (Ludwig et al., 1994). To estimate the influence of splice isoforms on $K_V10.1$ activation kinetics, a depolarization pulse after conditioning at two different negative holding potentials was applied, and the rise time of activation from 20% to 80% of maximal current was calculated for both -60 mV and -120 mV pre-pulses potentials for all the samples. All the recordings of cells expressing $K_V10.1$ channels, either alone or in combination with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ splice isoforms, showed strong dependence of activation kinetics on pre-pulse potentials (Fig. 15 A). In particular, no difference was detected between samples expressing $K_V10.1$ and expressing $K_V10.1^{\Delta4-9}$ or $K_V10.1^{\Delta4-7}$ in 1:1 ratio with the full-length channel, having rise time of 45.8 ± 8 ms, 36.9 ± 5 ms ($p=0.38$) and 47.02 ± 7 ms ($p=0.91$) at -120 mV pre-pulse potential, respectively. At -60 mV the rise time values for $K_V10.1$, $K_V10.1+$

$K_V10.1^{\Delta4-9}$ and $K_V10.1 + K_V10.1^{\Delta4-7}$ were: 5.9 ± 1 ms, 9.12 ± 1 ms ($p=0.09$) and 9.41 ± 3 ms ($p=0.11$) (Fig. 15 B), respectively. On the other hand, when co-expressed in 1:10 proportions, both $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ caused significant deceleration of the channel activation after -60 mV conditioning: $257 \pm 47\%$ ($p<0.0001$) and $220 \pm 37\%$ ($p<0.0001$), while at -120 mV the increase of the rise time did not reach statistical significance ($20 \pm 27\%$; $p=0.46$ and $41 \pm 24\%$; $p=0.09$) (Fig. 15 B).

Figure 15 $K_V10.1$ activation kinetics result decelerated under co-expression (in 1:10 ratio) with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$. Two-electrode voltage clamp recordings: (A) Representative traces of $K_V10.1$ activation kinetics after pre-pulse potentials sweeps of -120 mV and -60 mV. (B) Bar graph describing the rise times of $K_V10.1$ activation from 20% to 80% of maximal current for each pre-pulse potential.

4.4 $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ impact on $K_V1.4$ -elicited currents

In order to determine if the dominant-negative effect exerted by $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ on $K_V10.1$ current are specific to $K_V10.1$ channel, TEVC recordings on oocytes co-expressing $K_V10.1^{\Delta4-9}$ or $K_V10.1^{\Delta4-7}$ with $K_V1.4$ channel were carried out; the same voltage step protocol to study the current-voltage relation previously described was applied (Fig. 16 A). $K_V1.4$ is a voltage-gated potassium channel from Shaker-related subfamily, encoded by *KCNA4* gene (Bett and Rasmusson, 2004). Unlike $K_V10.1$, $K_V1.4$ undergoes rapid N-type inactivation (Fan et al., 2013). $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ splice isoforms expression did not result in any consistent effect on $K_V1.4$ current, with the exception of the $K_V10.1^{\Delta4-9}$ co-expression in 1:10 ratio group, where a significant reduction of $37 \pm 16\%$ ($p=0.02$) of $K_V1.4$ current at 80 mV was detected (Fig. 16 B). Overall, the effects on current magnitude mediated by $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ splice isoforms are likely to be specific for $K_V10.1$ channel family.

Figure 16 $K_v1.4$ current is not altered by co-expression with $K_v10.1^{\Delta4-9}$ and $K_v10.1^{\Delta4-7}$ (except for $K_v1.4/K_v10.1^{\Delta4-9}$ samples in 1/10 ratio). Two-electrode voltage clamp recordings: (A) $K_v1.4$ macroscopic current traces recorded in $K_v1.4$, $K_v1.4$ with $K_v10.1^{\Delta4-9}$ or with $K_v10.1^{\Delta4-7}$ samples at 1:1 and 1:10 ratios. (B) I-V graph representing the mean $K_v1.4$ current at each voltage step.

4.5 $K_v10.1^{\Delta4-9}$ and $K_v10.1^{\Delta4-7}$ effects on $K_v10.1$ currents in a heterologous expression system of human origin.

Studies on the impact of $K_v10.1$ splice isoforms on the electrophysiological properties of the channel were also performed using a mammalian cell line system: HEK cells stably transfected with $K_v10.1$ were transiently co-transfected with DNA constructs encoding $K_v10.1^{\Delta4-9}$ and $K_v10.1^{\Delta4-7}$ fused with the fluorescent protein mVenus. As control group, HEK- $K_v10.1$ cells co-transfected with a plasmid containing mVenus alone were used. The patch clamp technique under whole cell configuration was the method used for recordings of $K_v10.1$ macroscopic currents. Current traces were obtained using the following protocol: discrete depolarization pulses between -60 mV and +80 mV (in 20 mV increments) of 300 ms length were applied from a holding potential of -80 mV (Fig. 17 A). $K_v10.1$ produced slowly activating, outward rectifying currents, which did not inactivate; an inward rectification was observed with strong depolarizations. This is compatible with a block exerted by intracellular sodium (Pardo et al., 1998). The detected steady state current was averaged (between 80% and 90% of the time of the depolarization pulse) and normalized by the size of cell membrane before analysis. As already observed in TEVC experiments, also in this context

$K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ co-expression with the full-length channel resulted in a marked $K_V10.1$ current reduction of $41.7 \pm 20.5\%$ ($p=0.04$) for $K_V10.1^{\Delta4-9}$ and $53.8 \pm 21.1\%$ ($p=0.01$) for $K_V10.1^{\Delta4-7}$ (Fig. 17 B and C), respectively.

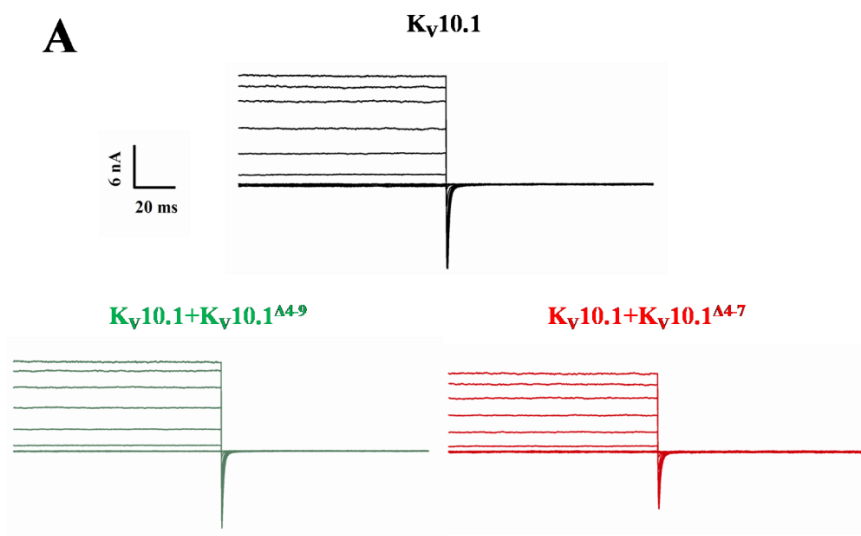

Figure 17 $K_V10.1$ current is down-regulated under co-expression with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ in a human-derived heterologous expression system. Patch clamp experiments: HEK cells expressing $K_V10.1$ co-expressing either mVenus (depicted in black), $K_V10.1^{\Delta4-9}$ mVenus (in green) or $K_V10.1^{\Delta4-7}$ mVenus (in red). Only green fluorescent cells visualized under epifluorescence microscope were used for recordings. (A) Representative current traces. (B) To determine the current-voltage relationship, the steady-state current was measured at the end of each pulse and normalized against cell size. (C) Bar graph resuming the $K_V10.1$ current density values at +80 mV.

4.5.1 Investigations on the voltage dependence of the $K_V10.1$ conductance under co-expression with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$

To determine the impact of co-expression with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ on the voltage dependence of $K_V10.1$, tail current protocols in high extracellular potassium were used. The membrane potential was depolarized for 300 ms to a range of voltages between +80 and -80 mV in 20 mV decrements, followed by a hyperpolarization step to -120 mV for 300 ms (Fig. 18 A). The relative conductance (G/G_{max}) values were obtained by extrapolating the peak tail current amplitudes for each voltage (as described in section 3.4.2 of materials and methods) and normalizing them against the peak tail current recorded at +80 mV.

Normalized current amplitude plotted was against the voltage then fitted with a Boltzmann sigmoid function. The resulting V_{half} (voltage of half-maximal activation) was 21 ± 1.7 mV for $K_V10.1$ control, 23 ± 7.3 mV for $K_V10.1 + K_V10.1^{\Delta4-9}$ and 20 ± 1.3 mV, for $K_V10.1 + K_V10.1^{\Delta4-7}$. The slope factor k obtained were 19 ± 1.5 mV, 20 ± 3.3 mV and 19 ± 1.2 mV (Fig. 18 B), respectively. In conclusion, no significant changes in voltage dependence of $K_V10.1$ conductance were detected upon co-expression with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$.

Figure 18 Voltage dependence of the $K_V10.1$ conductance is not affected by co-expression with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$. Patch clamp recordings of HEK cells: samples expressing $K_V10.1$ and co-expressing either mVenus are depicted in black, $K_V10.1^{\Delta4-9}$ mVenus (in green) or $K_V10.1^{\Delta4-7}$ mVenus (in red). Only green fluorescent cells visualized under epifluorescence microscope were used for recordings. (A) Representative $K_V10.1$ tail currents. (B) G-V graph was generated from tail current analyses utilizing the Boltzmann function, representing the mean of $K_V10.1$ conductance *versus* the maximal conductance at each voltage step.

4.6 Mechanism of current amplitude reduction of $K_V10.1$ channels induced by $K_V10.1^{\Delta4-9}$ or $K_V10.1^{\Delta4-7}$ co-expression

The changes in total current I occurring when the short isoforms $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ are expressed together with the full-length channel may result from altered number of channel surface expression (N), changed single channel conductance (i) or open probability (P_o) or by a combination of these (see equation 3 in materials and methods). To distinguish between these possibilities, non-stationary noise analysis was performed on excised *Xenopus laevis* oocyte macropatches in the outside-out configuration, in order to quantify single channel conductance i , probability P_o at a given voltage, as well as the number of channels N in the patch. However, due to the tendency of the channels to be clustered on the membrane surface of the cell, the detected number of channels in each patch would have a different ratio with the total number of channels. This would make pointless to compare or to average N between different patches. Therefore, changes in the amount of $K_V10.1$ channel expressed at the

surface under co-expression with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ will be quantified using a biochemical approach (section 4.7).

Noise analysis recordings were carried out applying to the membrane patch several hundreds of depolarizing stimuli to 40 mV. Then the variance of each trace with respect to the average trace was determined, and a parabola function was fitted to the current against the variance data (Fig. 19 A). The results of the fitting in terms of single channel current i showed unaltered values between $K_V10.1$ (985 ± 322 fA) and $K_V10.1$ co-injected with $K_V10.1^{\Delta4-7}$ (872 ± 69 fA, $p=0.86$, Fig. 19 B) samples, whereas in the case of $K_V10.1^{\Delta4-9}$ co-injection, the single channel currents showed a reduction reaching statistical significance (596 ± 236 fA, $p=0.041$, Fig. 19 B).

The extrapolated open probability at 40 mV did not show significant changes between the $K_V10.1$ ($47.5 \pm 17\%$), $K_V10.1$ co-injected with $K_V10.1^{\Delta4-9}$ ($45.7 \pm 13\%$; $p=0.94$, Fig. 19 C) and $K_V10.1$ co-expressing $K_V10.1^{\Delta4-7}$ samples ($42 \pm 15\%$; $p=0.71$, Fig. 19 C). The lack of changes for ' i ' and ' P_o ' under co-expression with $K_V10.1^{\Delta4-7}$ suggest that the previously recorded reduction in macroscopic channel both in oocytes and HEK cells would be caused by a reduced amount of channel N . On the other hand, the interaction of $K_V10.1^{\Delta4-9}$ with $K_V10.1$ mediating total current I reduction is likely to be related (at least in part) to the reduced i detected applying noise analysis recordings.

Figure 19 Impact of $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ co-expression on $K_V10.1$ single channel current and open probability. Non-stationary noise analysis of $K_V10.1$ -mediated currents. Variance of several hundreds of depolarization pulses at +40 mV was calculated from excised *Xenopus laevis* oocyte macropatches in the outside-out configuration. (A) Representative plots of the variance *versus* the mean current for $K_V10.1$ (depicted in black), $K_V10.1+K_V10.1^{\Delta4-9}$ (in green) and $K_V10.1+K_V10.1^{\Delta4-7}$ (in red) samples, with the corresponding fitting parabola. (B) Bar graph showing the mean single channel current '*i*' for each recorded group. (C) Bar graph showing the mean open probability P_o for each recorded group.

4.7 $K_V10.1$ Surface amount modification in presence of $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$

The neurotoxin α -bungarotoxin (BTX) binds with high affinity the nicotinic acetylcholine receptor (AChR)(Changeux et al., 1970). Researchers took advantage of the fact that BTX can also bind with high affinity a small 13 amino acids peptide that is homologous to the binding region of the subunit of AChR (Harel et al., 2001) and inserted this sequence (bungarotoxin-binding site, BBS) into AMPA receptor subunits. Using fluorescent and biotinylated BTX allowed for specific and quantitative surface labeling of the AMPA receptor (Sekine-Aizawa and Haganir, 2004). Kohl and coworkers adapted this approach to $K_V10.1$ channels, generating the $K_V10.1$ -BBS system, a novel tool for quantitative analysis of surface $K_V10.1$ (Kohl et al., 2011; Herrmann et al., 2012). In this part of work, we aimed to quantify the surface amount of $K_V10.1$ channels utilizing the $K_V10.1$ -BBS cells system. Bungarotoxin-biotin labeled $K_V10.1$ channels contained in the cell lysates were immobilized on streptavidin-coated plates, and a sandwich ELISA was performed. The results of five independent experiments are summarized in Fig. 20. Data represent the amount of surface $K_V10.1$ in HEK- $K_V10.1$ -BBS cells transfected with $K_V10.1^{\Delta4-9}$, $K_V10.1^{\Delta4-7}$ or pCDNA3-mVenus

alone (transfected control), normalized against values of untransfected cells. No relevant difference ($p=0.618$) was detected between $K_V10.1^{\Delta4-7}$ (0.96 ± 0.07) and the control samples (0.91 ± 0.06); conversely the amount of membrane-bound $K_V10.1$ -BBS resulted significantly increased ($p=0.015$) in case $K_V10.1^{\Delta4-9}$ was co-expressed with the full-length channel (1.22 ± 0.09). Cells containing the BBS without α -bungarotoxin treatments as well as cells not containing the BBS were used as negative controls.

Figure 20 $K_V10.1$ surface amount increases in presence of $K_V10.1^{\Delta4-9}$ but not with $K_V10.1^{\Delta4-7}$. ELISA experiments: surface $K_V10.1$ -BBS amount was quantified for HEK- $K_V10.1$ -BBS transfected either with pCDNA3 (depicted in black, control group), $K_V10.1^{\Delta4-9}$ (in green), or $K_V10.1^{\Delta4-7}$ (in red). The presented data are normalized against HEK- $K_V10.1$ -BBS untransfected cells values, and are derived from five independent experiments.

These results, contrary to what had been hypothesized after noise analysis recordings, point against the possibility that $K_V10.1^{\Delta4-7}$ reduce the amount of surface $K_V10.1$ channels. However, if we consider that noise analysis takes in account only active channels, whereas the bungarotoxin used for our surface $K_V10.1$ quantifications tags all the $K_V10.1$ subunits located at the membrane surface, we propose that the factor underlying the $K_V10.1^{\Delta4-7}$ -mediated $K_V10.1$ current down-regulation is a reduction in the number of active channels situated at the membrane surface. For the same reason, the observed increase of $K_V10.1$ surface amount in $K_V10.1$ - $K_V10.1^{\Delta4-9}$ samples could be due to functionally defective $K_V10.1$ channels in the cell membrane.

4.8 K_V10.1, K_V10.1^{Δ4-9} and K_V10.1^{Δ4-7} organization in native conditions

In order to study the oligomeric state of K_V10.1, K_V10.1^{Δ4-9} and K_V10.1^{Δ4-7} in native conditions, and to address the question whether K_V10.1^{Δ4-9} and/or K_V10.1^{Δ4-7} form heteromeric complexes with the full-length K_V10.1, we performed biochemical assays maintaining native conditions, preserving the quaternary structure of the protein complexes. Blue Native PAGE (BN-PAGE) experiments were therefore carried out: membrane-enriched lysates from HEK-K_V10.1 cells transfected either with mVenus, K_V10.1^{Δ4-9} mVenus or K_V10.1^{Δ4-7} mVenus were subjected to electrophoretic separation on native polyacrylamide gel, then blotted on PVDF membrane. Membranes were decorated with an anti K_V10.1 antibody targeting the C-terminal part of the full-length sequence and therefore recognizing also K_V10.1^{Δ4-9} and K_V10.1^{Δ4-7} epitopes. Under these conditions, broad bands of apparent molecular weight of approximately 900 kDa were detected in all the K_V10.1 positive cells; the same was observed for the K_V10.1^{Δ4-9} and K_V10.1^{Δ4-7} samples not containing K_V10.1, indicating that also the short isoforms are arranged in macrocomplexes of apparent molecular weight of ~900 kDa (Fig. 21 A).

To determine whether the macro-complexes detected here contained both short and full-length isoforms, rather than only one of these components, two-dimensional SDS-PAGE were carried out. With these experiments we could dissociate the components of the macro-complexes and separate them according to their molecular weight. In both K_V10.1+ K_V10.1^{Δ4-9} and K_V10.1+ K_V10.1^{Δ4-7} samples, the 900 kDa complex contained full-length monomers of respectively ~140 kDa together with short isoform monomers of apparent molecular weight respectively ~90 kDa and ~105 kDa (Fig. 21 B).

Based on their electrophoretic mobility we propose that in native conditions, full-length channel and short isoforms are likely to be assembled in supramolecular complexes, probably together with additional proteins. Yet, we are not able to tell whether they are organized in homo- or heterotetramers. However, despite our effort to refine the experimental conditions, in our experiments we still noticed a consistent amount of protein retained into the wells, which could be a sign of incomplete protein solubilization (Reisinger and Eichacker, 2007). Improvement in solubilization could change the electrophoretic behavior of our protein complexes, helping us to

discriminate between the presence of $K_V10.1$ homo- or heterotetramers in our preparations.

Figure 21 $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ interact with $K_V10.1$ in native conditions. (A) BN-PAGE: ~900 kDa macromolecular complexes were detected in all the $K_V10.1$ positive and $K_V10.1^{\Delta4-9}/ K_V10.1^{\Delta4-7}$ $K_V10.1$ negative samples; the band at ~150 kDa was unspecific because revealed also in $K_V10.1$ negative samples. (B) Two-dimensional SDS-PAGE: the macromolecular complex contained both the full-length channel and the short isoforms.

4.9 Structural determinants of the interaction between $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ and full-length $K_V10.1$

The tetramerizing coiled coil (TCC) is a 41 amino acid sequence in $K_V10.1$ C-terminus region, responsible for its correct assembling in the tetrameric structure characteristic of the functional channel. A leucine to tyrosine mutation at position 20 within this sequence (L20Y) has been described to impair the ability of the channel to tetramerize and to preclude formation of functional ion channels (Jenke et al., 2003). Here, the L20Y mutation was used to check whether TCC is critical for the interaction between short isoforms $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$, and the full length $K_V10.1$. TCC sequence was mutated in both splice variants $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ sequences by site directed mutagenesis, and the existence of interaction was investigated by means of co-IP experiments: immunoprecipitation of mVenus protein fused to $K_V10.1^{\Delta 4-9}$ L20Y and $K_V10.1^{\Delta 4-7}$ L20Y samples was followed by blotting the membrane with an antibody against $K_V10.1$ (C-terminus): both mutated $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ coprecipitated with $K_V10.1$ (protein size ~130 kDa), although in $K_V10.1^{\Delta 4-9}$ immunoprecipitation resulted quantitatively less efficient than in $K_V10.1^{\Delta 4-7}$ L20Y samples (Fig. 22).

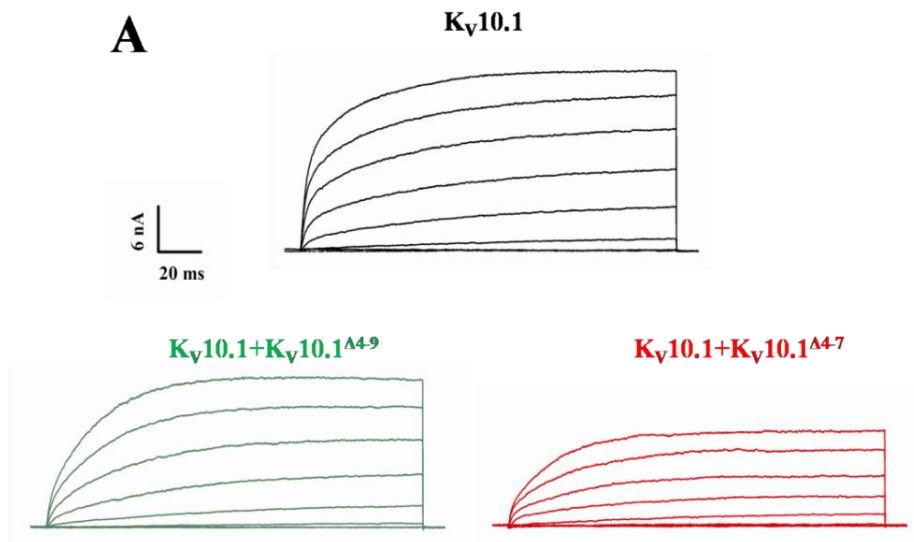

Figure 22 $K_V10.1$ short isoforms expressing a defective TCC domain coprecipitate with the full-length channel. Co-IP experiments: immunoprecipitation of mVenus in $K_V10.1 + K_V10.1^{\Delta 4-9}$ L20Y and $K_V10.1 + K_V10.1^{\Delta 4-7}$ L20Y co-precipitated $K_V10.1$ protein (~130 kDa). Input samples consist of 10% (20 μ g) cell extracts.

4.9.1 Impact of TCC inactivation on the $K_V10.1$ current modulation exerted by $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$

Provided that $K_V10.1$ and short isoforms having altered TCC domain still co-immunoprecipitate, the $K_V10.1$ electrophysiological properties under co-expression with the L20Y splice variants constructs were analyzed with patch clamp recordings in the whole cell configuration (Fig. 23 A). Using as reference $K_V10.1$ -expressing cells, at 80 mV voltage, $K_V10.1$ current density was down-regulated by $45.3 \pm 20.3 \%$ ($p=0.03$) in $K_V10.1 + K_V10.1^{\Delta 4-7}$ L20Y samples (Fig. 23 B and C), similarly to prior recordings with $K_V10.1 + K_V10.1^{\Delta 4-7}$ WT.

Conversely, in $K_V10.1 + K_V10.1^{\Delta 4-9}$ L20Y samples the mild current reduction recorded ($20.8 \pm 21.9 \%$) was not statistically significant compared to the reference group ($p=0.34$, Fig. 23 B and C), in contrast with the outcome of previous electrophysiological analysis performed with $K_V10.1 + K_V10.1^{\Delta 4-9}$. This result strongly indicates that current reduction of $K_V10.1$ requires an intact TCC, therefore suggesting that the TCC sequence plays a critical role in the $K_V10.1^{\Delta 4-9}$ -induced $K_V10.1$ current decrease.

Figure 23 $K_v10.1$ current amplitude is unaffected by co-expression with $K_v10.1^{\Delta 4-9}$ -L20Y, whereas diminished with $K_v10.1^{\Delta 4-7}$ -L20Y. Patch clamp recordings of HEK cells: cells expressing $K_v10.1$ co-expressing either mVenus are depicted in black, $K_v10.1^{\Delta 4-9}$ -L20Y-mVenus (in green) or $K_v10.1^{\Delta 4-7}$ -L20Y-mVenus (in red). Only green fluorescent cells visualized under epifluorescence microscope were used for recordings. (A) Typical $K_v10.1$ current traces. (B) I-V graph representing the mean of $K_v10.1$ current density at each voltage step. (C) Bar graph resuming the $K_v10.1$ current density values at +80 mV.

4.9.2 Effects on $K_v10.1$ glycosylation pattern mediated by $K_v10.1^{\Delta 4-7}$ interaction with the full-length channel

N-Linked glycosylation is a common post-translational modification of membrane proteins. Proper glycosylation is required for correct trafficking of $K_v10.1$ protein to the membrane and important for the regular function of the channel already inserted in the membrane (Napp et al., 2005). $K_v10.1$ glycosylation pattern (after immunoblotting using a specific antibody) consists of two distinct bands, with electrophoretic mobilities corresponding to ~110 and ~130 kDa (termed E110 and E130). E110 corresponds to core glycosylated $K_v10.1$ located in the ER and Golgi, while E130 is a post ER, complex glycosylated isoform (Napp et al., 2005). Results from co-IP experiments

previously performed showed that under co-expression with $K_V10.1^{\Delta4-7}$, $K_V10.1$ protein presented an altered electrophoretic pattern, compared with $K_V10.1^{\Delta4-9}$ co-expression (Fig. 12 A). We wanted now to determine whether this phenomenon was a result of modified glycosylation occurring to $K_V10.1$ under co-expression with $K_V10.1^{\Delta4-7}$. To this aim, we performed an immunoprecipitation with an antibody targeting mVenus, then we digested the samples with the enzymes Endo H (removing only core oligosaccharides) and PNGase F, (which fully deglycosylates proteins). $K_V10.1$ glycosylation pattern resulted indistinguishable in both the cases $K_V10.1$ is expressed alone or in combination with $K_V10.1^{\Delta4-9}$. Unlike the previous cases, $K_V10.1$ glycosylation pattern was changed under co-expression with $K_V10.1^{\Delta4-7}$: E130 band was very faint (Fig. 24 A) in the control lane, and virtually absent in the PNGase F-treated samples. This would suggest that interaction between the full-length and $K_V10.1^{\Delta4-7}$ occurs when the $K_V10.1$ protein is at immature state and that under these conditions its further glycosylation is impaired. The result of this phenomenon is a progressive reduction of $K_V10.1$ complex glycosylated fraction in a $K_V10.1^{\Delta4-7}$ dose-dependent manner. This is accompanied by a parallel increase of E110 $K_V10.1$ form, as resulting from this IP experiment using oocytes injected with different ratios $K_V10.1/K_V10.1^{\Delta4-7}$ (Fig. 24 B and C).

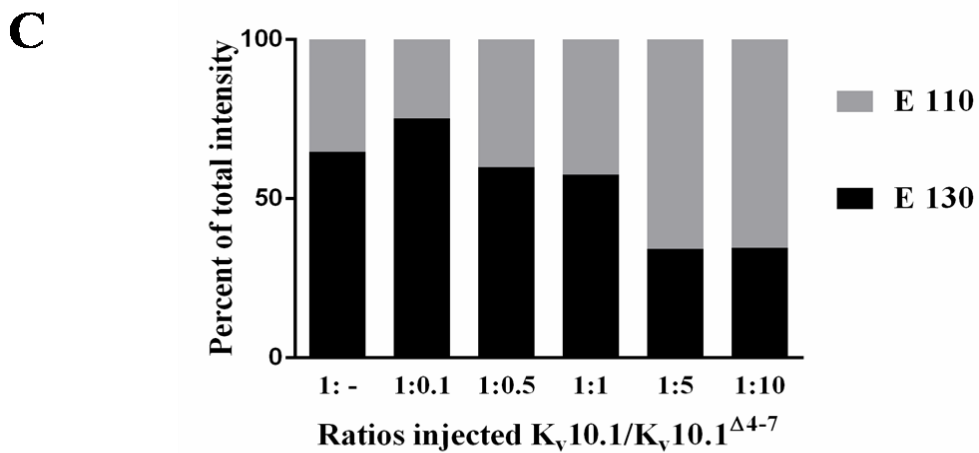

Figure 24 Analyses of K_V10.1 glycosylation under co-expression with K_V10.1^{Δ4-7} and K_V10.1^{Δ4-9}. (A) Co-immunoprecipitation of K_V10.1 with the short isoforms K_V10.1^{Δ4-9} and K_V10.1^{Δ4-7} performed using Endo H and PNGase F to highlight the K_V10.1 glycosylation pattern. Notice that E130 is virtually absent under co-interaction K_V10.1-K_V10.1^{Δ4-7}. (B) Immunoprecipitation of K_V10.1 and K_V10.1^{Δ4-7} proteins in oocytes injected with increasing ratios K_V10.1^{Δ4-7}-K_V10.1. E110/E130 ratio increases together with increasing ratios of K_V10.1^{Δ4-7}/ K_V10.1cRNA injected. (C) Densitometric analysis of Fig. 4.16 B: for each injected group, single E110 and E130 densitometry values were normalized against the sum of E110 + E130.

4.10 Analyses of the possible impact of $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ on the proliferation and cell cycle progression of $K_V10.1$ -expressing cells

$K_V10.1$ channels expression and function has been related to cell proliferation (Pardo et al., 1999; Weber et al., 2006). Moreover, $K_V10.1$ channel activity is thought to be dependent on the cell cycle phase (Meyer and Heinemann, 1998; Camacho et al., 2000). Here we investigated whether the $K_V10.1$ interaction with $K_V10.1^{\Delta4-9}$ and $K_V10.1^{\Delta4-7}$ and the underlying channel functional reduction lead to consequences in terms of cell proliferation and variations in cell cycle distribution. We performed live cell imaging with an IncuCyte Zoom device on cells transiently transfected with either $K_V10.1^{\Delta4-9}$ or $K_V10.1^{\Delta4-7}$. pCDNA3-mVenus was the construct transfected in the cells of the control group. A cell confluency mask was created, and the confluency percentage was plotted *versus* the time of culture (analyses always started 5 hours after transfections) (Fig. 25). In HEK- $K_V10.1$ cells, the proliferation rate was virtually indistinguishable between short isoforms-transfected cells and the control group (data not shown). In SH-SY5Y, $K_V10.1^{\Delta4-9}$ transfected cells showed a mild reduction in proliferation, which peaked (-8.37%) at about 50 hour after the analysis started, albeit not statistically significant ($p \geq 0.608$). Similarly, the proliferation rate of the $K_V10.1^{\Delta4-7}$ -transfected cells was reduced. The difference was the most prominent at ~60 hour after analysis start (-18.1%); however this difference was also not statistically significant ($p \geq 0.145$). Overall, no significant changes in $K_V10.1$ expressing cell proliferation were observed under co-expression with $K_V10.1^{\Delta4-9}$ or $K_V10.1^{\Delta4-7}$.

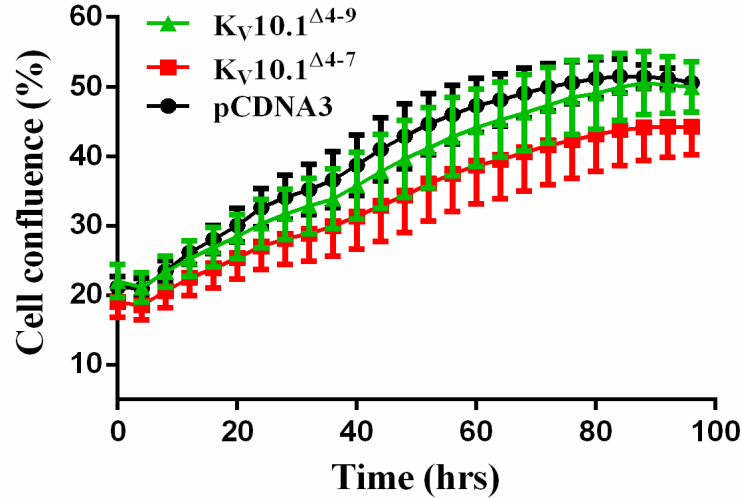

Figure 25 $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ overexpression does not significantly affect the growth rate of SH-SY5Y cells. In the graph are depicted the growth kinetics of SH-SY5Y cells transiently transfected with either $K_V10.1^{\Delta 4-9}$ (green line), $K_V10.1^{\Delta 4-7}$ (red line), or a pCDNA3 empty vector (black line; control group). The time interval between each measurement is 4 hours.

We also evaluated the cell cycle distribution of $K_V10.1$ expressing cells, under co-expression with either pCDNA3 empty vector, $K_V10.1^{\Delta 4-9}$ or $K_V10.1^{\Delta 4-7}$. To this aim we stained the cells' DNA with Pi and performed flow cytometry experiments. Both cells natively expressing splice variants (SH-SY5Y) as well as non-expressing $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ cells (CHO- $K_V10.1$ cells) were used in these experiments (Fig. 26). No evident changes in the fraction of cells retained in different cell cycle phases were observed in any of the cell lines investigated.

Figure 26 Expression of $K_V10.1^{\Delta 4-9}$ and $K_V10.1^{\Delta 4-7}$ does not alter the cell cycle profile of CHO- $K_V10.1$ and SH-SY5Y cells. The fraction of cells in G0/G1 is depicted in black; cells in S phase are in grey; and G2/M cells represent the dark grey fraction.

5. Discussion

The general aim of the present thesis work has been to study the impact of alternative splicing on K_V10.1 biological properties, by first confirming the expression of K_V10.1 short isoforms in native system, and then studying the mechanisms and consequences of interaction in detail. We started providing direct evidence of E65 and E70 expression in native systems. Both of the short isoforms coprecipitated and colocalized with K_V10.1 full-length channel in a reconstituted system. Remarkably, E65 and E70 also occurred together with the full-length channel in the same supramolecular complex in native conditions. A robust down-regulation of ion currents through K_V10.1 channels was observed when K_V10.1 was co-expressed with E65 and E70. The modulation is dose-dependent and most likely specific to K_V10.1 channels, since there was generally no effect on K_V1.4 current properties. Possible mechanisms underlying E65- and E70-induced current down-regulation were also investigated. The two short isoforms seem to affect K_V10.1 function through different mechanisms. In the case of E65 the TCC, although not required for the interaction between the two proteins, seems to play a critical role in the modulation of K_V10.1 current amount. On the other hand E70 expression impaired the glycosylation of K_V10.1 channels and was independent of TCC; this would probably result in the production of ‘immature’ ion channels which, although capable of reaching the membrane, would be defective in terms of function.

5.1 K_V10.1 short isoforms are expressed in normal brain and cell lines from diverse origins

E65 and E70 are non-channel proteins recently identified in our laboratory that are derived from alternative spliced K_V10.1 voltage-gated potassium channels. By PCR analysis, E70 was found in human brain (Pardo LA, unpublished data) and in the

melanoma cell line IPC 298 (Ramos Gomes PhD thesis, 2010), while E65 was isolated IGR 39, another melanoma cell lines.

It was crucial to confirm that the expression of the splice variants was not due to artifacts derived from DNA amplification. This was achieved using the nuclease protection assay (Cocquet et al., 2006; Roy and Irimia, 2008). E65 expression was found in IGR 39 melanoma cell lines (experiments performed by Dr. Ramos Gomes) whereas E70 was detected in the neuroblastoma cell lines IMR 32 and SH-SY5Y (Fig. 11). Nuclease protection assay (RPA) did not confirm the expression of E70 previously detected with nested PCR in IPC 298 cells

Nested PCR experiments were also carried out in a panel of cancer as well as non-cancer cell lines (see table 6). The outcome matched with the result of RPA experiments, and moreover suggested that expression of short isoforms is not limited to cancer cells, since E65 was detected in the prostate epithelium cells and E70 was found in human brain. Presumably, E65 and E70 expression does not derive from cancer-specific events driving alternative splicing. E65 and E70 production would rather be the result of a conserved splicing mechanism occurring in both physiological and pathological scenarios.

Unfortunately, expression of E65 and E70 could not be quantitatively measured by real-time PCR analysis. Specifically designed E65/E70 primers and TaqMan probes showed high sensitivity towards plasmid DNA as a template (Fig. 10), but could not detect the splice variants in cells natively expressing the short isoforms. PCR in general is a very sensitive technique (10-50 copies mRNA target represent a realistic detection limit (Piatak et al., 1993)), but the relative sensitivities of nested and real-time PCR are under dispute. Some reports claim that real-time PCR sensitivity is equivalent or even superior to nested PCR (Drago et al., 2004; Kawada et al., 2004; Kim et al., 2008), but others conclude the opposite (Elmaagacliet al., 2000; Guo et al., 2002; Takenokuchi et al., 2004). In agreement with the latter reports, in this work we could successfully amplify E65 and E70 with nested PCR, but not with real-time PCR.

We successfully detected both isoforms in RPA assays, which have a detection limit of $\sim 10^5$ transcript copies (Foley et al., 1993), much less sensitive than PCR techniques.

However, the amount of template used for RPA was ~400 times higher (80 µg) than for PCR (~200 ng), and therefore sensitivities cannot be compared.

In accordance with the scarce E65 and E70 transcripts expression, we did not detect the presence of bands of molecular weight compatible with the predicted 65 and 70 kDa by western blot in natively expressing systems, although they were detected in lysates from cells overexpressing constructs encoding both the K_V10.1 short isoforms.

The scant E65 and E70 expression levels in the heterogeneous cell population can be due to low expression levels in a majority of cells, but also to a higher level in a restricted subpopulation. In this regard, AS regulation driving E65 and E70 expression could be a time-selective process, depending on a particular phase of cell cycle, or triggered by defined transcription factors or protein modifications. Interestingly, full-length K_V10.1 channel expression is selectively regulated along the cell cycle, as initially described (Meyer and Heinemann, 1998; Pardo et al., 1998; Camacho et al., 2000), and more recently by Urrego Blanco from our research group (Urrego Blanco PhD thesis, 2014)). Therefore it is conceivable that E65 and E70 expression could also be cell cycle-dependent. This would not be unique for K_V10.1, because the AS pattern of Cav3.1 and K_V11.1 (which belongs to the eag family) channels changes during differentiation of neuroblastoma cells (Crociani et al., 2003; Bertolesi et al., 2006). We tested this hypothesis by synchronizing cells natively expressing K_V10.1 at the G1/S boundary of the cell cycle using the double thymidine block strategy (Prescott et al., 1971): we noticed changes in E65 and E70 expression pattern along the cell cycle (data not shown). However, since we were forced to use the nested PCR technique (see above), the quantification was arduous and we could draw no conclusive statement regarding this assumption.

In a recent publication, Sun and coworkers reported that calcium influx (mediated by ionomycin) or activation by either PKA or PKC (Sun et al., 2009) stimulate the production of a short isoform of D-Eag1, the K_V10.1 ortholog in *Drosophila*. Importantly, this truncated splicing isoform was generated from cDNA of the full-length channel transfected in mammalian cells, not from genomic DNA in a native system. We tested if a similar mechanism takes place in mammalian cells transfected with full-length K_V10.1 and in cells natively expressing E65 and E70. Ionomycin treatment or stimulation of protein kinase A and C failed to increase transcript

expression, and no E65 or E70 proteins were observed (data not shown). However, it has to be kept in mind that for E65 and E70 transcripts analysis we have to deal with the limitation of nested PCR technique, which is not meant to be a quantitative assay and therefore we may have missed subtle expression changes.

Further investigation will be required to elucidate the factor(s) triggering K_V10.1 short isoforms expression. This would certainly benefit from the comprehension of E65 and E70 physiological and pathophysiological functions.

5.2 E65 and E70 interact with K_V10.1 channel and modulate its function

AS is emerging as a mechanism for the modulation of ion channel function. There are several cases where interaction occurs between functionally inactive splice isoforms and the correspondent full-length ion channel. This is usually associated with modulation of current flow, leading to a dominant negative-effect on current amplitude (Kupersmidt et al., 1998; Chu et al., 2005; Guasti et al., 2008; Veale et al., 2010; Wagner et al., 2010; Ohya et al., 2011; Bidaux et al., 2012).

Here we show for the first time that both non-conducting E65 and E70 splice isoforms interact with full-length K_V10.1 channels (Fig. 12 and 13) and modulate K_V10.1 current amplitude (Fig. 14 and 17), in a dose-dependent manner (Fig. 14). K_V10.1 current undergoes a mild voltage dependent inward rectification in all our recordings. Such a phenomenon appears to be exacerbated upon co-expression with splice variants. This is yet another consequence of the functional modulation mediated by the short isoforms on the full-length channel. Rectification can be caused by at least two different processes (Hille, 2001). In some channels, it is caused by soluble factors blocking the pore, such as Mg²⁺ or polyamines. In others, the rectification is directly caused by voltage- and/or state-dependent conformational changes of the channel. A member of the *eag* family, K_V11.1, undergoes the latter rectification mechanism (Schönherr and Heinemann, 1996; Smith et al., 1996; Spector et al., 1996). K_V10.1 channels expressed in *Xenopus laevis* oocytes can exhibit a dramatic voltage-dependent inward rectification (due to

intracellular Na^+ ions), although this phenomenon is restricted upon onset of maturation (Pardo et al., 1998).

The current modulation by E65 and E70 seems restricted to $\text{K}_V10.1$ channel since the expression of either short isoform did not affect the activity of $\text{K}_V1.4$ voltage-gated potassium channels, albeit E65/ $\text{K}_V1.4$ injected oocytes (at 10:1 ratio) significantly decreased the current through $\text{K}_V1.4$ (Fig. 16). However, E65 is capable of inducing maturation of *Xenopus laevis* oocytes (Ramos Gomes, PhD thesis, 2010). Moreover, current flowing through potassium channels can be altered depending on the cell cycle phase: apart from the already mentioned case of $\text{K}_V10.1$, this phenomenon has been observed in $\text{K}_V11.1$ and $\text{K}_V1.3$ channels (Arcangeli et al., 1995; Chittajallu et al., 2002). It is therefore conceivable that the maturation triggered by E65 may account for the effect on $\text{K}_V1.4$ current, without the need of a direct interaction between E65 and $\text{K}_V1.4$. Nonetheless, it has been reported that the $\text{K}_V1.4$ current amplitude does not dramatically change upon oocyte maturation (Brüggemann et al., 1997).

$\text{K}_V10.1$ activation kinetics were slowed down by an excess (10:1) of either isoform (Fig. 15). Mutations induced in both intracytoplasmic PAS and cNBD domain sequences of $\text{K}_V10.1$ channel also result in decelerated activation kinetics (Stevens et al., 2009). Furthermore, it has been recently described that in the $\text{K}_V10.1$ crystal structures the cNBD and PAS domains interact extensively. Destabilizing the molecular bridge connecting these two regions also affects gating of the channel, resulting in slower activation kinetics (Haitin et al., 2013). Thus, one possibility would be that E65 and E70 expression at high concentration affect the canonical $\text{K}_V10.1$ channel intracytoplasmic folding, modifying the cNBD/PAS domain interaction and affecting the channel activation kinetics.

Further electrophysiological analyses have been carried out to understand the determinant(s) underlying the reduction in $\text{K}_V10.1$ current amplitude induced by the splice variants. Changes in voltage dependence have been excluded (Fig. 18). Total current I flowing through ion channels in a membrane is the product of the number of channels expressed on the plasma membrane N , the channel unitary conductance i , and open probability P_o (see equation 3). Noise analysis revealed that P_o was not significantly affected upon co-expression of $\text{K}_V10.1$ with E65, whereas single channel current i was reduced by ~40% (Fig. 19). This would explain the ~42% reduction in

total current amplitude I that this short isoform exerts on $K_V10.1$ current, albeit surface $K_V10.1$ was significantly increased upon co-expression $K_V10.1$ -E65 (Fig. 20). i and P_o values were unaltered by co-expression of E70, indicating a reduced amount of surface $K_V10.1$. Biochemical binding assays did not corroborate with the assumption of a reduced $K_V10.1$ surface expression in E70 expressing samples.

However, regarding the method used to measure the surface $K_V10.1$, although we know that the stoichiometry of bungarotoxin binding to the BBS of each $K_V10.1$ monomer is 1:1, we cannot exclude the possibility that steric hindrance would allow only one bungarotoxin-biotin molecule binding to the $K_V10.1$ tetramer. Therefore, since the BBS is only present in $K_V10.1$, and not in E65 or E70, if the latter two form heteromultimers with the full-length channel, we could still quantify them with the α -bungarotoxin approach, being unable to distinguish between homotetramers of full-length channel and heteromers with short isoforms. The heteromers are most likely functionally inactive, and not measured by noise analysis recordings. Functionally defective channels arising from a scenario where E65 and E70 would lock the membrane surface $K_V10.1$ in a functionally inactive state without necessarily heterotetramerize would also be measured by our biochemical binding assay, whereas not counted by noise analysis recordings. Ultimately, if we consider that noise analysis takes in account only active channels, whereas the bungarotoxin used for our surface $K_V10.1$ quantifications tags all $K_V10.1$ surface channel subunits, we infer that the reduction in the number of active channels situated at the membrane surface is the factor underlying the E70-mediated $K_V10.1$ current down-regulation.

Unlike what observed with E70, E65 co-expression with $K_V10.1$ results in diminished single channel current i . Moreover, the detected increase in surface expression of $K_V10.1$ subunits could be due to simultaneous effect of this splice variant on trafficking and/or turnover rate of the full-length.

Recapitulating, each of the two short isoforms would achieve the same effect (reducing the $K_V10.1$ current amplitude) through a different mechanism of action: E65 expression would mainly diminish the $K_V10.1$ single channel current, while E70 may render a fraction of channels locked in a non-conducting state.

Both E65 and E70 isoforms occur in the same supramolecular complex together K_V10.1 full-length, as deduced from membrane-enriched extracts in native conditions (Fig. 21). This supports our assumption that each of the short isoforms interacts with the full-length at the plasma membrane. Moreover it suggests that E65/K_V10.1 and E70/K_V10.1 could be components of a bigger macromolecular complex in native conditions. Additional K_V10.1 interaction partners have been identified. The K⁺ channel regulator 1 (KCR1) is a plasma membrane-associated protein binding to the C-terminal region of the rat K_V10.1, modulating its electrophysiological properties (Hoshi et al., 1998). Rabaptin-5 is a binding partner K_V10.1, crucial for trafficking (Ninkovic et al., 2012). Cortactin is an actin-interacting protein implicated in cytoskeletal architecture, binding the K_V10.1 C-terminus and modulating the channel's surface expression (Herrmann et al., 2012). Moreover, Hsu and co-workers reported that 14-3-3 θ , which belongs to a family of proteins abundantly expressed in the brain and implicated in the modulation of several neuronal processes, is a binding partner of the rat K_V10.1 channel. Both the N- and C-termini of the channel are required for association with 14-3-3 θ . Co-expression of 14-3-3 θ with K_V10.1 reduces current amplitude. Interestingly, no apparent alteration of the steady-state voltage dependence, gating kinetics, single channel conductance or changes in surface protein level or membrane trafficking were detected (Hsu et al., 2012). This scenario strongly resembles what we observed for E70.

Speculating about the molecular association between full-length and short isoforms, one of the possibilities would imply heterotetramerization between full-length and short isoforms. Heterotetramerization is a rather common phenomenon among ion channels, also involving voltage-gated potassium channels (Pongs, 1992). Furthermore, both E65 and E70 retain the TCC domain (situated within the C-terminal sequence), critical for channel tetramerization (Jenke et al., 2003; Ludwig et al., 1997). However, despite the presence of these elements, we tend to exclude that heterotetramerization between full-length and short isoforms is taking place for the following reasons. Coiled coils (whose formation underlies tetramerization) are protein-protein interaction domains having a helical arrangement consisting in repetition of a heptad structural motif (*abcdefg*), where the positions *a* and *d* are preferably occupied by hydrophobic amino acids (Lupas, 1996). The lack of hydrophobic region within the splice variants sequences would make the heterotetramer formation energetically unfavorable, as well as result in

functionally inactive channels, because all four subunits must contribute to form the pore, and therefore mutations in the pore are dominant-negative (Kuzhikandathil and Oxford, 2000). Furthermore, TCC-defective E65 and E70 short isoforms conserve the interaction with K_V10.1 (Fig. 22), ruling out the occurrence of heterotetramerization between short isoforms and full-length channel. Consequently, the interaction between short isoforms and K_V10.1 would occur by means of interaction site(s) across the N- and/or C-termini regions, which are mostly conserved in the splice variants and full-length channels.

5.3 Involvement of the TCC domain in the modulation of K_V10.1 channels by E65

We suppose that co-expression of E65 with K_V10.1 causes a reduction of single channel conductance leading to a current amplitude reduction. Additionally, results from the measurement of the surface K_V10.1 subunits, together with the ones from the analysis of further K_V10.1 biophysical properties, suggest that under E65 co-expression a fraction of functionally inactive K_V10.1 channels could be produced (as also observed in the context of E70 co-expression with K_V10.1).

Moreover, we have evidence strongly suggesting that TCC domain is accounting for the observed functional modulation: E65 bearing a TCC domain defective in its ability to tetramerize (mutation L20Y) (Jenke et al., 2003) fails to diminish K_V10.1 current amplitude (Fig. 23), in contrast to co-expression with the E65 WT. To our knowledge, this is the first case in which a channel function alteration mediated by a non-conductive splicing isoform is associated to a specific domain.

E65 L20Y co-precipitates with the full-length K_V10.1 (Fig. 22). This implies that occurrence of physical interaction *per se* is not sufficient to trigger E65-mediated functional modulation of K_V10.1 current. As previously mentioned, K_V10.1 voltage dependent inward rectification in all our recordings was augmented when K_V10.1 was expressed together with the short isoforms. However, this phenomenon was conserved upon co-expression of L20Y splice variants (also in E65 L20Y, where K_V10.1 current down-regulation is virtually absent). This suggests that the voltage-dependent

rectification may be linked to the physical interaction between splice variants and full-length channel rather than to the functional modulation of the channel exerted by E65 and E70.

5.4 Altered K_V10.1 glycosylation could explain the modulation of K_V10.1 channels by E70

Based on experiments, we propose that E70 modulates K_V10.1 by rendering a fraction of K_V10.1 channels non-conductive (this may occur also for E65). How could E70 exert this action? Our data provides a possible answer: E70 coprecipitates prevalently with an immature glycosylated form of K_V10.1 (Fig. 24 A) and its expression diminishes the ratio of complex glycosylated to core glycosylated K_V10.1 in a dose-dependent manner (Fig. 24 B and C). The relevance of glycosylation of K_V10.1 channels has been exhaustively investigated in a previous report from our lab. Interestingly, a K_V10.1 mutant unable to undergo complex glycosylation (N406Q) showed dramatically reduced current amplitude and decelerated activation kinetics (Napp et al., 2005). This resembles the electrophysiological behavior of K_V10.1 channels co-expressed with E70. However, unlike what we observe in K_V10.1/E70 cells, N406Q also exhibits a dramatically reduced surface expression. The latter does not appear to be a general rule: complex N-glycosylation is not required for surface expression of Trpm4b channel (Woo et al., 2013), K_{Ca}1.1 (Pabon et al., 2000), K_V1.1 (Deal et al., 1994) and K_V11.1 (Gong et al., 2002). Altered glycosylation may also reduce the stability of K_V10.1 and K_V11.1 channels, increasing their turnover rate (Napp et al., 2005; Gong et al., 2002). Based on our data, we cannot exclude the occurrence of the latter phenomenon upon co-expression of K_V10.1 with E70.

Endogenous K_V10.1 channels enter the synapses of hippocampal neurons by lateral diffusion (Gómez-Varela et al., 2010). Moreover K_V10.1 channels partition to different membrane subdomains, and this affects current amplitude (without any noticeable effects on other biophysical parameters) (Jiménez-Garduño et al., 2014). In this scenario, E70 expression could modulate K_V10.1 function by influencing membrane

subdomain localization without the need to alter the overall surface expression of channels.

5.5 Possible physiological role of K_v10.1 splice variants

Potassium channels are implicated in diverse physiological and pathophysiological processes. Cell cycle and proliferation, cell migration, invasion and apoptosis are all processes that can be modified by the expression of potassium channels (Pardo and Stühmer, 2014). K_v10.1 has been extensively studied in this context since it displays oncogenic properties: cells expressing K_v10.1 have in general increased proliferation rate and its down-regulation reduces proliferation. Indeed, K_v10.1 blockade mediated by astemizole and siRNA reduces tumor cell proliferation both *in vitro* (Ouadid-Ahidouch et al., 2001; Gavrilova-Ruch et al., 2002; Weber et al., 2006) and *in vivo* (Downie et al., 2008).

RNA interference represents a potent tool to disclose the function of a specific gene. For this reason, siRNA sequences specifically targeting E65 and E70 have been designed to down-regulate the short isoforms. The only primary sequence differences between full-length and splice variants lie in the boundary between exon three and ten (for E65) and exon three and eight (for E70). This limitation adds to the notorious difficulties for the design of an optimal siRNA. Nevertheless, we failed to successfully knock-down the splice variants transcript levels (real-time PCR using overexpressing models, data not shown).

Given these issues with RNA interference methods, we set to gain insights into the E65 and E70 function investigating the effects of their overexpression. In particular, since reduction in K_v10.1 channel activity decreases cell proliferation, it is conceivable that also short isoforms could reduce cell proliferation by diminishing currents through K_v10.1 channels. We tested this hypothesis using K_v10.1 expressing cells that simultaneously overexpress the short isoforms. We did not observe any statistically significant reduction of cell proliferation in E65- nor in E70- transfected cells (Fig. 25). However, low transfection efficiency of the E65 and E70 constructs could account for

the lack of effect on cell proliferation. In this regard, generation of stable cell lines co-expressing short isoforms and full-length channels will help to clarify this issue. Remarkably, it has been recently found that E65 directly activates the maturation of *Xenopus laevis* oocytes, suggesting a role in cell cycle regulation for this splicing isoform (Ramos Gomes Ph.D. thesis, 2010). However, we did not detect obvious changes in cell cycle profile of cells transfected with either E65 or E70 (Fig. 26).

In conclusion, in this study we undoubtedly confirmed the concomitant expression of E65 and E70 with K_V10.1, and we further identified mechanism involved in their modulation of K_V10.1 function. However, more studies will be required in order to unravel the physiological and pathophysiological significance of the E65 and E70 splice variants. So far, the lack of specific knock-downs and pharmacological tools restricted our ‘arsenal’ of methods. Future improvement of the techniques available to manipulate and quantitatively detect the splice variants expression will certainly help to further advance this complex but promising field.

6. Summary

In the past few years, several publications highlighted the role of alternative splicing as additional source of modulation of ion channels activity. E65 and E70 (also termed as $K_V10.1^{\Delta 4-7}$ and $K_V10.1^{\Delta 4-9}$) represent two recently identified non-channel proteins derived from alternative splicing of $K_V10.1$ voltage-gated potassium channels. The two short isoforms were identified with PCR techniques and their physiological significance was largely obscure.

This thesis work primarily aimed at studying the impact of E65 and E70 on $K_V10.1$ properties.

Firstly, the expression of $K_V10.1$ short isoforms in native system was definitely demonstrated by means of nuclease protection assays. Afterwards, occurrence of interaction between both E65 and E70 with $K_V10.1$ was investigated: the two splice isoforms coprecipitated and colocalized with the $K_V10.1$ full-length channel in a reconstituted system. Remarkably, E65 and E70 also occurred together with the full-length channel in the same supramolecular complex in native conditions. A robust down-regulation of ion currents through $K_V10.1$ channels was observed when $K_V10.1$ was co-expressed with E65 and E70. The modulation was dose-dependent and most likely specific to $K_V10.1$ channels, since there were generally no effects on $K_V1.4$ current. The two short isoforms affect the $K_V10.1$ function through different mechanisms. In the case of E65, the TCC domain, although not required for the interaction between the two proteins, seems to play a critical role in the modulation of $K_V10.1$ current. On the other hand E70 co-expression with the full-length channel impairs glycosylation of $K_V10.1$; this would probably result in the production of 'immature' ion channels that, although capable of reaching the membrane, would be defective in terms of function.

$K_V10.1$ channels expression has been implicated in physiological and pathophysiological processes like cell proliferation, cell cycle and cancerogenesis. It was finally investigated whether E65 and E70 could also be involved in cell proliferation and cell cycle modulation. No obvious alterations of cell cycle profile and

growth rate of $K_v10.1$ -expressing cells were observed under overexpression of E65 or E70.

In conclusion, this study unequivocally demonstrated the expression of E65 and E70 in natively expressing systems and provided mechanistic insights into their modulation of $K_v10.1$ channel function; yet further studies will be required in order to unravel the overall E65 and E70 physiological (and eventually pathophysiological) significance.

8. Acknowledgments

I am very grateful to Prof. Dr. Walter Stühmer for hosting me in his department, for all the interesting scientific as well as non-scientific discussions. I am definitely proud of having been part of the staff of this outstanding and open-minded scientist. I would like to thank him also for the organization of exciting departmental lab outings. I enjoyed them a lot.

I express my deepest gratitude to Prof. Dr. Luis Pardo, who represented for me not only an excellent supervisor, but also a wonderful person and a mentor. Whenever I asked, no matter how busy he was, or what time of the day it was, he was always willing to discuss with me any type of issue.

Further, thanks to Prof. Dr. Tobias Moser and to Prof. Dr. Michael Hörner, for their punctual participation to my thesis committee meetings, for the fruitful scientific discussion and suggestions guiding me through the project development. Additional credits to Prof. Dr. Michael Hörner for his great work with the management of the CMPB, the program I am affiliated to, as well as for his commitment to the organization of interesting seminars and retreats.

Many thanks also to Dr. Miso Mitkovski for introducing me to the world of confocal microscopy; I express gratitude also to Kerstin, Uschi and Michael for their excellent technical assistance, and to Ute for her kindness in helping me solving any sort of issue I had along my doctorate path.

Moreover I would like to thank Diana, Camilo, Fernandinha, Ara, Alonso, Aura, Lisa and all the other present and former MBNS colleagues. Thanks to the pleasant atmosphere you created it was much easier for me to work hard and enjoy the everyday's life in the lab.

I also owe a lot to my dearest friends I had the fortune to meet in Göttingen during the last three and half years. They shared with me the joys and helped me to nurse the

sorrows during the nevertheless magnificent adventure of my PhD. Thanks wherever you are now, I hold you in my heart.

And, last but not least....cari mamma e papà se sono arrivato fino a questo punto il merito è anche vostro. Mille grazie per il vostro sostegno incondizionato, vi voglio e vi vorrò sempre bene!

9. Curriculum vitae

PERSONAL DATA

NAME, SURNAME Vincenzo, Romaniello
DATE AND PLACE OF BIRTH June 1st, 1985 in Aversa, Italy
CITIZENSHIP Italian
E-MAIL romaniello@em.mpg.de; siemprevince@hotmail.it

STUDIES AND ACADEMIC CAREER

October 2010 – April 2014 PhD thesis at Oncophysiology group, dept. Molecular Biology of Neuronal Signal, Max-Planck-Institute of Experimental Medicine, Göttingen, Germany.

October 2007- September 2010 Internship at Dept. of Neuroscience with prof. Maurizio Tagliatela, Faculty of Medicine at Università "Federico II", Naples, Italy.

March 2008 - March 2010 Master's degree in Medical Biotechnology at Università Federico II, Naples, Italy (Mark 110/110).

October 2003-March 2008 Bachelor's degree in Medical Biotechnology at Università Federico II, Naples, Italy (Mark 98/110).

LABORATORY SKILLS

CELL CULTURES

- Propagation of primary (rNSC) and secondary cell cultures (HEK293, CHO, COS, C2C12, HeLa, SH-SY5Y, IGR39, etc.).
- Transfection of mammalian cell lines using liposomal and electroporation approaches.

MOLECULAR BIOLOGY

- Total RNA and mRNA isolation from mammalian cells and tissues.
- DNA isolation from bacterial and mammalian cells and tissues.
- PCR: reverse transcriptase PCR (RT-PCR), nested PCR, real-time PCR.
- Molecular cloning: DNA purification from PCR products, ligation, transformation of *Escherichia coli* cells.
- Northern Blot.
- Ribonuclease Protection Assays (RPA) using custom-designed ³²P labeled RNA antisense probes.
- Gene silencing strategies (siRNA, shRNA) in mammalian cells.
- Proliferation assays (MTT, ³H-thymidine, Alamar Blue).
- Site directed mutagenesis.
- RNA injection in *Xenopus laevis* oocytes.

BIOCHEMISTRY

- Protein electrophoresis: SDS-PAGE, blue native PAGE (BN-PAGE), two-dimensional gel electrophoresis (2D SDS-PAGE).
- Protein immunoprecipitation and Western blot.
- Immunocytochemistry (ICC) using mammalian cell lines (HEK293 and C2C12).
- Expertise in inverted and confocal microscopy (Zeiss and Leica devices).

ELECTROPHYSIOLOGY

- Two-electrode voltage clamp in *Xenopus laevis* oocytes.
- Patch clamp recordings in outside out configuration with *Xenopus laevis* oocytes.
- Patch clamp recordings in whole cell configuration with HEK293, CHO, SH-SY5Y and IGR39 mammalian cell lines.

CONFERENCE PARTICIPATIONS

October 2013: 18th World Congress on Advances in Oncology and 16th International Symposium on Molecular Medicine; Hersonissos, Crete, Greece.

<http://tessera.spandidos-publications.com/home>

Giving a talk titled "*Identification of the role of Kv10.1 (Eag1) splice variants in tumors.*"

September 2012: 3rd International Conference on Ion Channels and Transporters in Cancer; Würzburg, Germany. <http://campus.uni-muenster.de/itc2012-wuerzburg.html>

Presenting a poster titled "*Role of alternative splicing on the biological properties of Kv10.1 channels.*"

PUBLICATIONS

Romaniello V, Ramos Gomes F*, Sánchez A, Weber C., Stühmer W. and Pardo LA.*
E65 and E70 represent two novel splicing isoforms modulating Kv10.1 channel function through different biological mechanisms (*in preparation*).

*equal contribution
