

**Quantitative analysis
of protein-protein interactions governing
TASK-1/TASK-3 intracellular transport**

Dissertation

zur Erlangung des mathematisch-naturwissenschaftlichen Doktorgrades

“Doctor rerum naturalium”

der Georg-August-Universität Göttingen

-

im Promotionsprogramm

der Georg-August-University School of Science (GAUSS)

vorgelegt von

Markus Kilisch

aus Osterode

Göttingen, 2016

Betreuungsausschuss:

1. Betreuer Prof. Dr. Ulf Diederichsen, Institut für Organische und Biomolekulare Chemie, Fakultät für Chemie
2. Betreuer Prof. Dr. Blanche Schwappach, Institut für Molekularbiologie, Universitätsmedizin Göttingen

Mitglieder der Prüfungskommission:

- Referent: Prof. Dr. Ulf Diederichsen, Institut für Organische und Biomolekulare Chemie, Fakultät für Chemie
- Korreferentin: Prof. Dr. Blanche Schwappach, Institut für Molekularbiologie, Universitätsmedizin Göttingen

Weitere Mitglieder der Prüfungskommission:

Prof. Dr. Peter Rehling, Institut für Zellbiochemie, Universitätsmedizin Göttingen

Prof. Dr. Claudia Höbartner, Institut für Organische und Biomolekulare Chemie, Fakultät für Chemie

Prof. Dr. Kai Tittmann, Abteilung Bioanalytik, Albrecht-von-Haller-Institut der Pflanzenwissenschaften

Prof. Dr. Michael Meinecke, Pro Futura Research Group, European Neuroscience Institute Göttingen

Tag der mündlichen Prüfung:

Acknowledgements

I wish to express my sincere gratitude to...

... my supervisor, Blanche Schwappach, for having given me the opportunity to work on this project, for continuous scientific council, guidance, encouragement and her endless patience extended during my time in the lab

... my supervisor in the chemistry department, Prof. Dr. Ulf Diederichsen, who agreed to be my first supervisor bridging the cleft between chemistry and medicine.

... Dr. Daniela Bertinetti, who introduced me to fluorescence polarization and extended a hearty welcome to the Department of Biochemistry in Kassel, for her patience, continuous scientific discussions and for letting me use their facilities without reservations.

... my colleague and friend, Dr. Eric Arakel, for the various science related and non-science related discussion, for planning and executing experiments, for his guidance and assistance during my PhD.

... the morons (friends), Jhoncito and Javi (a.k.a. marica), without whom work in the lab wouldn't have been that much fun, for handling Isabella, the SPR machine, in my absence.

... Anne, Eric, Olga, Fabio, Jhon, Javi and all former and recent members, I may have forgotten to mention here, for reading my thesis (special thanks to Anne), for extending a helpful hand performing the various experiments during my PhD, for constant scientific council and providing a stimulating and encouraging working atmosphere.

... Jimena, the most important person in my life, who supported me during the time I was working on the paper and the time I spend isolated at home writing

my thesis, who encouraged me to not give up halfway, for stopping me from going insane formatting the thesis and making the figures and for her endless patience and love during times of extreme stress.

... my sister, Sarah, who had to listen to all the scientific gibberish, for always being there for me.

... my parents, who supported me throughout my studies, for always being there for me and for their endless patience listening to me talking about work and who encouraged me to make everything a little more colorful.

Abstract

The transport of the K⁺-channels TASK-1 and TASK-3 to the cell surface is regulated by protein-protein interactions with either the COPI vesicle coat, or members of the phosphoadaptor protein family 14-3-3. Interactions are mediated via a trafficking control region present at the distal C-terminus of either K⁺-channel. This trafficking control region comprises a polybasic ER retention and retrieval motif and an adjacent mode III 14-3-3 binding motif. Phosphorylation of a conserved serine residue, as part of the mode III 14-3-3 binding motif, is followed by the recruitment of 14-3-3, thereby releasing the channel from ER retention by sterically preventing the COPI vesicle coat from binding to the overlapping ER retention and retrieval motif. Following phosphorylation and 14-3-3 binding, the channel is transported forward to the cell surface. In this thesis I determined the binding parameters of all seven human 14-3-3 isoforms to the trafficking control regions of TASK-1 and TASK-3. Furthermore, I investigated the direct effect of phosphorylation of the TASK-1 and TASK-3 C-terminus on COPI binding. I observed distinctly different binding parameters between individual 14-3-3 isoforms and different channel C-termini demonstrating that 14-3-3 isoforms bind the same substrate in an isoform specific manner. Surprisingly, the binding affinities determined for TASK-1 were approximately two orders of magnitude lower than the binding affinities determined for TASK-3. I explain these differences by small, but physiologically relevant, amino acid sequence differences within the trafficking control regions of TASK-1 and TASK-3. While TASK-3 presents a second lysine residue that allows for high affinity binding of 14-3-3 proteins to this trafficking control region, TASK-1 presents a second serine residue that upon phosphorylation inhibits 14-3-3 binding. I further correlate my *in vitro* observations with reporter protein assays performed *in vivo* (COS7), assessing the relative cell surface expression of TASK-derived reporter proteins. My findings indicate that the control of TASK-1 protein trafficking is highly dynamic, modulated by COPI, 14-3-3, kinases and phosphatases. Binding experiments performed with the yeast COPI vesicle coat and phosphorylated or unphosphorylated constructs comprising the distal C-

terminus of TASK-1 and TASK-3 (the last 15 amino acids) demonstrate that the phosphorylation of these trafficking control regions is sufficient to interfere with COPI binding, in absence of 14-3-3. In summary, my findings contribute substantially to the quantitative understanding of events governing the intracellular transport of TASK-1 and TASK-3.

Introduction

The role of protein-protein interactions in membrane protein transport along the secretory pathway

Different cell types, such as neurons and cardiac myocytes, are required to perform highly specific functions. To achieve a directed and coordinated response to external stimuli with its neighboring cells, each cell needs to be aware of its surroundings and sense changes in its environment. Several classes of surface membrane proteins enable this sensing, e.g. receptor proteins, ion-channels, transporters and structural proteins (1). To maintain the function and physiology of such cell types the cell surface expression of distinct membrane proteins is required to be tightly regulated, whereas deviation and disturbance of this dynamic equilibrium can lead to severe phenotypes, such as arrhythmias and neurodegenerative diseases (2). The cell surface expression of each surface membrane protein is regulated by interactions with other proteins, e.g. vesicular coat proteins, which enable the cell to tailor specific sorting steps to the needs of an individual membrane protein while facilitating the anterograde or retrograde transport of various proteins along the secretory pathway (3).

In general, protein-protein interactions can affect the biogenesis of membrane proteins in different ways. Interactions with chaperone-like proteins allow for an enhanced folding of the protein into its native state, or can have a stabilizing effect on intrinsically unstable macromolecules (3–5). Interactions with regulatory and inhibitory subunits can regulate the activity of membrane proteins, e.g. K⁺-channels (6). Furthermore, interactions with vesicular coat proteins can affect the localization of membrane proteins and thereby modulate the cell surface expression of a membrane protein and consequently alter the biophysical properties of a distinct cell-type (7).

Interactions between cargo and vesicle coat or trafficking adaptor proteins are often mediated by short peptide stretches, commonly referred to as trafficking

Introduction

control, or sorting motifs. For example, the retrieval of membrane proteins to early compartments of the secretory pathway is mediated by di- or tribasic amino acid motifs that are recognized by the COPI vesicle coat. These motifs have been classified as canonical retention and retrieval motifs RKXX (8), KKXX (9), RXR (10) and non-canonical retention and retrieval motifs, e.g. KRR (11). Another type of trafficking motif was found to facilitate the internalization of membrane proteins from the cell surface via interactions with components of the clathrin vesicle coat. The two most commonly instances of this motif can be classified as YXX Φ and the di-leucine containing motif [DE]XXXL[LI], with X representing any amino acid and Φ representing a hydrophobic amino acid (12). Some protein-protein interactions require the previous posttranslational modification of the client protein, e.g. recognition of clients by 14-3-3 proteins. Thus interactions can be modulated by kinases and phosphatases. Interactions with 14-3-3 proteins are mediated via discrete peptide motifs, such as mode I (RSX(pS/pT)XP), mode II (RX Φ X(pS/pT)XP) (13) and mode III (RXSX₍₁₋₂₎-COOH) (14, 15) 14-3-3 binding motifs. The cell surface expression of multiple membrane proteins was found to depend on the mutually exclusive binding of either COPI, or 14-3-3, e.g. to the cargo proteins Kir6.2, TASK-1, TASK-3, ADAM22 or human $\alpha 4$ (1, 3, 6, 11, 16–19), further emphasizing the importance of 14-3-3 and COPI in membrane protein trafficking. **Figure 1** illustrates the complexity of the underlying mechanism that targets the membrane protein ADAM22 to the cell surface. This example is particularly informative since the phosphorylation-dependent binding of 14-3-3, similar to TASK-1 and TASK-3, promotes the expression of ADAM22 at the cell surface. At the same time, Golgi passage of ADAM22 can be monitored based on its maturation (cleavage) in this compartment (20, 21).

The presence of K⁺-selective ion channels at the cell surface can be studied with high resolution (3, 22). However, detailed insight into the different mechanisms that regulate the cell surface expression of different K⁺-channels is lacking. I am particularly interested in the mechanism modulating the cell surface expression of two-pore-domain acid-sensitive K⁺-channels (TASK).

Introduction

The cell surface expression of TASK-1 and TASK-3 has previously been found to depend on the mutually exclusive binding of either COPI, vesicular coat proteins that retrieve the protein in early compartments of the secretory pathway, or 14-3-3, a phosphoadaptor protein that binds in a phosphorylation dependent manner to a trafficking control region located at the distal C-terminus of both channels (11, 17, 18). This mechanism is thought to operate based on the notion that COPI binding collects and retrieves the protein to the ER until the client protein is phosphorylated by PKA (23) and subsequently associates with 14-3-3. Interactions with 14-3-3 are mediated via a mode III 14-3-3 binding motif (14, 15) and 14-3-3 binding is thought to sterically prevent COPI from binding to an adjacent ER retention and retrieval motif, thus facilitating the forward transport of the channel to the cell surface. This thesis aims to quantitatively evaluate binding events thought to regulate the cell surface expression of TASK-1 and TASK-3. Thereby, I would like to contribute to elucidating the physiological role, structure and function of various K^+ -channels and the importance of 14-3-3 in various cellular processes. In a detailed analysis of the relationship between 14-3-3 and binding properties to the trafficking control region of TASK channels I endeavor to gain insight into the complexity of 14-3-3 isoform-specific binding.

Introduction

Figure 1: Protein-protein interactions involved in the cell surface targeting of membrane proteins. The cell surface targeting of the membrane protein ADAM22 involves multiple protein-protein interactions that are employed to regulate the transport and the activation of the protein on its way to the cell surface. Following synthesis and insertion into the membrane of the endoplasmatic reticulum (ER) the immature and inactive precursor protein of ADAM22 is transported forward to the Golgi. Two RXR-type ER retention and retrieval motifs have been identified in ADAM22 that when exposed mediated interactions with the COPI vesicle coat, returning the protein to early compartments of the secretory pathway. Both retention and retrieval motifs partially overlap with adjacent 14-3-3 binding motifs. Phosphorylation of these 14-3-3 binding motifs results in the recruitment of 14-3-3 proteins (21). This 14-3-3 binding is thought to sterically prevent COPI from binding, thus releasing the protein from ER retention and allowing for progression of the immature precursor through different compartments of the Golgi. Within the Golgi, the

immature and inactive precursor protein is proteolytically processed (a). This processing converts the immature and inactive precursor into its active form (20), making the pre- and post-Golgi population of ADAM22 readily distinguishable (20). Upon exit from the Golgi, the mature and active protein dissociates from 14-3-3 and is subsequently dephosphorylated (21). This example emphasizes the role of COPI and 14-3-3 in membrane protein transport. The basic layout was adapted from Smith et al., 2011 (1).

Potassium channels

K⁺-channels are ubiquitous and can be found in diverse cellular membranes of the animal and plant kingdom. K⁺-channels represent the most abundant ion-channel family in vertebrates with more than 78 genes encoding for pore-forming subunits (24). In general, K⁺-channels regulate the flux of K⁺-ions across the plasma membrane, setting the membrane resting potential and maintaining the electrical excitability of cell-types such as neurons and cardiac myocytes (2, 6, 24, 25). The K⁺-channel superfamily can be divided into different structural subclasses namely inwardly-rectifying K⁺-channels (Kir), voltage gated K⁺-channels (Kv) and two-pore domain K⁺-channels (K2P). Whereas Kv and K2P channels are involved in the repolarization of the membrane following an action potential, Kir channels stabilize the membrane potential close to the K⁺ equilibrium potential (26).

Each subfamily possesses its very own distinct membrane topology: Kir channels comprise one pore-forming domain (P-domain) and two trans-membrane segments (1P-4M); Kv channels contain in addition to one pore-forming domain six trans-membrane segments, of which the fourth trans-membrane segment functions as a voltage sensor (1P-6M). In contrast to Kir and Kv channels, K2P channels are composed of two pore-forming domains and four trans-membrane segments (2P-4TM) (26). Although, each subfamily displays a large structural diversity, a 20 amino acid long stretch within the pore-forming domain is remarkably well conserved across different K⁺-

Introduction

channels. This sequence contains a T-X-G-X-G motif, which was initially employed to screen the mammalian genome for K^+ -channel subunits and is also known as the ' K^+ -channel signature sequence' (27, 28). A fully functional K^+ -channel comprises four P-domains, which form a K^+ -selective pathway across the membrane. Consequently, Kir and Kv channels assemble into tetramers with each channel subunit contributing one P-domain and K2P channels, containing two P-domains, accordingly assemble into dimers (29, 30). The membrane topology of each K^+ -channel is depicted in **Figure 2**.

Figure 2: Membrane topology of different K^+ -channels. **A:** The predicted membrane topology of inward-rectifying K^+ -channels (Kir). Two trans-membrane segments (M1 and M2) and one pore-forming domain (P1) are shown. **B:** The membrane topology of voltage gated K^+ -channels (Kv). Six transmembrane segments (M1 to M6) and one pore-forming domain are shown. The voltage sensor is depicted in green (M4). **C:** A

simplified scheme of the membrane topology of two pore-domain potassium channels (K2P). Four transmembrane segments (M1 to M4) and two pore-forming subunits are shown. The N- and C-termini of each K⁺-channel subunit are located within the cytosol. A functional channel requires four pore-forming domains. Thus functional Kir and Kv channels consist of four subunits and K2P channels of two channel forming subunits (adapted from O'Connell et al., 2002 (26)).

K2P channels

Currently 15 genes encoding for pore-forming subunits of K2P channels within the mammalian genome are known. Based on sequence conservation, functional properties and localization, these channels were divided into six major subgroups. The first subgroup is classified as weakly inward rectifying K2P channels (TWIK), according to the properties of the first mammalian K2P cloned by Lesage et al. in 1996. This group comprises TWIK-1 (K2P 1.1; KCNK1 (31)), TWIK-2 (K2P 6.1; KCNK6 (32)) and TWIK-3 (K2P 7.1; KCNK7 (33)). The second subgroup is comprised of channels, which are lipid and mechanosensitive (TREK). K2P channels classified as such are TREK-1 (K2P 2.1; KCNK2 (34)), TREK-2 (K2P 10.1; KCNK10 (35)) and TRAAK (K2P 4.1; KCNK4 (36)). The third subgroup contains channels that are highly sensitive to changes in extracellular acidification and were accordingly named two pore-domain acid-sensitive K2P channels (TASK). This subgroup of K2P channels contains three members: TASK-1 (K2P 3.1; KCNK3 (37)), TASK-3 (K2P 9.1; KCNK9 (38, 39)) and TASK-5 (K2P 15.1; KCNK15 (40–42)). Although expression of TASK-5 in oocytes or mammalian cells yielded non-functional, 'silent' K2P channels, structural similarities to TASK-1 and TASK-3 classified this channel as acid-sensitive. The fourth subgroup of potassium channels is inactivated upon acidification of the extracellular matrix and exhibits high pH-sensitivity in the alkaline range. Accordingly, this subgroup of potassium channels was classified as two pore-domain alkaline-pH sensitive K2P channels (TALK), comprising TASK-2 (K2P 5.1; KCNK5 (43)), TALK-1 (K2P 16.1; KCNK16 (44)) and TALK-2 (K2P 17.1; KCNK17 (44, 45)). Although

Introduction

TASK-2 was initially grouped with acid-sensitive K^{2P} channels, low sequences similarity with TASK-1 and the inactivation of the channel upon extracellular acidification attributed this channel to the TALK subgroup. The fifth subgroup of K^{2P} channels was classified as tandem pore domain halothane inhibited K⁺-channels comprising THIK-1 (K^{2P} 13.1; KCNK13 (46)) and THIK-2 (K^{2P} 12.1; KCNK12 (46)). The last mammalian K^{2P} channel discovered was named according to its predominant expression in sensory neurons TWIK-related spinal cord K⁺-channel (TRESK). This subgroup comprises only one member TRESK (K^{2P} 18.1; KCNK18 (47)).

K^{2P} subunits assemble into homo- and heterodimeric K⁺-channels

Two K^{2P} channel subunits are required to constitute a functional K⁺-selective ion-channel. Each subunit comprises two pore-forming domains (P-domain) and four transmembrane segments (TM), with the first P-domain located between TM1 and TM2 and the second P-domain located between TM3 and TM4. The selectivity filter forms a K⁺-selective pore across the membrane and comprises four P-domains. In **Figure 3** the general membrane topology of K^{2P} channels is illustrated. Current literature demonstrates that homodimeric K^{2P}-channels exhibit unique biophysical properties when expressed at the cell surface (31–47). Based on structure predictions and similarities found to be relevant for channel regulation K^{2P} channels could potentially form heterodimeric, functional K⁺-channels (48).

A study by Czirj'ak & Enyedi (2002) reported the formation of a heterodimeric K⁺-channel composed of TASK-1 and TASK-3 *in vitro*. These channels were found to partially retain properties of each monomer, which constitute the channel. Furthermore it was found that the novel (heterodimeric) channel exhibited electrophysiological properties different to homodimeric TASK-1 and TASK-3 K⁺-channels (48, 49). The formation of heterodimeric K^{2P} channels was later found to be physiologically relevant in different cell-types, such as cerebellar granule neurons (50). In these cells TASK-1/TASK-3 heterodimeric K⁺-channels are responsible for a major part of the 'standing' outward current.

Furthermore it could be shown that approximately one half of the background current detected in motoneurons is caused by TASK-1/TASK-3 heterodimers (49, 51). Recently Kim et al. (2009) demonstrated that the major part of the pH-sensitive background K⁺ current in carotid body glomerulus cells is regulated by TASK-1/TASK-3 heterodimers (52, 53). Besides TASK-1 and TASK-3 other K₂P channels have recently been reported to form heterodimeric and functional channels. Blin et al. (2014) studied the formation of functional channels between THIK-1 and THIK-2 (54). Whereas Plant et al. (2012) described the formation of a heterodimeric and functional channel of TWIK-1 with either TASK-1 or TASK-3, followed by Hwang et al. (2014) who demonstrated that heterodimeric channels are formed between TWIK-1 and TREK-1 (55, 56). These reports emphasize the formation of heterodimeric K₂P channels as a cellular mechanism to acquire distinct properties in a cost efficient way (57).

Protein-protein interactions involved in the regulation and localization of K₂P channels

A tight equilibrium between forward transport of K⁺-channels along the secretory pathway and endocytosis from the plasma membrane is required to maintain the electrical properties of excitable tissue, such as neurons and cardiac myocytes (58). The number of K⁺-channels reaching the cell surface can either be regulated on the transcriptional level (59–62) or the posttranslational level (11, 17, 18, 63, 64). Interactions with accessory proteins affect the function and/or the localization of the K⁺-channel.

For example, a study by Sandoz et al. (2008) reported that TREK-1 and TREK-2 interact directly with the microtubule-associated protein 2 (Mtap2). Co-expression of Mtap2 with TREK-1 or TREK-2 led to an increased cell surface expression of these channels (63). These observations could later be explained by simultaneous binding of Mtap2 to TREK-1, or TREK-2 and microtubules facilitating increased forward transport of the channel to the cell surface (63). Another study by Sandoz et al. (2006) demonstrated that direct

Introduction

interactions of TREK-1 and TREK-2 with the A-kinase anchoring protein (AKAP)-150 stimulate channel activity (65). The binding of AKAP-150 occurs via the fourth transmembrane segment of either subunit.

Figure 3: General membrane topology of K2P channels. The illustrated structure is based on a crystal structure reported for TWIK-1 by Miller et al., (2012) (29). **A:** A refined structural model of the membrane topology of K2P channels. Depicted are the N-terminal region of K2P channels including M1, M2, P1 and both cap-domains (C1, C2). Observations made for TWIK-1 suggest a covalent linkage between both pore-

forming subunits via cysteine residues present in the loop connecting C1 and C2. TASK-1 and TASK-3 lack these cysteine residues. A crystal structure reported by Miller et al. (2012) showed that transmembrane segment M1 of subunit one (red) and M2 of subunit two (blue) forming intricate contact sites. **B**: The C-terminal region of K2P channels including M3, M4, P2 and the unstructured C-terminal region of each subunit (dashed line) is depicted. **D**: View of the channel from the cytosolic side. The general alignment of the different transmembrane segments and pore-forming domains is based on a crystal structure of TWIK-1 (29). **D**: Functional topology of TASK-1 and TASK-3, highlighted in blue are ER retention, or retrieval motifs; highlighted in yellow are 14-3-3 binding domains. TASK-1 possesses an additional 20 amino acid long i20-domain that binds to the cytosolic retention factor p11, which is absent in TASK-3. Highlighted in purple and in red letters are potential endocytosis motifs. The channel subunit is comprised of four trans-membrane segments (M1 – M4), two pore-forming domains (P1, P2) and two cap-domains (C1, C2). The helices are not drawn to scale. The pore-forming domains are represented as smaller helices for the purpose of illustration and K⁺-ions are depicted as yellow spheres (adapted from Kilisch et al., 2015 (3)).

Interaction partners of TASK-1 and TASK-3

TASK-1 and TASK-3 have been found to associate with various interaction partners, which affect their activity or localization, *in vivo*. A report by Rajan et al. (2002) demonstrated that TASK-1, TASK-3 and TASK-5 directly interact with proteins of the phosphoadaptor protein-family 14-3-3 and that association with 14-3-3 is required to release TASK-1 and TASK-3 from ER retention (17). Channels which failed to associate with 14-3-3, were strongly retained in compartments of the early secretory pathway (17). In parallel, O'Kelly et al. (2002) demonstrated that the retention of TASK-1 is mediated by interactions of a dibasic N-terminal ER retention motif (KR) with the COPI vesicle coat (18). Both reports emphasize that phosphorylation of a C-terminal serine residue is essential to mediate interactions with 14-3-3 (17, 18). A subsequent study by Zuzarte et al. (2009) described interactions of TASK-1 and TASK-3 with COPI as mediated via a tribasic, non-canonical ER retention and retrieval

Introduction

motif (KRR), located at the distal C-terminus of either channel and that binding of COPI to this trafficking control motif is sufficient to retain these channels intracellularly (11). Recently, Mant et al. (2011) demonstrated that protein-kinase A (PKA) was capable of phosphorylating the conserved serine residue present at the distal C-terminus of TASK-1 and TASK-3, *in vitro* (23). The conserved serine residue is part of a mode III 14-3-3 binding motif and phosphorylation leads to the recruitment of 14-3-3 proteins and subsequent release of TASK-1 and TASK-3 from ER retrieval by the COPI vesicle coat. Mant et al. (2011) further demonstrated that other kinases, which recognize a similar phosphorylation consensus site, failed to phosphorylate different TASK C-termini *in vitro*, indicating a potential involvement of PKA in the modulation of TASK-trafficking *in vivo* (1, 23). A study by Renigunta et al. (2006) reported that TASK-1 interacts with another cytosolic adaptor protein, p11 (A100S10). Interactions with p11 occur via a 20 amino acid long C-terminal region (i20-domain) upstream of the previously described trafficking control region and lead to a collective retrieval of the adaptor protein and the channel to intracellular compartments (66). A subsequent study by Renigunta et al. (2014) reported interactions of TASK-1 with the endosomal SNARE protein Syntaxin-8. Association with Syntaxin-8 is thought to allow for cooperative endocytosis of the SNARE protein and TASK-1 (67). Both reports demonstrate that the cell surface expression of TASK-1 is tightly regulated and that multiple factors alter the localization of TASK-1 *in vivo* (66, 67). In **Figure 3** the functional topology of TASK-1 and TASK-3 is illustrated, highlighting residues involved in protein-protein interactions, which influence the subcellular localization of TASK channels.

14-3-3 proteins

The ubiquitous family of phospho-adaptor proteins, called 14-3-3, was initially described by Moore and Perez (1967) and named accordingly by its position on two-dimensional DEAE chromatography and subsequent starch gel electrophoresis (68). The most intriguing observation made was that 14-3-3 proteins were highly abundant in the mammalian brain, with approximately 1%

of the total soluble protein. Subsequent studies emphasized the uniquely important role of 14-3-3 proteins in brain and neuronal function (69–71). The understanding of 14-3-3 proteins as a heterogeneous family of proteins with a molecular mass of approximately 30 kDa that form homo- and heterodimers (**Figure 4**), which persists up until today, was gained only 20 years after their discovery (72). In 1987, Ichimura et al. reported that 14-3-3 proteins play a key-role in the activation of tyrosine and tryptophan hydroxylase in the presence of calcium and calmodulin-dependent protein kinase II (CaMKII) (69, 73, 74). Following these observations, systematic studies identified and cloned representative members of the 14-3-3-protein family from bovine brain (75, 76). According to their elution position after reverse-phase high-performance liquid chromatography (HPLC) Greek letters (α , β , γ , δ , ϵ , ζ , and η) were assigned to the different 14-3-3 proteins (75). Two additional 14-3-3 isoforms were later found in T- and epithelial cells and accordingly termed 14-3-3 τ and 14-3-3 σ , both isoforms are also referred to as T- or epithelial cell markers, τ and σ (77, 78). Subsequent studies demonstrated that 14-3-3 proteins could be found in all eukaryotic organisms, i.e. mammals, insects, plants and yeast and that 14-3-3 proteins are ubiquitously expressed in different tissues (79, 80). Furthermore 14-3-3 proteins were found to be involved in various cellular processes, such as modulation of protein kinase C (PKC) activity (81, 82), activation of calcium-dependent exocytosis in permeabilized adrenal chromaffin cells (83, 84), stimulation of exoenzyme S of *Pseudomonas aeruginosa* (85), association with the G-box DNA-protein complex in maize and *Arabidopsis thaliana* (86) and function as binding partner of the phytotoxin fusicoccin (87). Furthermore it was shown that 14-3-3 proteins are involved in cell-cycle-control of the DNA-damage checkpoint in yeast (88), that 14-3-3 proteins form a complex with the protein kinases c-Bcr and Bcr-Abl (89) and that 14-3-3 proteins associate with the mammalian cdc25 phosphatase (90), by which the entry into the cell cycle is regulated (91). A study by Muslin et al. (1996) demonstrated that interactions between 14-3-3s and their client proteins are mediated via phosphorylated residues and further proposed that the amino acid sequence RSXpSXP represents the

Introduction

structural basis for specific and high affinity 14-3-3 binding (92). In parallel Zha et al. reported that binding of 14-3-3 to the pre-apoptotic protein BAD prevented apoptosis, interfering with the formation of a complex between Bcl-2, or Bcl-X_L and BAD. They further demonstrated that binding of 14-3-3 is directly dependent on phosphorylation of two potential phosphorylation sites

Figure 4: Fundamental structure of 14-3-3 proteins. **A:** The common structure of a 14-3-3 monomer composed of nine α -helices. The helices are labeled from the N-terminal end to the C-terminal end with αA (blue) to αI (red). **B:** Two 14-3-3 monomers constitute a 14-3-3 dimer. The representative crystal structure for a 14-3-3 homodimer of 14-3-3 ζ (93) is illustrated. **C:** The same 14-3-3 dimer as in B, rotated by 90° along the horizontal axis (top view). **D:** The same crystal structure of 14-3-3 ζ as in B and C, rotated by 180° along the horizontal axis (bottom view). The crystal structure of 14-3-3 ζ was obtained from the protein database Europe (PDB), filed under 1QJA (93). Images were generated using the PyMol software.

present in BAD, of which one phosphoserine residue is directly adjacent to a BH3 domain that mediates interactions of BAD with Bcl-2 and Bcl-X_L. Association with 14-3-3 is thought to sterically mask this motif, retaining BAD in the cytosol (94–96). A subsequent study by Yaffe et al. reported that the interactions between 14-3-3 proteins and various client proteins are mediated via discrete binding motifs (**Figure 5**).

Figure 5: Structural basis of 14-3-3 binding to peptides/proteins containing mode I, mode II and mode III 14-3-3 binding motifs. **A:** Crystal structure of 14-3-3 ζ in complex with a peptide containing a mode I 14-3-3 binding motif (ARSHpSYPA). The bound peptide is illustrated in green. The residues involved in peptide binding are indicated as K49, K120, L172, N173, E180, L216, I217, L220, N224 and W228 (93). **B:** Crystal structure of 14-3-3 ζ in complex with a client containing a mode II 14-3-3 binding motif (RLYHpSLPA). The bound peptide is illustrated as green sticks and the phosphoserine residue is depicted as a red and orange tetrahedron, which faces into

Introduction

the binding pocket. The residues involved in peptide binding are indicated as K120, L172, N173, V176, Y179, E180, L216, I217, L220, N224, L227 and W228. In comparison to the residues involve in binding mode I 14-3-3 binding motifs the bound mode II peptide is mainly stabilized by hydrophobic interaction with the inside of the 14-3-3 binding groove (93). **C:** Crystal structure of 14-3-3 σ in complex with a TASK-3-derived hexapeptide. This hexapeptide contains a mode III 14-3-3 binding motif (KRRKSV). The bound peptide is depicted as green sticks and the C-terminal residues of TASK-3 are labeled accordingly, K369, R370, R371, K372, S373 and V374. Residues involve in the binding of this mode III peptide are labeled as R56, K122, R129, Y130, E133, N175 and E188. A comparison between mode I, mode II and Mode III demonstrates that binding of mode I and mode II is chiefly facilitated by interactions formed between the hydrophobic part of the peptide backbone and hydrophobic side chains (93). In contrast, the binding of mode III peptides is mainly stabilized by intricate interactions formed between the phosphoserine residue and multiple residues on the inside of the 14-3-3 binding groove (107). These observations demonstrate that the previous phosphorylation of a mode III binding motif is essential and it further demonstrates that 14-3-3 can bind mode I and mode II binding motifs in a phosphorylation independent manner. The crystal structures were obtained from the Protein Data Bank in Europe, filed under PDB: 1QJA, 1QJB and 3P1N (93, 107).

The two most commonly found motifs were designated mode I, RSX(pS/pT)XP and mode II, RX Φ X(pS/pT)XP, with X corresponding to any amino acid, pS and pT corresponding to a phosphorylated serine or threonine residue and Φ corresponding to any hydrophobic amino acid (13). In 2002 several groups reported the association of 14-3-3 proteins with phosphorylated C-terminal peptides of two pore-domain potassium channels (K2P) (17, 18). These observations emphasized the role of 14-3-3 in intracellular protein transport of K⁺-channels. The C-terminal binding motif was subsequently characterized as a mode III 14-3-3 binding motif (RXSX₍₁₋₂₎-COOH), which operates exclusively in a phosphorylation dependent manner (14, 15). Although 14-3-3 binding is most often dependent on the phosphorylation state of its client protein, some exceptions are known, where

bind 14-3-3 binds in a phosphorylation independent manner. A study by Michelsen et al. (2006) demonstrated that the C-terminus of the inward rectifying, ATP-dependent K⁺-channel Kir6.2 binds to 14-3-3 when presented as a multimer (16), whereas phosphorylation of an adjacent Serine residue abolishes 14-3-3 binding (6). Yang et al. (1999) demonstrated that R18 binds 14-3-3 with high affinity in a phosphorylation independent manner, emphasizing the use of R18 as an inhibitor that interferes with the binding of all 14-3-3 isoforms (98).

In general, 14-3-3 proteins engage in various crucial cellular processes and the selected examples mentioned above represent only a small fraction of all the processes 14-3-3 proteins are involved in. The most important of which are: cell cycle control, apoptosis, membrane protein trafficking, signal-transduction and cell growth (99). These examples should provide a broad overview on the action of 14-3-3 proteins in a cellular context.

Structure of 14-3-3 proteins

14-3-3 proteins compose a family of highly conserved homo- and heterodimeric proteins, which are abundantly expressed in eukaryotic cells (79, 80). In vertebrates seven genes give rise to 10 distinct 14-3-3 isoforms (α , β , γ , δ , ϵ , ζ , η , θ , τ , σ), where three isoforms, 14-3-3 α , 14-3-3 δ and 14-3-3 θ , represent phosphorylated variants of 14-3-3 β , 14-3-3 ζ and 14-3-3 τ respectively (13). Several reports demonstrated that all 14-3-3 isoforms could form homo- and heterodimers, except 14-3-3 σ , *in vitro* and *in vivo* (72, 100–102). Furthermore, Gu et al. (2006) and Woodcock et al. (2003) demonstrated that the phosphorylation of serine residues at the dimerization interface influences the dimerization process, allowing for a regulated formation of homo- and heterodimeric 14-3-3 proteins (101, 102). Furthermore these reports emphasize a functional role of 14-3-3 monomers *in vivo*. A subsequent study by Yang et al. (2006) confirmed the existence of monomeric 14-3-3 proteins as part of a highly dynamic equilibrium between monomeric, dimeric and heterodimeric 14-3-3 proteins (**Figure 6**) (97).

Introduction

Figure 6: 14-3-3 proteins form homo- and heterodimers *in vivo* and *in vitro*. **A:** Overview of the crystal structure of the 14-3-3 ζ homodimer (93). The dimerization interface is framed with a dashed red line. **B:** Enhanced view of the dimerization interface of 14-3-3 ζ . Salt-bridges formed between residues in the α -helices αA , αB and αD allow for the formation of a stable homodimer (93). **C:** Mechanism of 14-3-3 heterodimer formation: Two residues are conserved among all 14-3-3 isoforms. Interactions between these residues are sufficient to form a functional 14-3-3 dimer.

Introduction

These residues are Arg19 and Glu92 in 14-3-3 ϵ and the corresponding amino acids in 14-3-3 ζ are Arg18 and Glu89. In comparison the formation of the 14-3-3 ζ heterodimer is supported by salt-bridges formed between two additional residues, Asp21 and Lys85. 14-3-3 ϵ possesses a glutamine and methionine residues at positions equivalent to Asp21 and Lys85 in 14-3-3 ζ , which do not form salt-bridges and are not involved in the dimer formation (97). A heterodimer formed between 14-3-3 ϵ and 14-3-3 ζ was found to form an additional salt-bridge between Glu22 and Lys85. Dashed black lines: salt-bridges found and confirmed between these residues. Dashed grey line: additional salt-bridges that can contribute to the formation of a 14-3-3 homo-, or heterodimer, mechanism adapted by Yang et al. (2006) (97). The crystal structures were obtained from the Protein Data Bank in Europe, filed under PDB: 1QJA (93).

The first crystal structures of 14-3-3 ζ , 14-3-3 σ and 14-3-3 τ revealed the remarkable structural conservation between different 14-3-3 isoforms (13, 103, 104). Each 14-3-3 monomer is comprised of nine α -helices (α A – α I), of which three helices (α A, α C and α D) are involved in the formation of the 14-3-3-dimer interface. The horseshoe-shaped amphipathic binding-groove is formed by helices α E, α G and α I (105). In a ligand bound state residues present in these helices form intricate interactions with the accommodated phosphopeptide, or protein. The sequence alignment of all mammalian 14-3-3 isoforms illustrates the high degree of sequence conservation of the amphipathic binding-groove (the binding groove is formed by helices α E, α G and α I) (13). Crystal structures reported for all mammalian 14-3-3 proteins in their ligand bound state confirmed that interactions are facilitated by equivalent residues present in all mammalian 14-3-3 isoforms (13, 93, 105, 106). A study by Yang et al. (2006) further elucidated the structural basis of protein-protein interactions of all known mammalian 14-3-3 isoforms, demonstrating that the 14-3-3 monomer/dimer undergoes a conformational change from an open (ligand-unbound) state to a closed (ligand-bound) state upon binding of a ligand peptide, or protein. This mechanism is thought to allow for rapid adaptation of the 14-3-3 homo-, or heterodimer to size, structure

Introduction

and phosphorylation state of the client peptide/protein (97). **Figure 7** illustrates the structural difference between ligand-unbound and ligand unbound state.

Figure 7: Superimposition of two crystal structures of 14-3-3 β in a ligand bound state (red) and a ligand unbound state (blue). **A:** An overlay of two crystal structures demonstrating the differences in the conformation 14-3-3 adopts before and after binding of a peptide substrate. Shown in red is a 14-3-3 β monomer bound to a peptide derived from the *Pseudomonas aeruginosa* ExoS (peptide hidden) (97). Shown in blue is a 14-3-3 β homodimer in its apo-form (PDB entry: 4DNK). **B:** Superimposition of two crystal structures of a 14-3-3 β dimer in a ligand bound and

Introduction

unbound state. The major structure displacement between ligand bound (red) and unbound state (blue) can be observed. The crystal structures were obtained from the Protein Data Bank in Europe, filed under PDB: 2C23 (97) and PDB entry: 4DNK.

A recent report by Anders et al. (2013) gained insight into the structural basics of 14-3-3 binding to peptides containing mode III 14-3-3 consensus sites. A crystal structure of 14-3-3 σ in complex with a TASK-3-derived hexapeptide demonstrated that peptide binding depends on intricate interactions formed between the inner side of the 14-3-3 binding groove and the accommodated phosphate group, indicating that a deletion of the corresponding residue will also lead to a loss of 14-3-3 binding (107). Although the structural basis of 14-3-3 binding to mode I, mode II and mode III consensus sites is well understood the following question remains: What determines the binding properties of a 14-3-3 isoform to a given 14-3-3 client and how can the need for seven distinct 14-3-3 isoforms be explained?

Introduction

Aims of this thesis

The antagonistic action of COPI and 14-3-3 regulates the cell surface expression of TASK-1 and TASK-3. Whereas the protein-protein interactions involved in TASK-trafficking have not been described quantitatively yet.

1) The first aim of this study is to investigate interactions between all seven mammalian 14-3-3 isoforms and TASK-derived C-terminal peptides quantitatively. A comparison of binding parameters obtained for TASK-1-derived peptides and TASK-3-derived peptides will yield further information on the impact of small sequence differences between TASK-1 and TASK-3 on 14-3-3 binding.

Current literature reports that 14-3-3-binding to TASK-1 and TASK-3 is lost upon truncation of the C-terminus (11, 17, 18), or mutation of the conserved serine residue, which is part of a mode III 14-3-3 binding motif. Both modifications

2) The second aim of this study is to compare the effect of truncation and mutation of the mode III 14-3-3 binding motif quantitatively. A detailed analysis of the obtained binding parameters will either confirm previous reports, or allow for a more detailed assessment of the underlying mechanism that leads to the reported observations.

Based on a report by Zuzarte et al. (2009), the underlying mechanism of TASK-1 and TASK-3 cell surface expression can be examined employing reporter protein assays (11).

3) The third aim of this thesis is to study the functional consequence of mutation and truncation of the C-termini of TASK-1 and TASK-3 *in vivo*. Therefore, I wished to study the cell surface expression of different reporter

Aims

proteins (wild type and mutant reporter proteins) quantitatively and correlate my findings with the previously obtained *in vitro* binding data. If my observations can be correlated, I will feel confident that the *in vitro* and *in vivo* observations are indeed of biological relevance.

Mant et al. (2011) demonstrated that the TASK-1 and TASK-3 C-terminus can be phosphorylated *in vitro* by PKA (23), but little is known about the phosphorylation state of different channel/protein variants *in vivo*.

4) The fourth aim of this study is to investigate the phosphorylation state of different reporter protein constructs *in vivo*. Furthermore, I wish to study the efficiency, by which different recombinantly expressed TASK-derived fusion proteins are phosphorylated *in vitro*.

Many reports describe the antagonistic role of COPI and 14-3-3 in TASK-1 and TASK-3 cell surface expression based on experiments performed with cellular extracts (11, 18). These extracts contain both proteins/protein complexes and signal transduction events, such as phosphorylation, cannot be assessed individually.

5) The final aim of this thesis is to investigate the effect of phosphorylation of TASK-1 and TASK-3 on binding of the COPI vesicle coat. These experiments will yield insight into the mode of action 14-3-3 performs in cellular context and will allow for a direct comparison between TASK-1 and TASK-3 C-termini.

Material and Methods

Molecular biology

A list of all plasmids used for this study can be found in **Table 1**.

Restriction enzyme digest

Plasmid DNA and DNA fragments obtained by polymerase chain reaction were digested with one or multiple restriction enzymes.

For plasmid DNA: 1 – 2 μg of the target vector were incubated with 1-5 units of the restriction enzyme in its respective buffer. Depending on the restriction enzyme, the reaction mix was incubated for 60 – 90 minutes at 37 °C. To avoid re-annealing of the linearized vector, during ligation, 1 unit of calf intestinal alkaline phosphatase (CIAP) was added to the reaction mix and incubated at 37 °C for ~ 10 minutes. Alkaline phosphatase catalyses the removal of 5' phosphate groups from DNA strands.

For DNA fragments obtained by PCR: The DNA fragments were purified using the Highpure PCR product purification kit (Roche). Each purification step was carried out according to the manufacturers instructions. The restriction enzyme and its respective buffer were added and the reaction mix was incubated at 37 °C for 60 minutes.

Digested DNA was then supplemented with DNA loading buffer, which contained a dye to visualize the running front during electrophoresis, and loaded into the wells of an agarose gel.

Polymerase chain reaction

Polymerase chain reaction (PCR) was employed to exponentially amplify DNA fragments encoding proteins of interest, *in vitro*. For this method a small quantity of template DNA (20 – 100 ng) was mixed with a mixture of dNTPs (the 10 mM stock contained 2.5 mM dATP, dTTP, dGTP, dCTP) two

Material and Methods

oligonucleotide primers that can hybridize with target regions of the template DNA and flank the region of interest, and a thermostable proof-reading DNA polymerase. The reaction mixture was then subjected to multiple cycles of DNA-melting, annealing of the oligonucleotide primers and extension of the oligonucleotide primers by DNA polymerase until sufficient DNA was made available for further analysis and sub-cloning.

In general a 50 μ l reaction mix contained 20 – 100 ng of template DNA, 800 μ M dNTPs, 3 – 5 units of polymerase, 400 nM of each oligonucleotide primer and sterile water to constitute the final volume.

PCR primers were designed with an average length of 26 – 42 base pairs. A thermo cycler block with the following program was used to amplify target DNA:

1. 2 min @ 94 °C
2. 30 sec @ 94 °C
3. 30 sec @ $T_m - 2$ °C; where T_m [°C] = $4x(G + C) + 2x(A + T)$
4. X min @ 74 °C; where X = For every kilo-base of DNA 1 minute amplification
5. Repeat step 2 to 5 for 25 – 30 cycles
6. 5 min at 74 °C

A list of all primers used for PCR can be found in **Table 2**.

Cloning with phosphorylated oligonucleotides

The ligation of DNA requires 5'-phosphate groups that can be linked to the unphosphorylated 3'-end of another strand of DNA. Regarding this property, cloning of short synthetic, phosphorylated DNA fragments into dephosphorylated recipient vectors can be employed to reduce the background during cloning.

Phosphorylated oligonucleotides encoding the last 15 amino acids of TASK-1, TASK-3 and their respective mutants were annealed and ligated into the respective vector. In general, 20 μ l annealing mix contained 8 μ l

Material and Methods

oligonucleotide 1 (FP), 8 μ l oligonucleotide 2 (RP, where FP and RP can hybridize) and 4 μ l 5x annealing buffer (200 mM Tris-HCl, 100 mM MgCl₂, 250 mM NaCl, pH 7.5). The annealing mixture was incubated at 90 °C for ~ 5 minutes. Following melting, the reaction mixture was steadily cooled down to 37 °C and transferred to ice until further use. For ligation into the recipient vector the annealing mixture was diluted 1:100, 1:1,000 and 1:10,000 with sterile water.

A list of phosphorylated oligonucleotides used in this study can be found in **Table 3**.

Ligation

In general 30 μ l ligation mix contained 50 – 100 ng of linearized cloning vector, a 3 – 10 fold molar excess of linearized insert (PCR product and DNA fragments obtained by restriction digest) or diluted annealed oligonucleotide mixture, 1 – 2 units of T4DNA ligase, 3 μ l of 10x ligation buffer and sterile water to constitute the final volume. The reaction mix was incubated at 18 °C for 16 hours. The ligase was subsequently heat inactivated at 65 °C.

Agarose gel electrophoresis

Agarose gel electrophoresis was utilized to separate DNA fragments based on their size for later purification, to halt the progression of restriction enzyme or phosphatase treatment and to determine the yield of a PCR and or restriction enzyme digest. The DNA samples were mixed with loading buffer, containing a dye to mark the running front during gel electrophoresis, and loaded into the wells of the agarose gel. Gels were electrophoresed at 80 – 100 V (constant Voltage, small gels) or 160 – 200 V (constant Voltage, large gels). A DNA ladder was co-electrophoresed to determine the size of the DNA fragments. All gels were cast with SafeView, a fluorescent dye with an emission wavelength of ~ 490 nm. Gels containing 1 – 2% percent agarose were used

Material and Methods

to separate DNA fragments respectively to their size (1% gels for bigger fragments, 2% gels for smaller fragments).

Purification of DNA fragments from agarose gels

Following agarose gel electrophoresis, bands containing DNA fragments of estimated size were excised and weighed. The excised bands were purified using the Highpure PCR product purification kit (Roche). Therefore, each band was resuspended in binding buffer (3 M guanidine-thiocyanate, 10 mM Tris-HCl, 5% ethanol (v/v), pH 6.6) (3 times the weight of the excised agarose piece) and melted at 55 °C for ~ 10 minutes. The mixture was supplemented with isopropanol and transferred to a purification column, containing a silica matrix. The column was washed twice to purge residual contaminants from the system with washing buffer (20 mM NaCl, 2 mM Tris-HCl, 80% ethanol (v/v), pH 7.5) and dried by centrifugation. Bound DNA was eluted with elution buffer (10 mM Tris-HCl, pH 8.5).

Transformation of bacterial cells by electroporation

1.5 μ l of heat inactivated ligation mix or ~ 0.5 ng of plasmid DNA sample were mixed with 50 μ l of electro-competent DH5alpha cells (for amplification of plasmid DNA), or electro-competent BL21(pREP4) cells (for protein expression) and transferred to a pre-cooled electroporation cuvette. The electroporation unit (Gene Pulser, BioRad) was pre-set at 25 μ F and 2.5 kV. The pulse controller was set to 400 Ω . One pulse was applied to the cell suspension at the above settings. The cuvette was removed and 1 ml of SOC medium (20 g/l tryptone, 5 g/l yeast extract, 0.5 g/l NaCl, 2.5 mM KCl, 10 mM MgCl₂, 20 mM glucose) pre-warmed to 37 °C was added. The cells were resuspended with a Pasteur pipette and transferred to an Eppendorf cup, followed by incubation at 37 °C for 30 minutes. For ligations, the entire suspension was plated onto LB plates containing selective antibiotics. For retransformations (plasmid amplification, or later protein expression) 100 μ l of the suspension was plated onto LB plates containing selective antibiotics.

Amplification of plasmid DNA

Single colonies were picked and 5 ml (small scale) or 100 ml (large scale) LB-medium supplemented with the appropriate antibiotic were inoculated. Cultures were incubated at 37 °C for 14 – 16 hours. Cells were harvested by centrifugation and plasmid DNA was extracted. DNA extraction was carried out according to the manufacturers instructions (NucleoSpin Plasmid, 5 ml cultures; NucleoBond Xtra Midi, 100 ml cultures; Macherey-Nagel).

Protein expression

MBP-tagged 14-3-3 proteins and GST-fused TASK-1 and TASK-3 C-termini were expressed in the *Escherichia coli* strain BL21(pREP4). All expressions were performed in 2YT medium (16 g/l Bacto tryptone, 10 g/l Bacto yeast extract, 5 g/l NaCl, 30 mM K₂HPO₄, 2% Glycerol, pH 7.0) supplemented with the appropriate antibiotics and carried out at 37 °C incubation temperature. A starter culture grown over night in 2YT medium supplemented with the appropriate antibiotics was diluted to an OD₆₀₀ = 0.2 (1L) and protein expression was induced upon addition of IPTG (final concentration 1 mM) at OD₆₀₀ = 0.8. The cells were induced for 3 h at 37 °C and harvested by centrifugation at ~4,000 x g for 20 minutes, washed with water and stored at -20 °C until further use.

Protein purification

Cells expressing MBP-tagged 14-3-3 proteins were harvested, washed with water, resuspended in MBP-column buffer (150 mM NaCl, 5 mM MgCl₂, 50 mM Tris-HCl, 1 mM PMSF, pH 7.5) and subjected to ultrasonication. The cell suspensions were sonicated at 40% amplitude, 6 times for 10 seconds with a recovery period of 30 seconds between each step. The crude cellular lysates were centrifuged at 100,000g (36,000 RPM, Rotor: 55.2Ti, Beckman Coulter) for 30 minutes at 4 °C. In parallel, the affinity matrices (Amylose resin, New England Bio Labs) were equilibrated in MBP-column buffer (4 washing steps) to purge remaining traces of ethanol. After centrifugation, pre-

Material and Methods

cleared cell lysates were incubated with the washed affinity matrices for 90 minutes at 4 °C while rotating. The affinity matrices were then loaded onto purification columns and washed 6 times with MBP-column buffer to remove contaminants. Following column wash, matrix-bound proteins were eluted with 10 ml MBP-column buffer supplemented with 20 mM D-Maltose. 1 ml fractions were collected and 5 μ l from each fraction were loaded onto SDS-Page gels (12%). The gels were electrophoresed at 15 mA (constant amperage) for 80 minutes, followed by Coomassie staining to identify fractions containing the purified protein. Peak fractions were pooled and concentrated using a Spin-X UF concentrator (Corning). The MBP-tag was proteolytically removed by Factor Xa using the Factor Xa cleavage capture kit (Novagen). Subsequent gel filtration allowed the separation of cleaved MBP and dimeric 14-3-3 proteins. 14-3-3 proteins were gel filtrated at 1 ml/min flow rate into either SPR (20 mM HEPES, 150 mM NaCl, 0.005% TWEEN-20, pH 7.5), or FP buffer (20 mM MOPS, 150 mM NaCl, 0.005% CHAPS, pH 7.5) using a Superdex 75pg Hiload 26/60 column. Following gel filtration, proteins were concentrated and stored on ice until further use.

GST-tagged proteins were expressed in a similar manner to MBP-tagged proteins and purification steps were carried out as described above in GST-breaking buffer containing 150 mM KOAc, 5 mM Mg(OAc)₂, 20 mM HEPES, 1 mM EDTA, 1 mM DTT, 1 mM PMSF (during lysis) pH 6.5 using glutathione sepharose as an affinity matrix (glutathione sepharose 4FastFlow, GE Healthcare). Proteins were eluted with GST-breaking buffer supplemented with 20 mM glutathione, pH 8.5. Purified GST-fused proteins were gel filtrated into 1x PBS, pH 7.0 and subsequently concentrated, snap frozen and stored at -80 °C.

SDS-PAGE

High percentage gels were cast to separate small molecular weight proteins and low percentage gels were cast to better separate proteins of higher molecular weight. In general resolving gels of 12% were cast. The stacking

gel (4%) was prepared with a Tris*HCl buffer at pH 6.8, whereas the resolving gel was cast with Tris*HCl pH 8.8 to allow concentration of SDS denatured proteins at the interface and to also allow the formation of a narrow starting zone of migration. The height of the stacking gel was always maintained at a quarter of the height of the resolving gel. Gels were electrophoresed at 15 mA (constant amperage) for 80 minutes.

Phos-tag SDS-PAGE

To retard the migration of phosphorylated proteins phos-tag SDS-PAGE was employed. Standard SDS-PAGE gels (10%) were supplemented with 50 μ M phos-tag acrylamide and 50 μ M MnCl₂. A dinuclear metal complex is formed between manganese-ions (Mn²⁺) and the acrylamide linked 1,3-bis[bis(pyridin-2-ylmethyl)amino]propan-2-olato moiety (phos-tag acrylamide, in gel). This complex is bound by phosphate groups of phosphorylated proteins during electrophoresis retarding their migration, which results in a distinct band shift between phosphorylated and unphosphorylated proteins. For further analysis gels were stained with coomassie staining buffer solution.

Electro blotting and Western blot detection

Following gel electrophoresis, gels were transferred onto nitrocellulose membranes (Amersham Hybond-ECL, GE Healthcare) using a TE22 Mighty Small Transfer Tank. The gels were placed on a pre-wetted membrane and sandwiched between two sheets of blotting paper and two sponge pads. All the individual components were pre-equilibrated in transfer buffer. This set-up was held in place by a blotting cassette and placed in the blotting tank (with the membrane directed towards the anode). The tank was filled with transfer buffer (25 mM Tris, 192 mM Glycine, pH 8.3). Phostag SDS-PAGE gels were washed twice with transfer buffer, which was supplemented with 100 mM EDTA, with intervals of 15 minutes between each wash, prior to transfer. Standard SDS-PAGE gels were electroblotted at 60 V with the current limited to 0.5 A for 80 minutes. Phostag SDS-PAGE gels were electroblotted at 15 V

Material and Methods

for 18 hours with the current limited to 75 mA at 4°C. Following transfer, the blots of standard SDS-PAGE and Phostag SDS-PAGE gels were stained with Ponceau to visualize the protein bands. The blots were incubated in blocking buffer (5% milk powder (w/v), 25 mM Tris-HCl pH 7.4, 135 mM NaCl, 3 mM KCl, 0.02% NP-40) for 45 minutes at room temperature, or over night at 4°C. Primary antibodies were diluted in blocking buffer and incubated with the blots for 90 minutes at room temperature. Subsequently, the blots were washed three times with blocking buffer with intervals of 10 minutes between each wash. The fluorescently labeled secondary antibody was diluted in blocking buffer and incubated with the blots for 45 minutes. The blots were washed again three times with blocking buffer with intervals of 10 minutes between subsequent washes, followed by two subsequent washes with blocking buffer without the milk powder. The fluorescently labeled secondary antibodies were detected using an Odyssey LiCOR imaging system (LiCOR, Bad Homburg, Germany).

Coomassie staining of protein gels

To visualize the protein bands after SDS-PAGE or phos-tag SDS-PAGE, the gels were soaked in fixation buffer (30% v/v ethanol, 15% v/v acetic acid) for ~ 10 minutes. The gels were then stained with Coomassie staining buffer (30% ethanol, 10% acetic acid and 0.2% w/v coomassie brilliant blue), boiled in the microwave for ~ 30 seconds and incubated for 10 minutes at room temperature and agitated steadily.

***In vitro* phosphorylation assays**

Purified GST-fused TASK-1 and TASK-3 C-termini and their respective mutants were *in vitro* phosphorylated using recombinantly expressed cAMP dependent protein kinase A (PKA). *In vitro* phosphorylation was performed in binding buffer containing 150 mM NaCl, 50 mM Tris-HCl, 10 mM MgCl₂ pH 7.5, supplemented with 200 nM PKA and 100 μM ATP, according to Mant et al., 2011 (23). Proteins were either phosphorylated for 20 minutes at room

temperature or overnight at 4 °C. For overnight phosphorylation an ATP regeneration system was used (energy mix) as described by Yuan et al., 2006 (108). After phosphorylation GST-fused proteins were bound to glutathione sepharose beads. For each experiment 10 µg of protein was incubated with ~ 20 µl of bead slurry and incubated at 4 °C for 20 minutes, rotating. The bead slurry was subsequently transferred to a column and washed 4 times with binding buffer. The proteins were eluted with 75 µl 1x SDS-sample buffer and 10% of the total volume were loaded onto a SDS- or phos-tag SDS-PAGE gel. Gels were electrophoresed at 15 mA (const. amperage) for 80 minutes and stained with coomassie staining solution.

Surface plasmon resonance (SPR)

To determine binding parameters between two interacting proteins quantitatively, surface plasmon resonance (SPR) was employed. For this method one of the interacting proteins was immobilized onto the surface (ligand), covalently or by affinity capture, and the second protein (query) serially diluted and injected over the chip surface (analyte), at a constant flow rate. The system consisted of a Reichert SR7500DC biosensor, a pump (SR8500), a diverter valve (SR8600), an auto-sampler (SR8100) and a semi-automatic valve (SR8300). Chip modifications were performed at 15 µl/min, whereas all binding experiments were carried out at 40 µl/min. All experiments were performed at 20 °C (chip surface temperature).

For binding studies HC1000m sensor chips (Xantec Bioanalytics) were modified with a polyclonal anti-GST antibody (Carl Roth) previously described by Knape et al., 2015 (109). The chip surface was activated with 100 mM *N*-(3-Dimethylaminopropyl)-*N'*-ethylcarbodiimide hydrochloride (EDC, Sigma) in activation buffer containing 100 mM *N*-hydroxysuccinimide (NHS), 50 mM 2-(*N*-morpholino)ethane sulfonic acid, pH 5.0 and the ligand, a polyclonal anti-GST antibody (Carl Roth) was resuspended in pre-concentration buffer (50 mM NaOAc, pH 5.0), to a concentration of 30 µg/ml, and injected over the activated surface. Following immobilization, the surface was quenched with

Material and Methods

quenching buffer (1 M Ethanolamine, pH 8.5). After exchange of the running medium, from water to SPR running buffer (20 mM HEPES, 150 mM NaCl, 0.005% TWEEN-20, pH 7.4), three injections of glycine, pH 2.1 were performed. GST-fused TASK-3 C-termini were captured on a surface density of 300 μ RIU response on the left (ligand) channel and on the right (reference channel) by injecting 150 μ l of "ligand" solution (200 nM GST-fused TASK C-termin) at a flow rate of 15 μ l/min. The ligand was phosphorylated following its binding to the chip surface (on-chip phosphorylation) using recombinantly expressed protein kinase A (PKA) in SPR buffer (200 nM PKA, 5 mM MgCl₂, 20 mM HEPES, 150 mM NaCl, 0.005% TWEEN-20). Following phosphorylation the surface was purged of residual PKA and loosely associated proteins with buffer at a flow rate of 100 μ l/min. A serial dilution of the analyte was subsequently injected over the surface and the response was followed during injection (association phase) and during buffer wash (dissociation phase). The analyte was allowed to associate for 4:30 minutes, dissociation was followed for 7:00 minutes (injected volume = 250 μ l). Additional buffer injections were performed, analogous to the analyte injection, which served as a secondary reference. For injections of smaller volume the time of association and dissociation were scaled down accordingly. The obtained data was further processed with Scrubber 2.0c. Equilibrium binding was assessed and equilibrium-binding isotherms were plotted and analyzed with Graph Pad Prism 6.0.

Fluorescence polarization (FP)

Equilibrium binding parameters between fluorescently labeled C-terminal peptides of TASK-1, TASK-3, mutant C-termini and 14-3-3 proteins were evaluated employing fluorescence polarization (FP). The fluorescence polarization assay was set up according to Moll et al., 2006 (110) and Muda et al., 2014 (111).

This method is based on the excitation of the sample with vertically polarized light and an intensity measurement of the emitted light, via a polarizer. The

Material and Methods

ratio between vertically and parallel polarized light is formed and analyzed in a concentration dependent manner.

Peptides were purchased from Peps4Life sciences (Heidelberg, Germany). The lyophilized peptides were pre-dissolved in DMSO (5% *v/v*; where *v* is the final volume required for a 100 μ M stock solution) and diluted in FP-buffer (20 mM MOPS, 150 mM NaCl, 0.005% CHAPS, pH 7.5) to a final peptide concentration of 100 μ M). For each experiment a 20 nM working stock of each peptide used in this study was prepared. Purified proteins were serially diluted in FP-buffer and 30 μ l of each dilution were pipetted into the wells of a 384-well microtiter plate (Packard, Meriden CT, USA, Optiplate 384, black). Subsequently, 30 μ l of the peptide working stock (20 nM) was added (diluted in a 1:1 ratio). The fluorescence polarization signal was detected for 2 s at an excitation wavelength of 485 nm with an emission FP filter wavelength of 535 nm and a photomultiplier voltage of 1,100, using a FusionTM α -FP microtiter plate reader at room temperature.

Cell culture – Passaging cells

COS-7 cell cultures were grown in culture medium (Dulbecco's modified eagle medium [DMEM], Gibco) and periodically checked under the light microscope. The cells were passaged when 60 – 70% confluence was reached. Culture medium and trypsin were pre-warmed at 37 °C in a water bath. All material and surfaces were sterilized with 70% ethanol before use. The culture medium was carefully removed by aspiration and the cell containing petri dish was washed with 10 ml 1 x PBS to wash away dislodged cells from the growth medium. 2 ml of trypsin were added and the petri dish was incubated at 37 °C in a 5% CO₂ atmosphere for 3 minutes. Detaching of the cells was aided by gently tapping the petri dish. The cell suspension was subsequently checked under the light microscope to ensure no visible cell clumps were present within the cell suspension. 8 ml of culture medium was added to stop the trypsin treatment and to transfer the cell suspension to another petri dish. In general cells were transferred to either a 15 ml petri dish (to maintain cells in

Material and Methods

culture) or to a 6 well plate for subsequent transfection. In 15 ml dishes cells were seeded up to 30% confluence, whereas in 6 well plates 250,000 cells were seeded per experiment (~ 40% confluence).

Cell culture – Transient transfection

COS-7 cells were transfected one day after seeding to allow cells to properly adhere to the well floor. Typically 4 μ g of DNA were used per well for transient transfection. 150 μ l of Opti-MEM (serum free medium, Gibco) was mixed with 10 μ l FuGENE and incubated for 5 min at room temperature. To the mix 4 μ g of DNA was added and equilibrated at room temperature for 15 minutes. The existing culture medium from each well containing COS-7 cells to be transfected was aspirated and each well was washed once with 2 ml 1 x PBS. 2 ml of pre-warmed culture medium was added to the DNA-FuGENE transfection mix and transferred to the respective wells of the 6-well plate. The cells were incubated at 37 °C in a controlled environment containing 5% CO₂. Transfected cells were harvested 36 hours after treatment.

Flow cytometry

COS-7 cells expressing reporter proteins, which consist of the extracellular domain of CD8, an eCFP fluorophore and the last 15 amino acids of either TASK-1, TASK-3 or various mutant versions of each C-terminus, were harvested 36 h after transfection. Cells were washed once with 1 x PBS to remove the growth medium, treated with trypsin for 3 minutes at 37 °C and resuspended in culture medium (Dulbecco's modified eagle medium [DMEM], Gibco). The cell suspensions were centrifuged for 3 min at 300x g and resuspended in culture medium. Primary antibody, a monoclonal anti-CD8 antibody (Sigma, St Louis MO, USA, C7423), was diluted in 1 x PBS and added to each well of the 6 well plate. The cells were incubated for 60 – 90 minutes with primary antibody on ice. Following incubation, cells were washed and resuspended in culture medium. The secondary antibody (Alexa 647, Invitrogen, Waltham MA, USA) was diluted in 1 x PBS and added to the cell

suspension, followed by 30 minutes incubation on ice. The cells were washed twice with culture medium, resuspended in 1 x PBS and transferred to FACS tubes for further analysis.

Flow cytometry was performed with a FACS Calibur™ flow cytometer and FACS DIVA™ software (BD Biosciences, Heidelberg, Germany). Cells were counted and cell surface expression of the reporter protein, stained by the monoclonal anti-CD8 antibody, was assessed. Differences of relative cell surface expression between reporters were evaluated by forming the ratio between the mean intensity of the anti-CD8 staining (surface population of the reporter protein) and the mean intensity of the CFP signal (total amount of reporter protein expressed).

In vivo phosphorylation assays

COS7 cells were transiently transfected with 5 μ g DNA encoding the respective CD8 reporter protein. Cells were harvested 36 hours after transfection, washed twice with 1xPBS and resuspended in membrane preparation buffer (50 mM NaCl, 0.32 M sucrose, 2 mM EDTA, 20 mM HEPES, pH 7.4, cOmplete EDTA-free protease inhibitor cocktail (Roche, Mannheim, Germany) and 50 μ M PKA inhibitor H-89 dihydrochloride hydrate (Sigma-Aldrich)). The cell suspension was homogenized using a MICCRA-D-1 homogenizer disperser (ART Prozess- & Labortechnik, Müllheim, Germany), followed by 15 strokes with a Dounce homogenizer. The homogenate was centrifuged for 30 min at 100,000xg and the insoluble fraction was separated. The obtained pellet was solubilized in 250 μ l of solubilization buffer (1.5% Triton X-100, 0.75% Na-deoxycholate, 0.1% SDS, 50 mM Tris-HCl, 100 mM NaCl, 5 mM EDTA, 2.5 mM EGTA, pH 7.5) for 30 min on ice, followed by a second centrifugation step. Subsequently, the samples were precipitated with 12.5% trichloroacetic acid (TCA), washed with acetone and dried at 37°C. Dried protein pellets were resuspended in λ phosphatase buffer (1x PMP buffer, catalog number P0753, New England Biolabs, Frankfurt, Germany). Two samples were prepared for each reporter protein, of which one sample

Material and Methods

was supplemented with 1600 units of λ -protein phosphatase (λ -PPase). Both samples were then incubated for 30 minutes at 30°C. Following incubation samples were supplemented with 5x SDS loading buffer and loaded into the wells of a SDS-PAGE, or Phostag SDS-PAGE gel.

COPI pull-down experiments

COPI coat was purified from yeast, as described by Yip and Walz (Yip and Walz, 2011) by Dr. Eric Arakel. 10 μ g of affinity purified GST-MST27-TASK-1-CT15 and GST-MST27-TASK-3-CT15 (10, 112) was phosphorylated by recombinant PKA in phosphorylation buffer containing: 20 mM HEPES pH 6.8, 150 mM KOAc, 5 mM Mg(OAc)₂, 1 mM EDTA, 1 mM DTT, 2% glycerol, supplemented with an ATP regeneration system comprising 10 mM phosphocreatine, 0.5 mM ATP, 0.5 mM GTP and 50 μ g/ml creatine phosphokinase (108). Following phosphorylation, the bait proteins were immobilized on ~20 μ l of Glutathione-sepharose. The bead slurry was incubated with phosphorylated GST-fusion proteins for 90 minutes at 4°C, shaking. COPI was added to the bead slurry as indicated and incubated for a minimum period of 60 min. The bait proteins were subsequently washed four times with phosphorylation buffer. Proteins were eluted with 1x SDS sample buffer containing 100 mM DTT. The samples were analyzed by standard SDS-PAGE and Phostag SDS-PAGE.

Material and Methods

Table 1: Plasmids used in this study.

Plasmid name:	Description/Purpose:	Restriction sites used
pGEX-6P-1	Recombinant expression of N-terminally GST-tagged proteins	EcoRI – NotI
pGEX-6P-1 TASK1-C15 WT	Bacterial expression vector encoding GST-TASK1-C15 WT	Insert at EcoRI – NotI
pGEX-6P-1 TASK1-C15 S392A	Bacterial expression vector encoding GST-TASK1-C15 S392A	Insert at EcoRI – NotI
pGEX-6P-1 TASK1-C15 S393A	Bacterial expression vector encoding GST-TASK1-C15 S393A	Insert at EcoRI – NotI
pGEX-6P-1 TASK1-C15 S392A_S393A	Bacterial expression vector encoding GST-TASK1-C15 S392A_S393A	Insert at EcoRI – NotI
pGEX-6P-1 TASK3-C15 WT	Bacterial expression vector encoding GST-TASK3-C15 WT	Insert at EcoRI – NotI
pGEX-6P-1 TASK1 dV374	Bacterial expression vector encoding GST-TASK3-C15 dV374	Insert at EcoRI – NotI
pGEX-6P-1 TASK1 S373A	Bacterial expression vector encoding GST-TASK3-C15 S373A	Insert at EcoRI – NotI
pMAL2CX	Recombinant expression of N-terminally MBP-tagged proteins	EcoRI – HindIII
pMAL2CX 14-3-3 beta	Bacterial expression vector encoding MBP-14-3-3 beta	Insert at EcoRI – HindIII
pMAL2CX 14-3-3 gamma	Bacterial expression vector encoding MBP-14-3-3 gamma	Insert at EcoRI – HindIII
pMAL2CX 14-3-3 epsilon	Bacterial expression vector encoding MBP-14-3-3 epsilon	Insert at EcoRI – HindIII
pMAL2CX 14-3-3 zeta	Bacterial expression vector encoding MBP-14-3-3 zeta	Insert at EcoRI – HindIII

Material and Methods

pMAL2CX 14-3-3 eta	Bacterial expression vector encoding MBP-14-3-3 eta	Insert at EcoRI – HindIII
pMAL2CX 14-3-3 tau	Bacterial expression vector encoding MBP-14-3-3 tau	Insert at EcoRI – HindIII
pMAL2CX 14-3-3 sigma	Bacterial expression vector encoding MBP-14-3-3 sigma	Insert at EcoRI – HindIII
pcDNA3.1 (zeo+)	Mammalian expression vector, used for transfection	BamHI – EcoRI- NotI – XbaI
pcDNA3.1 CD8	Mammalian expression vector encoding the extracellular domain of hCD8	Insert at BamHI – EcoRI
pcDNA3.1 CD8-CFP	Mammalian expression vector encoding the reporter protein precursor CD8-CFP	Insert at EcoRI- NotI
pcDNA3.1 CD8-CFP-TASK1-C15 WT	Mammalian expression vector encoding the reporter protein CD8-CFP-TASK1-C15 WT	Insert at NotI – XbaI

Results

Quantitative characterization of 14-3-3 binding to TASK-derived C-terminal peptides

Current insight into 14-3-3 binding to a trafficking control region at the distal C-terminus of TASK-1 and TASK-3 is almost exclusively qualitative (11, 17–19). It is well understood that a prerequisite of 14-3-3 binding, is phosphorylation of a serine present at the distal C-terminus of TASK-1 (S393) and TASK-3 (S373). Also well established is that co-expression of the channel protein and 14-3-3 increases the relative amount of protein expressed at the cell surface, indicating the necessity of 14-3-3 binding to overcome ER retention. However, how binding affinities between different isoforms (seven isoforms are known in mammals, denoted with Greek letters β , γ , ε , ζ , η , τ , σ) and different substrates, such as TASK-1 and TASK-3, compare is unknown. In 2013 the first insight into molecular details of 14-3-3 binding to this trafficking control region was gained by Andes et al. (2013) determining the binding affinity of 14-3-3 σ to a TASK-3 derived hexapeptide with a dissociation constant of $K_D = 4.1 \pm 0.8 \mu\text{M}$ (107).

To assess the binding parameters of all seven 14-3-3 isoforms to a large variety of TASK-derived client peptides systematically, fluorescence polarization titration (FP) was employed. 14-3-3 clients comprising the last 15 amino acids of either TASK-3, various TASK-3 derived mutants and TASK-1-derived peptides are listed in **Table 5**. Employing a solution-based method and synthetic peptides appeared to be advantageous to determine 14-3-3 binding parameters for differentially phosphorylated TASK-1 derived peptides (TASK-1 presents two adjacent serine residues at its distal C-terminus (KRRS³⁹²S³⁹³V), compared to TASK-3 with one Lysine residue preceding the conserved Serine residue of the mode III 14-3-3 binding motif (KRRK³⁷²S³⁷³V)). Furthermore this method appeared to be particularly useful to investigate binding of one fluorescent TASK-derived peptide to one binding groove of 14-3-3 in solution.

14-3-3 proteins bind the TASK-3 C-terminus phosphorylation dependent and with high affinity

First I assessed binding of all seven mammalian 14-3-3 isoforms to peptides comprising the last 15 amino acids of TASK-3. Peptides employed were: an unphosphorylated version of the TASK-3 C-terminus (TASK-3 WT), a phosphorylated version of the TASK-3 WT (TASK-3 WT pS373) and a 14-3-3 binding deficient version of the TASK-3 C-terminus (TASK-3 S373A). All seven mammalian 14-3-3 isoforms were affinity purified as fusions of the maltose binding protein (MBP). After cleavage of the MBP protein-tag, by Factor Xa, dimeric 14-3-3 proteins were obtained by size exclusion chromatography.

Results

Binding parameters of all seven 14-3-3 isoforms to the TASK-3 WT C-terminus were determined, titrating 10 nM of the fluorescent peptide with 14-3-3 concentrations in a range of 1 nM to 120 μ M (**Figure 8**). The FP data was analyzed applying a sigmoidal dose-response curve fit (monophasic). Binding parameters determined for TASK-3 WT pS373 ranged from 110 \pm 10 nM (14-3-3 η , **Figure 8, E**) to 3,600 \pm 400 nM (14-3-3 σ , **Figure 8, G**). Titration of the unphosphorylated TASK-3 WT peptide with 14-3-3 proteins did not yield significant changes in fluorescence polarization. Similar observations were made, titrating TASK-3 S373A with 14-3-3 proteins. Calculated equilibrium binding constants are listed in **Table 6**.

	FP: K _D [nM]		
	TASK-3 WT	TASK-3 WT pS373	TASK-3 S373A

14-3-3η	n.b.	110 \pm 10	n.b.
14-3-3τ	n.b.	220 \pm 20	n.b.
14-3-3σ	n.b.	3,600 \pm 400	n.b.

Table 6: Equilibrium binding constants for respective interaction pairs of TASK-3 derived peptides and different 14-3-3 isoforms. n.b.: no binding observed. Values are displayed as average, error depicted as standard error of the mean (s.e.m.).

Taken together these findings demonstrate that 14-3-3 binding to the TASK-3 WT C-terminus depends on the phosphorylation state of S373, comparing interaction experiments performed with phosphorylated (TASK-3 WT pS373), unphosphorylated (TASK-3 WT) or 14-3-3 binding deficient (TASK-3 S373A) TASK-3-derived C-terminal peptides. It could furthermore be shown, that 14-3-3 proteins bind the phosphorylated TASK-3 C-terminus with high affinity in an isoform specific manner (**Figure 8, Table 6**).

Results

Figure 8: Isoform specific binding of 14-3-3 proteins to the phosphorylated TASK-3 WT C-terminus. **A** to **G** illustrate equilibrium binding isotherms obtained for interactions measured between 14-3-3 proteins and peptides comprising the distal (CT15), phosphorylated TASK3 C-terminus (Respective interaction pairs were

composed of TASK-3 CT15 pS373 and **A**: 14-3-3 β , **B**: 14-3-3 γ , **C**: 14-3-3 ϵ , **D**: 14-3-3 ζ , **E**: 14-3-3 η , **F**: 14-3-3 τ , **G**: 14-3-3 σ). The assay was repeated at least six times with two batches of independently purified protein. Error bars depict standard error of the mean (s.e.m.).

Introducing a K369A mutation into the TASK3 C-terminus does not disrupt 14-3-3 binding

We further investigated binding of all seven mammalian 14-3-3 isoforms to a COPI-binding deficient version of the TASK3 C-terminus, TASK3 K369A. Mutation of the non-canonical ER retention/retrieval motif present in TASK-3, K³⁶⁹R³⁷⁰R³⁷¹ (3, 11, 17–19, 113), disrupts COPI binding resulting in elevated cell surface expression of the channel. The disruption of COPI binding also removes the necessity of phosphorylation dependent 14-3-3 binding to overcome ER-retention (11), allowing COPI- and 14-3-3-independent cell surface expression of the channel.

Affinity purified and proteolytically processed and gel-filtrated 14-3-3 proteins were titrated with 10 nM of the fluorescent peptide. Experiments were carried out and analyzed as described above. Calculated binding affinities ranged from 70 \pm 5 nM (14-3-3 γ , **Figure 9, B**) to 2,200 \pm 50 nM (14-3-3 σ , **Figure 9, G**). A comparison of values obtained for respective interaction pairs of TASK3 WT pS373, TASK3 K369A pS373 with different 14-3-3 isoforms is illustrated in **Table 7**.

Comparing absolute values, 14-3-3 binding affinities for TASK-3 K369A pS373 were increased by up to 2-fold for 14-3-3 γ and 14-3-3 ζ , compared to binding affinities determined for TASK-3 WT pS373. In general, an increase in binding affinity was observed for all 14-3-3 isoforms, except 14-3-3 τ , for which a reduction in binding affinity by 2-fold was observed (see **Table 7** for a direct comparison).

Results

Figure 9: Mutation of K369 to Alanine does not interfere with 14-3-3 binding. **A** to **G** illustrate an overlay of equilibrium binding isotherms obtained for respective interaction pairs of TASK-3 K369A pS373 (blue line) and TASK-3 WT pS373 (black line) with different 14-3-3 isoforms. The assay was repeated at least six times with

two batches of independently purified protein. Error bars depict standard error of the mean (s.e.m.).

I conclude that 14-3-3 binding is not impaired upon replacement of K369 by Alanine. Hence reporter proteins containing such a mutation should maintain 14-3-3 binding properties once phosphorylated.

	FP: K _D [nM]						Change [fold]

Deletion of V374 does not abolish 14-3-3 binding

Based on the current literature (11, 18) deletion of a C-terminal valine, which is part of a mode III 14-3-3 binding motif in TASK3, abolishes 14-3-3 binding. Furthermore this valine residue appears to be required to bind 14-3-3 proteins with high affinity, facilitating channel release from ER retention (11, 17–19, 113–115). We tested this hypothesis and assessed 14-3-3 binding to peptides comprising the last 14 amino acids of TASK-3, lacking the penultimate Valine residue. Peptides used were phosphorylated at S373 to enable

Results

phosphorylation-dependent binding of 14-3-3 proteins. Experiments were carried out and analyzed as described above.

Interestingly, we found that almost all 14-3-3 isoforms, except 14-3-3 σ , bound the TASK-3 pS373 Δ V374 peptide, with binding affinities varying from $1.1\pm 0.1 \mu\text{M}$ (14-3-3 γ , **Figure 10, B**) to $18.0\pm 5.0 \mu\text{M}$ (14-3-3 ϵ , **Figure 10, B**). Binding affinities were reduced by three- (14-3-3 ζ) to 23-fold (14-3-3 ϵ), compared to affinities determined for TASK-3 WT pS373 (**Table 8**).

	FP: K _D [nM]						Change [fold]
	TASK-3 WT pS373			TASK-3 Δ V374 pS373			
14-3-3β	370	±	40	1,200	±	100	3.2

14-3-3ζ	1,000	±	60	3,300	±	300	3.3
14-3-3η	110	±	10	1,600	±	140	14.5
14-3-3τ	220	±	20	2,400	±	100	10.9
14-3-3σ	3,600	±	400	n.b.	±	n.b.	-

Table 8: Affinity binding constants determined for respective interaction pairs of TASK-3 WT pS373, TASK-3 pS373 Δ V374 and different mammalian 14-3-3 isoforms. Values are displayed as the average of six measurements. Error depicts standard error of the mean (s.e.m.). n.b.: no binding observed.

Comparing affinities, we conclude, that 14-3-3 binding to the truncated TASK-3 C-terminus (TASK-3 pS373 Δ V374) is changed significantly, but not entirely lost upon deletion of the penultimate Valine. A recent crystal structure also revealed that V374 forms only one hydrogen bond with a lysine residue in 14-3-3 σ , thereby not substantially contributing to binding affinities observed. Since all experiments were carried out with fully phosphorylated peptides, further information about the phosphorylation state of the truncated TASK-3 channel/reporter protein *in vivo* is required. Hence the lack of cell surface

expression reported in the literature cannot fully be explained by reduced 14-3-3 binding affinities.

Figure 10: Truncation of the TASK-3 C-terminus does not abolish 14-3-3 binding. **A** to **F** illustrate equilibrium binding isotherms for respective interaction pairs of TASK-3 pS373 Δ V374 (red line) and TASK-3 WT pS373 (black line) with different 14-3-3 isoforms. No interactions between 14-3-3 σ and TASK-3 Δ V374 pS373 were observed (isotherm not shown). The assay was repeated at least six times with two

Results

batches of independently purified protein. Error bars depict standard error of the mean (s.e.m.).

Modulation of 14-3-3 binding by differential phosphorylation of the client protein

Having systematically characterized interactions between 14-3-3 proteins and TASK-3 derived C-terminal peptides, I was further interested in how binding parameters compare between two different client proteins, such as TASK-3 and TASK-1. We utilized the same experimental approach as described for TASK-3 and employed fluorescently labeled peptides comprised of the last 15 amino acids of the distal TASK-1 C-terminus.

There are notable differences in the residues flanking the COPI retention-retrieval motif and the mode III 14-3-3 binding motif in TASK-1 and TASK-3. TASK-1 features a second serine residue (S392) that can potentially be phosphorylated and that precedes the conserved serine (S393) of the mode III 14-3-3 binding motif. This second serine is absent in TASK-3, where the corresponding residue flanking both motifs is lysine (K372). To address the presence of this second Serine residue in TASK-1 and the functional consequence of it being phosphorylated on 14-3-3 binding, individually phosphorylated C-terminal peptides, TASK-1 WT pS392 and TASK-1 WT pS393 as well as a double phosphorylated peptide TASK-1 WT pS392pS393 were employed. Additionally, I characterized interactions between all 14-3-3 isoforms and a truncated version of the TASK-1 C-terminus, TASK-1 pS393 Δ V394. A 14-3-3 binding deficient mutant of the TASK-1 C-terminus, TASK-1 S392/393A, and the unphosphorylated C-terminal TASK-1 peptide, TASK-1 WT were used as controls, which essentially did not bind 14-3-3. A list of all peptides employed in Fluorescence Polarization titration assays can be found in **Table 5**.

Binding affinities of 14-3-3 proteins for the TASK-1 WT C-terminus are significantly lower than for the TASK-3 WT C-terminus

I first determined the binding parameters for all seven mammalian 14-3-3 isoforms to TASK-1 WT pS393, in which the conserved Serine residue of the mode III 14-3-3 binding motif was phosphorylated (3, 11, 17–19, 107, 113, 116). Experiments were carried out and the obtained data was analyzed as described for TASK3 derived C-terminal peptides. Control experiments were performed employing an unphosphorylated TASK-1 WT peptide, as well as a 14-3-3 binding deficient mutant of the TASK-1 C-terminus (TASK-1 S392/393A). 14-3-3 proteins bound the TASK-1 WT pS393 peptide with affinities ranging from $7.5 \pm 0.1 \mu\text{M}$ (14-3-3 β , **Figure 11, A**) to $49.4 \pm 2.0 \mu\text{M}$ (14-3-3 τ , **Figure 11, E**). Compared to TASK-3 WT pS373, affinities were reduced by 20 (14-3-3 β : TASK-3 WT pS373 – 14-3-3 β : TASK-1 WT pS393) to 200-fold (14-3-3 τ : TASK-3 WT pS373 – 14-3-3 τ : TASK-1 WT pS393), comparing individual isoforms (**Table 9**). We did not observe 14-3-3 binding to either TASK-1 WT (not phosphorylated), or TASK-1 S392/393A.

	FP: K _D [μM]		
	TASK-1 WT	TASK-1 WT pS393	TASK-1 S392/393A

14-3-3 σ	n.b.	36.0 ± 2.9	n.b.

Table 9: Affinity binding constants determined for respective interaction pairs of TASK-1 WT, TASK-1 WT pS393, TASK-1 S392/393A and different mammalian 14-3-3 isoforms. Values are display as the average of six experiments. The error depicts standard error of the mean (s.e.m.). n.b.: no binding observed.

Results

Taken together my findings illustrate, that 14-3-3 proteins bind the phosphorylated TASK-1 WT C-terminus in an isoform specific manner with binding affinities substantially reduced (low μM range), compared to affinities determined for TASK-3 WT pS373 (low nM range). I further demonstrate, that 14-3-3 binding depends on the phosphorylation state of S393, compare experiments performed with phosphorylated (TASK-1 WT pS393), unphosphorylated (TASK-1 WT) and 14-3-3 binding deficient (TASK-1 S392/393A) TASK-1 derived C-terminal peptides.

Truncation of the TASK-1 C-terminus disrupts 14-3-3 binding

I further investigated binding of all seven mammalian 14-3-3 isoforms to the truncated TASK-1 C-terminus, TASK-1 pS393 ΔV394 . Although phosphorylated at S393, 14-3-3 binding to the truncated TASK-1 C-terminus was no longer detected. These findings are in agreement with current literature (11, 18). A comparison between TASK-3 pS373 ΔV374 and TASK-1 pS393 ΔV394 illustrates the impact of different residues presented by each C-terminal peptide on 14-3-3 binding. Whereas TASK-3 presents a lysine (K372) residue that possibly forms hydrogen bonds with the side chains present in the inner side of the 14-3-3 binding cleft, TASK-1 C-terminal peptides present a second serine residue (S392) that cannot interact in the same way and hence affects the 14-3-3 binding properties (**Table 9, Figure 11**).

Figure 11: Binding affinities of 14-3-3 proteins to TASK-1 pS393 are reduced by several orders of magnitude compared to affinities determined for TASK-3 WT pS373. **A to G** illustrate equilibrium binding isotherms obtained for respective interaction pairs of TASK-3 WT pS373 (green line) and TASK-1 WT pS393 (black

Results

line) with different 14-3-3 isoforms. The assay was repeated at least six times with two batches of independently purified protein. Error bars depict standard error of the mean (s.e.m.).

Phosphorylation of S392 inhibits 14-3-3 binding

To further evaluate the consequence of phosphorylation of the second Serine residue (S392), present in the TASK-1 C-terminus, on 14-3-3 binding, peptides phosphorylated at S392, TASK-1 WT pS392, and double phosphorylated peptides, TASK-1 pS392pS393 were employed. FP experiments were carried out and data was analyzed as described for TASK-3 derived C-terminal peptides. Theoretically phosphorylation of S392 could create another high/moderate affinity 14-3-3 binding site, which would fulfill the criteria of a mode III 14-3-3 binding motifs (-R-X-pS/T-X₁₋₂-COOH (15)). We tested this possibility and determined equilibrium binding parameters for all seven 14-3-3 isoforms binding to TASK-1 WT pS392 (**Figure 12**). Interestingly binding affinities determined were significantly lower than for TASK-1 WT pS393 and TASK-3 WT pS373, varying from $33.1 \pm 0.7 \mu\text{M}$ (14-3-3 β , **Figure 12, A, Table 10**) to $373.6 \pm 33.2 \mu\text{M}$ (14-3-3 ϵ , **Figure 12, C, Table 10**). Compared to TASK-1 WT pS393 affinities were reduced by five (14-3-3 β : TASK-1 WT pS393 – TASK-1 WT pS392) to 13-fold (14-3-3 ϵ : TASK-1 WT pS393 – TASK-1 WT pS392).

	FP: K _D [nM]			FP: K _D [μM]					
	TASK-3 WT pS373			TASK-1 WT pS393	TASK-1 WT pS392				
14-3-3β	370	±	40	7.5	±	0.1	33.1	±	0.7
14-3-3γ	150	±	20	9.8	±	0.6	51.4	±	2.7
14-3-3ε	800	±	80	29.0	±	1.0	373.6	±	33.2
14-3-3ζ	1,000	±	60	23.0	±	1.4	133.0	±	1.8
14-3-3η	110	±	10	9.2	±	0.1	81.5	±	7.8
14-3-3τ	220	±	20	49.4	±	2.0	123.2	±	9.0
14-3-3σ	3,600	±	400	36.0	±	2.9	58.8	±	5.3

Table 10: Affinity binding constants determined for respective interaction pairs of TASK-1 WT pS393, TASK-1 WT pS392 and different mammalian 14-3-3 isoforms. For comparison binding affinities of 14-3-3 proteins to TASK-3 WT pS373 are included. Values are display as the average of six experiments. Error depicts standard error of the mean (s.e.m.).

These findings confirmed that phosphorylation of S392 does not compensate for phosphorylation of S393 by creating another high/moderate affinity 14-3-3 binding site. On the contrary, phosphorylation of S392 seems to exert an inhibitory effect on 14-3-3 binding. I also predict a potential regulatory function of S392 in protein trafficking, implying an even more complex signal transduction cascade regulating TASK-1 anterograde protein trafficking.

Results

Figure 12: 14-3-3 affinities to TASK-1 WT pS392 are several fold reduced compared to TASK-1 WT pS393. **A to G** illustrate equilibrium binding isotherms obtained for respective interaction pairs of TASK-1 WT pS392 peptides (red line), TASK-1 WT pS393 (black line) and TASK-3 WT pS373 (green line) with different 14-3-3 isoforms.

Results

The assay was repeated at least six times with two batches of independently purified protein. Error bars depict standard error of the mean (s.e.m.).

Finally, I assessed the functional consequence of double phosphorylation on 14-3-3 binding, employing TASK-1 WT pS392pS393 peptides. I utilized the same experimental approach and compared binding parameters obtained for differentially phosphorylated TASK-1 derived peptides (**Figure 13**). Calculated affinities for TASK-1 WT pS392pS393 varied from $92.2 \pm 2.9 \mu\text{M}$ (14-3-3 β , **Figure 13, A; Table 11**) to $861 \pm 23 \mu\text{M}$ (14-3-3 ϵ , **Figure 13, C; Table 11**).

	FP: K _D [μM]

Table 11: Comparison of affinity binding constants determined for respective interaction pairs of TASK-1 WT pS393, TASK-1 WT pS392, TASK-1 WT pS392pS393 and different mammalian 14-3-3 isoforms. Values are displayed as the average of six experiments. Error depicts standard error of the mean (s.e.m.).

Results

Figure 13: Double phosphorylation of the TASK1 C-terminus results in strongly reduced binding affinities of 14-3-3 proteins indicating a potential inhibitory function of S392 on 14-3-3 binding. **A** to **G** illustrate equilibrium binding isotherms obtained for respective interactions pairs of TASK-1 WT pS392pS393 (blue line), TASK-1 WT

pS392 peptides (red line), TASK-1 WT pS393 (black line) and TASK-3 WT pS373 (green line) with different 14-3-3 isoforms. The assay was repeated at least six times with two batches of independently purified protein. Error bars depict standard error of the mean (s.e.m.).

A comparison of 14-3-3 binding affinities for TASK-1 WT pS392pS393, TASK-1 WT pS392 and TASK-1 WT pS393 clearly shows the impact of phosphorylation of S392 on 14-3-3 binding. Compared to TASK-1 WT pS392 14-3-3 binding- affinities are reduced by two (14-3-3 ϵ , ζ , σ : TASK-1 WT pS392pS393 – TASK-1 WT pS392) to six fold (14-3-3 η : TASK-1 WT pS392pS393 – TASK-1 WT pS393). More obvious differences are observed comparing 14-3-3 affinities determined for TASK-1 WT pS392pS393 and TASK-1 WT pS393. Between individual 14-3-3 isoforms, differences in affinity, ranging from three (14-3-3 σ : TASK-1 WT pS392pS393 – TASK-1 WT pS393) to 60-fold (14-3-3 η : TASK-1 WT pS392pS393 – TASK-1 WT pS393), were observed.

Taken together I show that the presence of a second Serine residue (S392) preceding the conserved Serine of the mode III 14-3-3 binding motif (S393) in TASK-1 reduces binding affinities by several orders of magnitude compared to binding affinities determined for TASK-3. I further conclude that *in vitro*, upon phosphorylation of S392, 14-3-3 binding to TASK-1 derived C-terminal peptides is inhibited, indicating a potential regulatory role of this residue (S392) *in vivo*.

Results

Correlation of 14-3-3 binding parameters by Surface Plasmon Resonance (SPR)

To confirm my findings by another quantitative method, I utilized surface plasmon resonance (SPR). The last 15 amino acids of the distal TASK-3 C-terminus were N-terminally fused to a glutathione S-transferase (GST) protein-tag, recombinantly expressed and affinity purified from *Escherichia coli* (*E.coli*). Since the proteins were expressed in bacteria they were not phosphorylated. To remove contaminants, affinity purified proteins were subjected to size exclusion chromatography. To study phosphorylation dependent binding of 14-3-3 proteins, we developed an on-chip phosphorylation assay based on studies by Mant et al., 2011, reporting that TASK-1 and TASK-3 C-terminal peptides are efficiently phosphorylated by the catalytic subunit of PKA, *in vitro* (23).

I assessed 14-3-3 binding of all seven mammalian 14-3-3 isoforms to GST-TASK-3 WT before and after phosphorylation. **Figure 14** illustrates a basic experimental setup, used to study phosphorylation dependent 14-3-3 binding to GST-TASK-3 WT fusion proteins.

For this assay, a polyclonal anti-GST antibody (Carl Roth, Karlsruhe, Germany, 3998.1) was crosslinked to the SPR sensorchip surface at high density (109). The sensorchip surface was washed with glycine to remove contaminants and equilibrated in SPR running buffer. TASK-3 WT GST-fusion protein (the ligand) was injected over the surface at a flow rate of 30 μ l/min and captured onto the chip surface at low density. Affinity captured ligand proteins were equilibrated in SPR running buffer and subsequently phosphorylated by injection of a phosphorylation solution containing an ATP regeneration system (108) and recombinant catalytic subunit of PKA. Following phosphorylation, contaminants were rinsed from the surface by multiple buffer injections.

Figure 14: Experimental setup of a Surface Plasmon Resonance (SPR) assay used to study phosphorylation dependent 14-3-3 binding to TASK-3 WT C-termini. **A:** Capture of the ligand onto the chip surface, which, prior to ligand capture, was modified with a polyclonal anti-GST antibody, at low density. **B:** Binding experiments performed after capture. At this stage 14-3-3 proteins did not bind to the unphosphorylated TASK3 C-terminus leading to the conclusion, that 14-3-3 proteins binding occurs exclusively in a phosphorylation dependent manner. **C:** Following capture, the ligand was phosphorylated by injection of a phosphorylation mix containing PKA and ATP followed by incubation for 20 minutes at 20 °C. 14-3-3 proteins were titrated and injected over the surface. At this stage binding of 14-3-3 proteins could be observed following the change of recorded response. Representative sensograms for various interactions measured are shown in **Figure 15** and **Figure 17**.

Results

Effective phosphorylation of the ligand was assessed employing a polyclonal phospho-PKA substrate antibody, raised against phosphorylated PKA consensus sites. The antibody was serially diluted and injected over the surface. High affinity binding of this antibody was observed with a dissociation constant of $K_D = 4.5 \pm 0.6$ nM (**Figure 15**)

Figure 15: The surface captured GST-TASK3 WT fusion protein is efficiently phosphorylated by recombinantly expressed catalytic subunit of PKA. GST-TASK3 WT fusion protein was captured onto the surface of a modified SPR biosensor chip, at low density. Subsequently, after capture and phosphorylation of the ligand (GST-TASK3 WT) by injecting PKA, a polyclonal anti-GST Antibody was titrated in running buffer and injected over the surface. The analyte was injected at concentrations of: 100 nM, 50 nM, 25 nM, 12.5 nM and 6.25 nM. The response was recorded (black line) and analyzed applying a simple 1:1 Langmuir interaction model (orange line). The affinity binding constant was determined with $K_D = 4.5 \pm 0.6$ nM. The surface was regenerated with Glycine pH 2.2 after each analyte injection (anti-GST antibody). The assay was repeated three times. The error is depicted as standard error of the mean (s.e.m.).

I next evaluated 14-3-3 binding before and after treatment with PKA, which allowed me to indirectly confirm that the ligand was phosphorylated. No 14-3-3 binding to the unphosphorylated C-terminus of TASK3 was observed, whereas upon phosphorylation, using recombinantly expressed catalytic subunit of PKA, all 14-3-3 isoforms bound the ligand (GST-TASK-3 WT) with

high affinity. Determined dissociation constants varied from 45 ± 9 nM (14-3-3 γ) to 742 ± 29 nM (14-3-3 σ).

Figure 16: Equilibrium binding isotherms (Dose-response curves) obtained for respective interaction pairs of GST-TASK3 WT with individual 14-3-3 protein isoforms by SPR. The data was analyzed applying a sigmoidal dose-response curve fit (monophasic, Goodness-of-fit: R^2 from 0.96 to 0.99). Calculated affinity-binding constants are listed in **Table 12**. The assay was repeated six times for each data point with two batches of independently purified protein. Error bars depict standard error of the mean (s.e.m.).

In general, differences between isoforms in binding affinity observed by fluorescence polarization (FP) were maintained comparing affinities determined by both methods. 14-3-3 γ and 14-3-3 η bound the TASK-3 WT C-terminus with higher affinity than the other isoforms, while 14-3-3 σ bound with a significantly lower affinity than all other isoforms tested. Absolute values

Results

obtained by FP and SPR varied between two-fold (14-3-3 β) and five-fold (14-3-3 ϵ , 14-3-3 ζ and 14-3-3 σ , **Table 12**).

These differences should not to be overrated, since small differences can be explained by a different steric presentation of the C-terminal peptide, immobilized at a solid interface (SPR) and in solution (FP). We conclude, that both methods yield comparable binding parameters, maintaining differences between isoforms and demonstrating high affinity binding of all 14-3-3 isoforms to the TASK-3 WT C-terminus. Corresponding equilibrium binding isotherms are depicted in **Figure 16**. A direct comparison of equilibrium binding constants determined by SPR and FP is illustrated in **Table 12**. In **Figure 17** representative sensograms obtained for respective interaction pairs of GST-TASK-3 WT and different 14-3-3 isoforms are displayed.

	FP: K_D [nM]			SPR: K_D [nM]			Difference [fold]
	TASK-3 WT pS373			GST-TASK-3 C15			
	WT	WT pS373		WT	WT pS373

Table 12: Affinity binding constants determined by Fluorescence polarization titration and Surface Plasmon Resonance. Values display the average of six measurements, error depicts standard error of the mean (s.e.m.).

Figure 17: Binding parameters obtained by fluorescence polarization (FP) were corroborated using Surface Plasmon Resonance (SPR). 14-3-3 proteins bind to the phosphorylated and immobilized TASK3 C-terminus with high affinity, maintaining differences between isoforms, previously observed by FP. Representative

Results

sensograms obtained by SPR for respective interaction pairs of GST-TASK-3 WT with individual 14-3-3 isoforms are displayed in **A** to **G**. The analyte was injected for 4:30 minutes and the dissociation of the protein from the surface was tracked for 7:00 minutes (displayed dissociation time \sim 4 minutes). 14-3-3 concentrations were titrated in a range from 15 nM to 4 μ M. The obtained response data (black line) was analyzed applying a simple 1:1 Langmuir interaction model (orange line). Kinetic parameters determined are listed in **Table 12**. The assay was repeated at least six times with two batches of independently purified protein. Error values are depicted as standard error of the mean (s.e.m.).

TASK-1 and TASK-3 C-termini are phosphorylated by PKA *in vitro*

After detailed characterization of phosphorylation-dependent 14-3-3 binding to various TASK-1 and TASK-3 derived clients quantitatively, we were further interested in understanding upstream regulatory events, mediating the phosphorylation of 14-3-3 client proteins *in vivo*. Our particular interest was focused on PKA catalyzed phosphorylation of different TASK-derived client proteins. It is well established that the catalytic subunit of PKA (PKAc, further referred to as PKA) phosphorylates TASK-1 and TASK-3 C-terminal peptides *in vitro* (23).

First I investigated phosphorylation of TASK-1 derived GST-fusion proteins *in vitro*. I further confirmed that PKA efficiently phosphorylates S392 and S393 *in vitro*, employing GST-TASK-1 CT15 fusion proteins, with either one (GST-TASK-1 S392A, GST-TASK-1 S393A), or both Serine residues (GST-TASK-1 WT) accessible to phosphorylation by PKA (**Figure 18**).

GST-TASK fusion proteins (TASK-1 WT, TASK-1 S392A and TASK-1 S393A) were used to conduct *in vitro* phosphorylation assays employing PKA. Phosphorylation experiments were performed with PKA in presence and absence of ATP. Samples incubated with PKA excluding ATP from the phosphorylation reaction were used as a control, in which the protein was

essentially not phosphorylated. **Figure 11** shows the GST-fusion proteins after PKA treatment and separation on a standard SDS-PAGE (lower panel) or Phostag SDS-PAGE gel (upper panel). For GST-TASK-1 WT two distinct protein bands were observed. The first band migrated at a position corresponding to the GST-fusion protein treated with PKA in absence of ATP. The second protein band observed was shifted upward relative to control incubations performed in absence of ATP (migrating at ~42 kDa in size), indicating that the TASK-1 fusion protein was efficiently phosphorylated by PKA. Similar observations were made for GST-TASK-1 S392A and GST-TASK-1 S393A. For each fusion protein two protein bands were observed after separation on a Phostag SDS-PAGE gel. The first band migrated at the same height as control incubations made in absence of ATP and the second band observed was shifted upward relative to the first band indicating retardation of the protein on Phostag SDS-PAGE gels due to efficient phosphorylation of the protein. The phosphorylation band observed for either GST-TASK-1 S392A, or GST-TASK-1 S393A migrated faster than the corresponding phosphorylation band observed for GST-TASK-1 WT, indicating a different phosphorylation state of the GST-fusion protein. Differences observed indicate that the TASK-1 WT fusion protein is double phosphorylated, whereas the migratory behavior of each mutant indicates a single phosphorylation of the protein.

These findings illustrate that phosphorylation of TASK-1 derived GST-fusion proteins is dependent on the presence of PKA and ATP. Furthermore these results demonstrate, that S392 and S393 are efficiently phosphorylated by PKA *in vitro*, confirming findings reported by Mant et al. 2011 (23). Comparing the migration of GST-TASK-1 WT, GST-TASK-1 S392A and GST-TASK-1 S393A I was also able to distinguish between doubly (GST-TASK-1 WT) and singly phosphorylated proteins (GST-TASK-1 S392A, GST-TASK-1 S393A) after samples were resolved on a Phostag SDS-PAGE gel. Interestingly small differences in migration between GST-TASK-1 S392A and GST-TASK-1

Results

S393A were observed, which might be attributed to differences in sterical presentation of the phosphorylated TASK-C-terminus.

Figure 18: S392 and S393 of TASK-1 are efficiently phosphorylated by the catalytic subunit of PKA (PKAc) *in vitro*. Affinity purified GST-TASK1 C-terminus fusion proteins (GST-TASK1 WT, GST-TASK-1 S392A and GST-TASK-1 S393A) were phosphorylated with recombinant catalytic subunit of PKA in presence (Lane 2, 4 and 6) and absence of ATP (Lane 1, 3 and 5) for 12 hours at 4°C, *in vitro*. Samples were resolved on Phostag SDS PAGE gels, upper panel or standard SDS-PAGE gels, lower panel and subsequently stained with coomassie solution to visualize protein bands. The assay was repeated 6 times. 'P' suffixes denote the number of phosphorylated residues.

Deletion of the distal Valine V374 in TASK-3 affects PKA phosphorylation

To evaluate how efficiently TASK-derived proteins are phosphorylated by PKA and how different substrates compare, we generated different TASK-3-derived GST-fusion proteins. We were particularly interested in how phosphorylation of the truncated TASK-3 C-terminus compares to phosphorylation of the wild

type TASK-3 C-terminus. For this purpose the last 15 amino acids of TASK-3, a truncated version of the TASK-3 C-terminus and a 14-3-3 binding deficient version were fused to the Glutathione-S-transferase (GST) protein-tag, expressed in bacteria and subsequently affinity purified. Since they were expressed in bacteria these proteins were not phosphorylated.

In vitro phosphorylation assays were conducted, as described for TASK-1 derived GST-fusion proteins. First, we investigated phosphorylation of the GST-TASK-3 WT fusion protein and a truncated variant, GST-TASK-3 Δ V374, with 12 h of PKA treatment (**Figure 19**). Similar to observations made for TASK-1 derived GST-fusion proteins, two distinct protein bands for GST-TASK-3 WT as well as GST-TASK-3 Δ V374 were observed after separation on a Phostag SDS-PAGE gel (**Figure 19**, Lane 2 and Lane 4, upper panel). The first band, faintly stained by Coomassie solution, migrated at the same height as control incubations performed with PKA in absence of ATP, indicating that a small portion of the protein was not phosphorylated. The second band observed was strongly stained by Coomassie solution and shifted upwards, indicating efficient phosphorylation of the client protein by the catalytic subunit of PKA. After 12 h of PKA-treatment in presence of ATP, we did not observe significant differences in the relative amounts of protein phosphorylated, neither for GST-TASK-3 WT, nor for GST-TASK-3 Δ V374. Incubation of GST-TASK-3 S373A fusion protein with PKA in absence, or presence of ATP did not alter the migration of the protein on a Phostag SDS-PAGE gel, confirming that the TASK-3 C-terminus is specifically phosphorylated at S373 by the catalytic subunit of PKA.

After 12 h of incubation with PKA and ATP, both substrates employed were fully phosphorylated, which is not an unexpected result, since the limiting factor, ATP, was constantly resupplied utilizing an ATP regeneration system (108), allowing PKA to continuously phosphorylate available substrates. In addition, for each substrate faintly stained protein bands corresponding to a

Results

protein population, which appeared to be ‘phosphorylation resistant’, were observed.

Figure 19: Phosphorylation of TASK-3 derived GST-fusion proteins. After 12 hours of phosphorylation GST-TASK-3 WT and GST-TASK-3 Δ V374 were phosphorylated efficiently by recombinant PKA. Affinity purified GST-TASK3 WT, Δ V374 and S373A fusion proteins were phosphorylated for 12 h at 4°C, utilizing the recombinant catalytic subunit of PKA. Experiments were carried out in presence of PKA and ATP (Lane 2, 4 and 6), or with PKA in absence of ATP (Lane 1, 3 and 5). Samples were resolved on Phostag SDS PAGE gels, upper panel, or standard SDS-PAGE gels, lower panel and subsequently stained with coomassie solution to visualize protein bands. The assay was repeated three times. ‘P’ denotes the number of phosphorylated residues.

To further clarify if both substrates are equally well phosphorylated within a shorter period of time, we quantified the relative amount of protein phosphorylated after 10 minutes of PKA treatment. *In vitro* phosphorylation assays were conducted as described for GST-TASK-1 fusion proteins and samples were resolved on either Phostag SDS-PAGE or standard SDS-PAGE gels. As described previously, proteins incubated with PKA in absence of ATP were essentially not phosphorylated and migrated faster on Phostag SDS-

PAGE gels. Whereas the migration of phosphorylated proteins was retarded resolving samples on Phostag SDS-PAGE gels, causing a band shift upwards relative to control incubations performed in absence of ATP.

For GST-TASK-3 WT, two protein bands were observed after separation of the sample on a Phostag SDS-PAGE gel. The first band was faintly stained by Coomassie solution and migrated at the same height as control incubations performed in absence of ATP, indicating that a small portion of the protein was not phosphorylated (**Figure 20**, Lane 1). The second band observed was strongly stained by Coomassie solution and shifted upwards, relative to control incubations performed with PKA in absence of ATP, indicating that the TASK-3 WT C-terminus was efficiently phosphorylated by the catalytic subunit of PKA within 10 minutes of treatment (**Figure 20**, Lane 2). Similar to these observations, two protein bands were observed for GST-TASK-3 Δ V374 after incubation with PKA in presence of ATP. However the first band, corresponding to unphosphorylated protein and migrating at the same height as control incubations performed in absence of ATP, was stained more strongly compared to the analogous protein band observed for GST-TASK-3 WT (**Figure 20**, Lane 3). The phosphorylated band, migrating at the same height as observed for GST-TASK-3 WT, was faintly stained by Coomassie solution (**Figure 20**, Lane 4), indicating that the truncated TASK-3 C-terminus was less efficiently phosphorylated than the wild type TASK-3 C-terminus. We quantified the amount of protein phosphorylated by forming the ratio of the amount of protein phosphorylated (upper band) with the total amount of protein loaded (SDS loading control, lower panel). For GST-TASK-3 WT we determined that ~60% of the protein employed was phosphorylated within 10 minutes of PKA treatment, whereas for GST-TASK-3 Δ V374 only ~20% of total protein employed was phosphorylated during the same incubation time, indicating that truncation of the TASK-3 C-terminus affected the efficiency of phosphorylation by PKA.

Results

Taken together, I conclude that the TASK-3 WT C-terminus was efficiently phosphorylated by the catalytic subunit of PKA in presence of ATP, confirming results reported by Mant et al., 2011 (23). I further demonstrate that the deletion of the distal valine, which affects 14-3-3 binding (see FP) also affected the efficiency of protein phosphorylation by PKA, reducing the amount of phosphorylated protein detected by three-fold. **Figure 20, B** illustrates our findings.

Figure 20: The GST-TASK-3 WT fusion-protein is more efficiently phosphorylated by PKA, than the truncated TASK-3 C-terminus ($\Delta V374$). Truncation of the TASK-3 C-terminus reduces the efficiency of phosphorylation by PKA significantly. Affinity purified GST-TASK-3 WT, GST-TASK-3 $\Delta V374$ and GST-TASK-3 S373A fusion proteins were phosphorylated for 10 minutes at room temperature, utilizing the recombinant catalytic subunit of PKA. Experiments were carried out with PKA in presence of ATP (Lane 2, 4 and 6), or in absence of ATP (Lane 1, 3 and 5). Samples were resolved on Phostag SDS-PAGE gels and SDS-PAGE gels as described above. The total pixel intensity was determined for each protein band. The amount of protein phosphorylated was determined by forming the ratio between values obtained for phosphorylated protein with values obtained for the total protein loaded from SDS-

PAGE gels. The assay was repeated six times. Error bars depict standard error of the mean (SEM).

Cell surface expression of different TASK-derived reporter proteins

After broad *in vitro* characterization of different events regulating cell surface expression of TASK-channels *in vivo*, we evaluated the functional consequence of mutation of TASK-3 and TASK-1 C-termini on cell surface expression by flow cytometry. We determined the relative cell surface expression of various TASK-derived reporter proteins. Reporter proteins were generated, fusing a fluorescent probe (CFP), as a linker, and the previously described TASK-derived C-terminal peptides to the cytosolic tail of the dimeric surface glycoprotein CD8. The fluorescent linker was introduced, to later on identify cells expressing the reporter protein. All constructs used to study cell surface expression of TASK-derived reporter proteins are listed in **Table 13**.

Construct	C-terminal tail attached	14-3-3 binding
CD8-CFP-TASK-3 WT	SFTD HQRLM KRR KSV-COOH	+++
CD8-CFP-TASK-3 ΔV374	SFTD HQRLM KRR KS-COOH	++
CD8-CFP-TASK-3 S373A	SFTD HQRLM KRR KAV -COOH	-
CD8-CFP-TASK-3 K369A	SFTD HQRLM A RRKSV-COOH	+++
CD8-CFP-TASK-1 WT	SLSTFRGLM KRR SSV-COOH	+
CD8-CFP-TASK-1 S392A	SLSTFRGLM KRR ASV -COOH	+
CD8-CFP-TASK-1 S393A	SLSTFRGLM KRR SAV -COOH	-
CD8-CFP-TASK-1 K389A	SLSTFRGLM A RRSSV-COOH	+ (predicted)
CD8-CFP-TASK-1 ΔV374	SLSTFRGLM KRR SS-COOH	-

Table 13: Reporter proteins used to study differences in cell surface expression and elucidate the role of different residues and sorting motifs *in vivo*. Observed 14-3-3 binding is denoted with +: for low affinity binding, ++: for moderate affinity binding, +++: for high affinity binding, -: for no binding.

Results

To investigate the functional consequence of high affinity 14-3-3 binding on cell surface expression of TASK-3-derived reporter proteins, I expressed the TASK-3-derived reporter proteins, listed in **Table 13**, in COS7 cells. The relative cell surface expression of CD8-CFP-TASK-3 WT, CD8-CFP-TASK-3 S373A, a 14-3-3 binding deficient mutant, CD8-CFP-TASK-3 K369A, a mutant deficient for COPI binding and CD8-CFP-TASK-3 Δ V374, a truncated version of the TASK-3 C-terminus was determined.

First I assessed the relative cell surface expression of CD8-CFP-TASK-3 WT, therefore I detected the extracellular domain of CD8 utilizing a monoclonal anti-CD8 primary antibody and an Alexa-Fluor-647 coupled secondary antibody. In parallel I assessed the relative surface expression of CD8-CFP-TASK-3 S373A, CD8-CFP-TASK-3 K369A and CD8-CFP-TASK-3 Δ V374. **Figure 21** illustrates my observations. The relative amount expressed at the cell surface of each reporter protein was normalized to the TASK-3 WT reporter protein, a bar diagram summarizing my findings is shown in **Figure 22**.

The TASK-3 wild type reporter protein was efficiently transported to the cell surface (**Figure 21 A**, Q2). Upon mutation of the S373, the conserved Serine residue of the mode III 14-3-3 binding motif, the relative cell surface expression of the reporter protein was decreased significantly (**Figure 21 B**, Q2). The relative cell surface expression of CD8-CFP-TASK-3 S373A was more than five fold lower compared to the wild type reporter protein. These results confirm that surface expression of the TASK-3 wild type reporter protein depends on the phosphorylation state of S373 and subsequent 14-3-3 binding. Furthermore, the relative cell surface expression of CD8-CFP-TASK-3 K369A, a COPI binding deficient reporter protein, was assessed (**Figure 21 C**, Q2). Only minor differences between CD8-CFP-TASK-3 K369A and CD8-CFP-TASK-3 WT were observed. Hence the CD8-CFP-TASK-3 K369A reporter reaches the cell surface efficiently, but no longer requires phosphorylation and subsequent 14-3-3 binding to escape retention/retrieval by COPI (11), we conclude that similar levels of the CD8-CFP-TASK-3 WT

reporter protein must be a result of efficient phosphorylation and subsequent high affinity 14-3-3 binding.

Figure 21: TASK-3 derived reporter proteins are differently expressed at the cell surface. Cos7 cells were transiently transfected with DNA encoding TASK-3 derived reporter proteins. Proteins were expressed for 36h. Surface localised proteins were detected employing a monoclonal anti-CD8 primary antibody and an Alexa-647 conjugated secondary antibody. Following detection, cells were subjected to Flow cytometry and the relative cell surface expression of different reporter proteins was determined. Displayed are representative dot-plots for each reporter protein employed. Each dot-plot was divided into four quadrants (Q1 - Q4). Q1: CFP-positive cells, cells expressing the reporter, in which the reporter was not detected at the cell surface. Q2: CFP/CD8-positive cells, cells expressing the reporter protein, in these cells the reporter protein was detected at the cell surface. Q3: untransfected cells. Q4: CD8-positive cells, background staining of the CD8 antibody used, these cells are not considered in our analysis. From Q2 a histogram was generated and is shown next to the dot plot (Alexa 647-A), from this histogram the mean of the CD8-

Results

signal was calculated. A second histogram was generated for all cells expressing the protein, identified by the CFP emission signal (Horizon V500-A), Q1 and Q2. The relative cell surface expression was expressed as a ratio of the mean of the CD8 signal with the mean of the CFP signal in CFP-positive cells. All values were normalized to the TASK-3 wild-type construct.

I have shown by *in vitro* binding assays that truncation of the TASK-3 C-terminus does not abolish 14-3-3 binding. To elucidate the functional consequence of truncation on 14-3-3 dependent cell surface expression of the reporter protein, I transiently transfected Cos7 cells with DNA encoding a truncated version of the TASK-3 reporter protein, CD8-CFP-TASK-3 Δ V374, (**Figure 21 D**) and determined the relative cell surface expression of the reporter protein after 36 hours of protein expression. In agreement with current literature, the cell surface expression of this reporter protein was significantly reduced compared to the wild-type reporter protein.

Figure 22: Relative cell surface expression of all TASK3 derived reporter proteins normalized to the TASK3 WT construct. The mean signal intensity of the anti-CD8 signal (Alexa 647) was expressed as a ratio with the mean signal intensity of the CFP signal (Horizon V500) in CFP-positive cells and normalized to the wild type TASK-3 construct. Significant differences in cell surface expression between the TASK3 WT construct and TASK3 $\Delta V374$, as well as TASK3 S373A were observed. Differences between CD8-CFP-TASK-3 WT and CD8-CFP-TASK-3 K369A are not significant. Bar plots are representative of six independent transfections. Error bars depict standard error of the mean (s.e.m.).

Taken together, minor differences were observed between CD8-CFP-TASK-3 WT (**Figure 22**, 1st Column) and a COPI-binding deficient mutant (CD8-CFP-TASK-3 K369A, **Figure 22**, 2nd Column), indicative of efficient anterograde trafficking of the wild type reporter-protein along the secretory pathway in a phosphorylation and 14-3-3-dependent manner. The relative cell surface expression of CD8-CFP-TASK-3 S373A and CD8-CFP-TASK-3 $\Delta V374$ was

Results

significantly reduced, compared to levels observed for the wild-type reporter-protein, varying from ~30% for CD8-CFP-TASK-3 Δ V374 (**Figure 22**, 3rd Column) to ~20% for CD8-CFP-TASK-3 S373A (**Figure 22**, 4th Column). In general, a reduction of the relative cell surface expression of these reporter proteins by four-fold for CD8-CFP-TASK-3 Δ V374 and more than five-fold for CD8-CFP-TASK-3 S373A was observed, compared to CD8-CFP-TASK-3 WT. Hence, it appears that the reported lack of cell surface expression observed for TASK-3 reporter constructs lacking the C-terminal valine (11, 17, 18), can only insufficiently explained by reduced 14-3-3 binding. To fully understand the regulatory mechanism retaining/retrieving the protein, other factors, such as phosphorylation of the protein by kinases, dephosphorylation of the protein by phosphatases in relation to 14-3-3-binding and its role in protecting the client protein from dephosphorylation (1), need to be considered.

Deletion of V374 decreases the efficiency by which PKA phosphorylates the TASK-3 C-terminus *in vivo*

We analyzed the phosphorylation state of each TASK-3-derived CD8-reporter-proteins, expressing each reporter protein in COS7 cells. Cells were lysed after 36 hours of protein expression, centrifuged and crude membranes were solubilized with 1.5% Triton X-100 and 0.1% SDS. Solubilized membranes were precipitated and the obtained membrane protein pellet was resuspended in phosphatase buffer. For each reporter-protein one sample was treated with λ -protein phosphatase (λ PPase). Samples were subsequently resolved on a Phostag SDS-PAGE gel, as well as a standard SDS-PAGE gel. Proteins were transferred to a membrane and CD8-reporter proteins were detected using a CD8- α -antibody (Santa Cruz Biotechnology, Santa Cruz, CA; clone H-160, catalog number SC-7188, lot number E2213) and a fluorescently labeled secondary antibody. Membranes were developed using an Odyssey LiCOR imaging system (LiCOR, Bad Homburg, Germany)

Figure 23: *In vivo* phosphorylation of indicated TASK-3-derived CD8-reporter-proteins. Precipitated proteins were treated with λ -protein phosphatase (λ PPase) and subsequently separated on either a standard SDS-PAGE, or Phostag SDS-PAGE gel. The phosphorylation state of each reporter protein was assessed by detection of proteins with a CD8- α -antibody and a fluorescently labeled secondary antibody. Phosphorylation bands are indicated by the upward band shift relative to samples treated with λ PPase on Phostag SDS-PAGE gels (upper panel). The experiment is representative for 11 independent transfections. TASK-3: unphosphorylated TASK-3-derived reporter-protein. TASK-3-P: phosphorylated TASK-3-derived reporter-protein.

For the CD8-CFP-TASK-3 WT reporter-protein one protein band shifted upwards relative to a sample treated with λ -protein phosphatase (λ PPase) was observed (**Figure 23**, Lane 1 and Lane 2), confirming that the reporter-protein was efficiently phosphorylated *in vivo*, in agreement with observations made for *in vitro* phosphorylation assays performed with GST-TASK-3 WT fusion proteins and recombinantly expressed catalytic subunit of PKA compare to **Figure 19** and **Figure 20**. The COPI binding deficient reporter-protein, CD8-CFP-TASK-3 K369A, was as equally well phosphorylated as CD8-CFP-TASK-3 WT. Treatment with λ PPase altered the migratory behavior of the reporter protein (**Figure 23**, Lane 5, upper band) to match that of CD8-CFP-TASK-3 S373A (**Figure 23**, Lane 6, lower band). The migration of a 14-3-3-binding deficient reporter-protein, CD8-CFP-TASK-3 S373A, was unaltered in presence or absence of λ PPase, after separation on Phostag

Results

SDS-PAGE gels. These observations are consistent with observations made for *in vitro* phosphorylation assays performed with GST-TASK-3 S373A fusion protein and recombinant PKA in presence and absence of ATP. Comparing the phosphorylation state of CD8-CFP-TASK-3 WT and CD8-CFP-TASK-3 Δ V374 substantial differences in the amount of protein phosphorylated were observed. In absence of λ PPase only a fraction of the Δ V374 reporter protein was phosphorylated by cellular kinases (approximately 60%, **Figure 23**, Lane 3), whereas treatment with λ PPase only partially altered the migratory behavior of the reporter protein, indicating inefficient dephosphorylation of the truncated reporter protein (**Figure 23**, Lane 4). These findings indicate, that a substantial amount of the reporter-protein expressed in Cos7 cells was indeed phosphorylated *in vivo*. Differences might be explained by considering other factors, such as kinases, phosphatases and interaction partners protecting the client protein from dephosphorylation, dynamically regulating the steady state phosphorylation of reporter proteins such as CD8-CFP-TASK-3 Δ V374.

Cell surface expression of TASK-1-derived reporter proteins reveals a potential regulatory role of S392

I performed additional flow cytometry assays to evaluate the functional consequence of low affinity 14-3-3 binding on cell surface expression of TASK-1-derived reporter proteins. To address the role of S392 and S393 together and individually I employed CD8-CFP-TASK-1 WT (containing both Serine residues), CD8-CFP-TASK-1 S392A and CD8-CFP-TASK-1 S393A reporter proteins, sequentially replacing the corresponding serine residue with alanine. Additionally we determined the relative cell surface expression of a COPI-binding deficient reporter protein, CD8-CFP-TASK-1 K389A and a truncated, 14-3-3 binding deficient reporter protein, CD8-CFP-TASK-1 Δ V394. In general, experiments were carried out as described for flow cytometry assays conducted with TASK-3-derived reporter-proteins.

The relative cell surface expression of CD8-CFP-TASK-1 WT was substantially lower compared to CD8-CFP-TASK-3 (**Figure 24**, A, B). These

observations are in agreement with previous findings reporting differences in cell surface expression of TASK-3 and TASK-1 (11). Replacing S392 with Alanine elevated the relative cell surface expression of the reporter protein to levels comparable to CD8-CP-TASK-3 WT, confirming a potential regulatory/inhibitory role of S392 on cell surface expression of the reporter-protein (CD8-CFP-TASK-1 S392A, **Figure 24**, C, Q2). Similar observations were made, replacing K389 with Alanine, mutating the ER retrieval/retention motif (CD8-CFP-TASK-1 K389A, **Figure 24**, D, Q2). Mutation of the conserved Serine residue (S393) of the mode III 14-3-3 binding motif (CD8-CFP-TASK-1 S393, **Figure 24**, E, Q2) on the other hand led to a significant decrease in cell surface expression of the reporter protein compared to CD8-CFP-TASK-1, demonstrating that S393 is required for efficient transport of the protein to the cell surface, consistent with observations made for CD8-CFP-TASK-3 S373A. The relative cell surface expression of the truncated reporter-protein CD8-CFP-TASK-1 Δ V394 was even further reduced (**Figure 24**, F, Q2).

Results

Figure 24: Flow cytometry assays to determine the effect of replacing S392, or S393 by Alanine on cell surface expression of the reporter-protein. Reporter protein assays reveal a potential regulatory role of S392 in TASK-1 protein trafficking. Cos7 cells were transiently transfected with DNA encoding TASK-1-derived reporter proteins. Surface localized proteins were detected employing a monoclonal anti-CD8 primary antibody and an Alexa-647 conjugated secondary antibody. Following detection, cells were subjected to Flow cytometry and the relative cell surface expression of different reporter proteins was determined. Displayed are representative dot-plots and

histograms for each reporter protein employed. As described for TASK-3-derived reporter-proteins, the relative cell surface expression was expressed as a ratio of the mean of the CD8 signal with the mean of the CFP signal in CFP-positive cells. All values were normalized to the TASK-3 wild-type construct.

Comparing CD8-CFP-TASK-3 WT and CD8-CFP-TASK-1 WT, I observed a reduction in cell surface expression of the TASK-1 reporter protein by three-fold (**Figure 25**, Compare 1st and 2nd Column). Replacement of S392 with alanine led to an increase in cell surface expression by almost three-fold, indicating an inhibitory role of S392 on cell surface expression *in vivo* (**Figure 25**, 3rd Column). Disruption of COPI binding by mutation of K389, also led to an increase in relative cell surface expression by three-fold, to levels comparable to CD8-CFP-TASK-3 WT (**Figure 25**, 4th Column). This finding is in agreement with findings reported by Zuzarte et al. 2009 (11) showing that mutation of this lysine residue removes the necessity of 14-3-3 to bind to the C-terminus, allowing the reporter-protein to reach the surface in an 14-3-3-COPI independent manner. On the other hand, mutation of S393 led to a decrease in cell surface expression of the reporter protein by five-fold compared to CD8-CFP-TASK-3 WT (two-fold compared to TASK-1 WT), strongly supporting the hypothesis, that transient phosphorylation of S392 is sufficient to inhibit 14-3-3 binding, thereby inhibiting cell surface expression of the reporter protein, retaining the protein in early compartments of the secretory pathway (**Figure 25**, Compare 1st and 5th Column). Additionally, I assessed the relative cell surface expression of a truncated version of the TASK-1 reporter-protein. Consistent with current literature (11), a significant decrease in relative cell surface expression of the reporter protein compared to the TASK-3 wild-type reporter-protein was observed. **Figure 25** illustrates our findings, allowing a direct comparison of all reporter proteins employed.

Results

Figure 25: Relative cell surface expression of all TASK1-derived reporter proteins normalized to CD8-CFP-TASK3 WT construct. Mutation of S392 led to a significant increase in cell surface expression of the CD8-TASK-1 reporter-protein, confirming a potential regulatory role of S392 in TASK-1 trafficking. The mean signal intensity of the anti-CD8 signal (Alexa 647) was expressed as a ratio with the mean signal intensity of the CFP signal (Horizon V500) in CFP-positive cells and normalized to the wild type TASK-3 construct. Cells were transfected in six independent experiments, error bars depict standard error of the mean (s.e.m.).

Transient phosphorylation of S392 reduces the relative cell surface expression of TASK-1-derived reporter proteins

We further assessed the phosphorylation state of each TASK-1-derived reporter-protein *in vivo*. Samples were prepared as described for TASK-3 derived reporter-proteins and subsequently resolved on Phostag and standard SDS-PAGE gels. Gels were westernblotted and proteins were detected with a CD8- α -antibody and a fluorescently labeled secondary antibody.

Figure 26: *In vivo* phosphorylation of indicated TASK-1-derived CD8-reporter-proteins. Membrane protein samples were incubated in presence and absence of λ -protein phosphatase (λ PPase) and subsequently separated on either standard SDS-PAGE, or Phostag SDS-PAGE gels. Gels were westernblotted and proteins were detected with a CD8- α -antibody and a fluorescently labeled secondary antibody. Phosphorylation bands are indicated by the upward band shift relative to samples treated with λ PPase. The blot is representative for seven independent transfections. TASK-1: unphosphorylated TASK-1-derived reporter-protein; TASK-1-P: single phosphorylated TASK-1-derived reporter-protein.

Similar to CD8-CFP-TASK-3 WT (**Figure 23**, Lane 1 and 2) one phosphorylation band, indicated by the upward band shift relative to samples treated with λ PPase, was observed for CD8-CFP-TASK-1 WT (**Figure 26**, Lane 1). Treatment with λ PPase altered the migratory behavior of the reporter protein (**Figure 26**, Lane 2) to a faster migrating protein species. Similar observations were made for CD8-CFP-TASK-1 K389A and CD8-CFP-TASK-1 S392A, indicating that the protein was efficiently phosphorylated by cellular kinases (**Figure 26**, Lane 5 and Lane 7). The migratory behavior of each reporter protein was altered after treatment with λ PPase, indicating efficient dephosphorylation of the reporter-protein (**Figure 26**, Lane 6 and Lane 8). For

Results

CD8-CFP-TASK-1 S393A a faint band corresponding to the phosphorylated reporter protein was observed (**Figure 26**, Lane 9) confirming that the reporter protein was 'transiently' phosphorylated *in vivo*. This band disappeared after treatment with λ PPase, demonstrating that this band corresponded to the phosphorylated reporter-protein. Similar to the phosphorylation state of CD8-CFP-TASK-3 Δ V374 only a fraction of CD8-CFP-TASK-1 Δ V394 reporter protein was phosphorylated *in vivo* (**Figure 26**, Lane 3). Two distinct protein bands were observed, corresponding to the phosphorylated (upper band) and unphosphorylated (lower band) reporter protein. Treatment with λ PPase partially altered the migratory behavior of the protein (**Figure 26**, Lane 4), suggesting that the protein was inefficiently dephosphorylated by λ PPase due to reasons unknown.

Strikingly, I observed only one phosphorylation band for CD8-CFP-TASK-1 WT, which corresponded to the single phosphorylated reporter-protein, when the migratory behavior is compared to CD8-CFP-TASK-1 K389A, CD8-CFP-TASK-1 S392A and CD8-CFP-TASK-1 S393A. From these observations I conclude that S393 is efficiently phosphorylated by cellular kinases, and possibly masked from cellular phosphatase by binding of 14-3-3 proteins (117). I observed a minor band reflecting the phosphorylated species of CD8-CFP-TASK-1 S393A, indicating inefficient phosphorylation by cellular kinases, or efficient dephosphorylation by cellular phosphatases.

Phosphorylation of TASK-1 and TASK-3 C-termini impairs COPI binding

Protein trafficking of TASK-1 and TASK-3 involves two key regulators, by which the relative amount of protein expressed at the cell surface is determined. One of these key regulators is COPI. COPI-binding retrieves the channel to early compartments of the secretory pathway. Interactions with COPI are mediated by an ER retention-retrieval motif present at the distal TASK-1 and TASK-3 C-terminus (KRR). The second key regulator facilitating anterograde protein trafficking is 14-3-3. Upon phosphorylation of S393 in TASK-1 and S373 in TASK-3, a conserved serine residue of a mode III 14-3-3-binding motif, 14-3-3-binding masks the adjacent ER-retention-retrieval motif, by sterically occluding COPI-interactions. In general, binding of 14-3-3 or COPI was considered to be mutually exclusive. So far COPI binding to the trafficking control region of TASK-1 and TASK-3 has been evaluated in presence of other potential interaction partners, using cellular fractions. To evaluate the functional consequence of phosphorylation of either S373 in TASK-3, or S392/S393 in TASK-1 on COPI binding we exploited previous findings, demonstrating that the ER retention-retrieval motif presented by TASK-1 and TASK-3 (KRR) can also be recognized by the yeast COPI coat. Therefore COPI coat was purified from yeast (purifications performed by Dr. Eric Arakel) and the binding to constructs presenting either the distal TASK-1, or TASK-3 C-terminus (C15) replacing the C-terminal KKXX ER-retention signal of the cytoplasmic tail of the yeast protein MST-27, fused to the GST-protein was studied. The MST27-linker increased the accessibility of COPI to the TASK C-terminal peptide, extensively characterized by several COPI binding experiments (10, 112).

GST-MST27-TASK-1 and GST-MST27-TASK-3 fusion proteins and the GST-protein-tag were recombinantly expressed in and affinity purified from E.coli. Since they were expressed in bacteria, fusion-proteins were not phosphorylated. GST-MST27 fusion proteins were incubated with PKA in presence and absence of ATP, as previously described for GST-TASK fusion-proteins. Each protein was phosphorylated for 12 hours at 4°C. To avoid

Results

further degradation of the protein, as observed in **Figure 27** (lower panel, Lane 4 – 6), every buffer used was supplemented with protease inhibitors (PMSF and aPMSF). Following phosphorylation fusion-proteins were incubated with affinity purified COPI coat. Following separation, gels were blotted and proteins were detected using a specific COPI coat antibody (T-270, kindly provided by Anne Spang). The total amount of GST or GST-fusion protein loaded was assessed after samples were separated on a standard SDS-PAGE gel and protein bands were stained with Coomassie solution. We further quantified the amount of COPI coat bound to the GST-MST27-fusion proteins treated with PKA in absence and presence of ATP (EM: Energy mix (108)).

Figure 27: Phosphorylation of TASK-C-termini disrupts COPI binding. Pull-down experiments were performed employing either GST, GST-MST27-TASK-1 or GST-MST27-TASK-3 proteins. Proteins were incubated with PKA in absence or presence of ATP prior to incubation with purified yeast COPI coat. Samples were separated on standard SDS-PAGE gels and subsequently stained with Coomassie solution to visualize the bait. The amount of COPI coat was determined by Western-blotting,

Results

utilizing a specific COPI coat antibody, with which several subunits of the yeast COPI coat were detected. **A**: representative Western-blot showing different amounts of COPI coat bound to GST-MST27 fusion-proteins treated with PKA in absence and presence of energy mix (EM). Control incubations with GST are shown in Lane 1 and Lane 2. **B**: Quantification of **A**, forming the ratio of COPI protein detected (the ratio of all subunits of the COPI vesicular coat complex, indicated above) with the total amount of protein loaded (Bait). The experiment was repeated three-times. Error depicts standard error of the mean (s.e.m.). The experiment was carried out with help of Dr. Eric Arakel.

We observed that a substantial amount of COPI coat bound to the TASK-3 WT protein (**Figure 27**, A: Lane 5, B: 5th Column), confirming observations made by O'Kelly et al., 2002 and Zuzarte et al., 2009 (11, 18). The amount of COPI coat bound was significantly decreased after phosphorylation of the bait protein by PKA (**Figure 27**, A: Lane 6, B: 6th Column) indicating that phosphorylation is sufficient to disrupt COPI binding. Similar observations were made for GST-MST27-TASK-1 fusion proteins incubated with PKA in absence and presence of ATP. The total amount of COPI coat bound to the unphosphorylated TASK-1 fusion-protein was reduced by approximately five-fold, indicating that the presentation of a second serine residue (S392) present in TASK-1 also affects COPI binding. After phosphorylation of the GST-MST27-TASK-1 fusion protein, COPI coat binding was reduced to levels similar to control experiments performed with the GST-protein tag on its own. GST essentially did not bind the COPI coat. These observations clearly demonstrate that phosphorylation of the TASK-1 or TASK-3 C-terminus is sufficient to impair COPI-binding. We further conclude that 14-3-3 proteins and COPI do not bind the TASK-1 or TASK-3 C-terminus in a mutually exclusive way, suggesting that the binding equilibrium rather exist between the phosphorylated (14-3-3 binding) and unphosphorylated state of the protein (COPI-binding), coupled by the action of kinases and phosphatases.

Results

Discussion

Small sequence differences in TASK-3 and TASK-1 cause biological relevant changes in 14-3-3 binding

It is well established that 14-3-3 proteins bind the C-terminus of TASK-1 and TASK-3 in a phosphorylation-dependent manner, thereby releasing the channel from ER retention by preventing COPI-binding to an ER retention-retrieval motif (KRR) presented by both C-termini (1, 3, 11, 17, 18, 64). The cell surface expression of these channels is thought to be controlled by mutually exclusive binding of either the COPI vesicle coat, or 14-3-3 proteins (1, 3, 18). Thus, the function of this trafficking control region is based on competitive binding of both interaction partners (1).

In 2002, a study by Rajan et al. (2002) reported that different 14-3-3 isoforms interact with a trafficking motif present at the distal C-terminus of TASK-1, TASK-3 and TASK-5 (17). By screening yeast two-hybrid libraries from rat brain, rat hippocampus and rat embryo using the full-length C-terminus of TASK-1, TASK-3 and TASK-5 four individual 14-3-3 isoforms were identified (17). Yeast two-hybrid analysis showed that all mammalian 14-3-3 isoforms could interact with a trafficking control motif present in the distal C-terminus of each channel, RRxS/Tx. According to their observations interaction with 14-3-3 proteins promoted functional expression of the channel at the cell surface (17).

In parallel, O'Kelly et al. (2002) found that 14-3-3 β interacts with the last 16 amino acids of TASK-1. Utilizing yeast two-hybrid (from a heart cDNA library) and *in vitro* pull-down experiments, which were performed with cellular extracts, then demonstrated direct interactions of 14-3-3 proteins and TASK-1 C-terminal peptides. They proposed a model, by which mutually exclusive binding of either the COPI vesicle coat, or 14-3-3 regulate the amount of protein expressed at the cell surface (18). Binding of COPI was thought to be

Discussion

mediated by a N-terminal dibasic ER retention motif, whereas 14-3-3 bound to a non-canonical 14-3-3 binding motif located at the distal C-terminus (18).

Both reports elucidate the role of 14-3-3 binding in protein trafficking along the secretory pathway and demonstrate that proteins unable to associate with 14-3-3 failed to reach the surface efficiently. The non-canonical 14-3-3 binding motif found at the C-terminus of TASK-1 and TASK-3 was subsequently described as a mode III 14-3-3 binding motif, which operates depending on phosphorylation of a conserved serine/threonine residue, RXpS/pT(X₁₋₂)-COOH (14, 116).

A subsequent study by Zuzarte et al. (2009) demonstrated by systematic mutation of the TASK-1 C-terminus that interactions with COPI are mediated by a C-terminal, tri-basic ER retention retrieval signal (KRR) adjacent to the conserved serine of the mode III 14-3-3 binding motif (14, 116), rather than a dibasic N-terminal retrieval and retention motif (18). The role of this trafficking control region was further emphasized using TASK-1 and TASK-3-derived reporter-proteins, showing that the cell surface expression of the channel/reporter protein is highly dependent on their ability to associate with 14-3-3 proteins. 14-3-3 binding deficient reporter/channel proteins failed to reach the cell surface efficiently (11, 17, 18). Based on a previous report, Zuzarte et al. (2009) highlighted that TASK-3 reaches the cell surface more efficiently than TASK-1, indicative of a different mechanism regulating TASK-1 transport to the plasma membrane (11, 66).

Up until recently, the molecular details of 14-3-3 binding to the trafficking control region of TASK-1 and TASK-3 were unknown. Anders et al. (2013) reported a crystal structure that emphasized intricate interactions formed between the phosphorylated TASK-3 C-terminus and multiple residues on the inner side of the 14-3-3 σ binding groove and additionally determined the binding parameters of this particular interaction (107).

Striking differences can be observed comparing the amino acid residues flanking the ER retention-retrieval motif, which precede the conserved serine residue of the mode III 14-3-3 binding motif at the distal C-terminus of TASK-1 and TASK-3. TASK-3 features an additional lysine residue (K372), whereas TASK-1 presents a second serine residue (S392) that could potentially be phosphorylated *in vivo*. In this thesis I investigated interactions between TASK-C-termini and 14-3-3 proteins, as well as COPI quantitatively and present evidence that small sequence differences cause biologically relevant changes in 14-3-3 and COPI binding.

To gain quantitative insight into the mechanisms, by which these trafficking control regions act, I first determined the binding parameters of all seven mammalian 14-3-3 isoforms to TASK-3 derived C-terminal peptides phosphorylated at S373 and TASK-1 derived C-terminal peptides phosphorylated at S393, quantitatively. Both residues correspond to the conserved serine residue of the mode III 14-3-3 binding motif (14, 116). Interestingly binding affinities determined for TASK-3 WT pS373 were two orders of magnitude higher than affinities determined for TASK-1 WT pS393, with dissociation constants varying between 100 nM for 14-3-3 η – TASK-3 WT pS373 and 10 μ M for 14-3-3 η – TASK-1 WT pS393. These findings illustrate that the numerous published pull-down and yeast two-hybrid experiments performed effectively operate down to K_D values of 10 μ M, obscuring substantial affinity differences between isoforms due to their qualitative nature (11, 17, 18). I further determined the binding affinity of 14-3-3 σ to TASK-3 WT pS373 with a K_D value of $3.6 \pm 0.4 \mu$ M. This value perfectly matches a value reported by Anders et al., 2013, with a K_D value of $4.1 \pm 0.8 \mu$ M for interactions measured between a TASK-3-derived hexapeptide and 14-3-3 σ by isothermal titration calorimetry (ITC). Affinity differences between TASK-1 and TASK-3 are in perfect agreement with a crystal structure by Anders et al., highlighting distinct hydrogen bonds formed between K372 in TASK-3 and D225 and N226 on the inner side of the 14-3-3 σ binding groove (107). Hydrogen bonds formed by these residues might

Discussion

contribute substantially to the high affinity binding of 14-3-3 proteins to the phosphorylated TASK-3 C-terminus. I reason that a serine, or phosphoserine residue at a position equivalent to K372 would potentially destabilize interactions between the C-terminal peptide and 14-3-3 proteins. And this is exactly what I observed for TASK-1 WT pS393, TASK-1 WT pS392 and TASK-1 WT pS392pS393 (**Figure 11**, **Figure 12**, **Figure 13** and **Table 11**). Affinities determined for interactions between 14-3-3 proteins and either TASK-1-derived peptide were substantially lower than for TASK-3 WT pS373.

Phosphorylation of S392 in TASK-1 impairs COPI and 14-3-3 binding

It is well established that trafficking control motifs consisting of multiple basic residues are involved in COPI-mediated retention and retrieval of membrane proteins, such as membrane receptors and ion channels.

Because the exact binding site of the trafficking control region of TASK-1 and TASK-3 in COPI is unknown, a potential contribution of K372 in TASK-3 or S392 in TASK-1 to COPI binding affinity could not be addressed quantitatively. In general interactions with COPI involve multiple basic residues, e.g. RKXX (8), KKXX (9), RXR (10) and KRR (11). Therefore, we predict that one additional lysine residue in TASK-3 will contribute significantly to COPI binding, compared to S392 in TASK-1.

We tested this hypothesis and conducted pull-down experiments with GST-MST27-TASK-1 WT, GST-MST27-TASK-3 WT fusion proteins and purified yeast COPI coat. We exploited a previous finding that the ER retention-retrieval motif of TASK-1 and TASK-3 can also be recognized by yeast COPI coat (11), therefore pull-down experiments performed with TASK-1 and TASK-3-derived fusion-proteins and purified yeast COPI coat should reflect biological relevant interactions. In addition, we assessed the functional consequence of phosphorylation of the TASK-1 and TASK-3 C-terminus on COPI binding.

Interestingly, the amount of protein co-purified with unphosphorylated TASK-3 fusion protein was approximately five-fold higher than the amount of protein co-purified with TASK-1 derived fusion proteins (**Figure 27 A and B**, 3rd and 5th lane). These results perfectly match our predictions and demonstrate that small sequence differences cause a biological/physiologically relevant change in COPI binding, in addition to the effects on 14-3-3 binding that I uncovered. We were even more intrigued by a substantial decrease in the amount of COPI coat co-purified with phosphorylated TASK-1 and TASK-3 fusion protein. These observations suggest that phosphorylation is sufficient to disrupt COPI binding and facilitate release of the protein from ER retention and retrieval.

Phosphorylation of S392 in TASK-1 perturbed both 14-3-3 and COPI-binding to TASK-1 derived C-terminal peptides. These observations are reminiscent of results reported by Arakel et al., demonstrating that ATP sensitive potassium channels (K_{ATP}) can reach the cell surface in a 14-3-3 and COPI independent manner, upon phosphorylation of a serine residue flanking a tribasic ER retention and retrieval motif (6).

Arakel et al. investigated the functional expression of ATP sensitive potassium channels (K_{ATP}) in cardiac tissue, emphasizing the role of 14-3-3 and COPI in the cell surface expression of the channel. Furthermore this study provides detailed insight into the tissue-specific expression of 14-3-3 proteins, demonstrating that, although ubiquitously expressed, the amount of available 14-3-3 may be restricted (6). In general, K_{ATP} channels exist as hetero-octamers formed by four pore-forming Kir6.1, or Kir6.2 subunits and four sulfonylurea (SUR1 or SUR2) subunits (118). Individual subunits and intermediary complexes exposing arginine-based COPI sorting motifs are retained at the ER until stoichiometrically assembled hetero-octamers are formed. In fully assembled channels, the tribasic ER retention and retrieval motifs (RKR) in Kir6.2 and SUR1 are masked by individual subunits allowing progression along the secretory pathway (16, 119).

Discussion

Based on a previous report by Heusser et al. (and others) demonstrated that 14-3-3 proteins associate with Kir6.2 potassium channels *in vitro* and *in vivo*, promoting the functional expression of K_{ATP} channels to the cell surface (120). 14-3-3 binding is thought to override ER retention by masking the RKR trafficking control motif, present in each Kir6.2 and SUR1 subunit, when presented as a di- or tetramer (108, 120–123). In case of Kir6.2, association with 14-3-3 proteins facilitates the regulated release of the channel from COPI-mediated ER retention and thereby promoting the functional expression of the channel at the cell surface.

According to Arakel et al. phosphorylation of a serine residue preceding the ER retrieval motif uncouples the cell surface transport of K_{ATP} channels, such as Kir6.2, from the antagonistic action of 14-3-3 and COPI, releasing stored pools of Golgi-retained K_{ATP} in order to respond to external stimuli, such as β -adrenergic stimulation.

Comparable to TASK-1 the presence of 14-3-3 is required to facilitate efficient cell surface transport of K_{ATP} channels. In cells, such as cardiac myocytes the amount of available ('free') 14-3-3 is limited and might therefore require an alternative mechanism facilitating the release of these potassium channels from the Golgi to respond to external stimuli (6).

Two well characterized cardiac potassium channels are Kir6.2 and TASK-1 (2). It would also be reasonable to consider a similar mechanism controlling the cell surface expression of both channels that maintains the electrical excitability of these cells, just like Kir6.2. The trafficking control region of TASK-1 might lead to an accumulation of preassembled TASK-1 channels in the Golgi that can be released upon β -adrenergic stimulation and concomitant phosphorylation. In this situation, double phosphorylation of the TASK-1 trafficking control region could trigger the 14-3-3 and COPI independent release of a pool of Golgi-stored/retained TASK-1 channels.

A previous report by Renigunta et al. demonstrated that TASK-1 interacts with another adaptor protein that retains the channel in compartments of the early secretory pathway, by exposure of a secondary ER retrieval motif present at its C-terminus – p11 (also denoted as S100A10). Interactions are mediated by a 40 amino acid long region in TASK-1, which is located upstream of the mode III 14-3-3 binding motif (66). The recruitment of a cytosolic retention factor represents another possibility to modulate the cell surface expression of TASK-1. Retention of the channel by p11 might thereby represent another mechanism by which an accumulation of TASK-1 in the Golgi could be achieved. Furthermore the substantially lower affinity of the TASK-1 trafficking control region for COPI might potentially be compensated by recruitment of p11. The higher affinity of the TASK-3 trafficking control region can be explained by the presence of a lysine residue flanking the ER retention and retrieval signal, thereby generating a dibasic ER retention and retrieval motif, RKXX (8).

Quantitative evaluation of two distinct mutations of TASK-1 and TASK-3 thought to abolish 14-3-3 binding

Two commonly and interchangeably used manipulations to disrupt 14-3-3 binding, in order to study the role of 14-3-3 in TASK channel trafficking, are:

1) deletion of the distal valine residue of TASK-1 or TASK-3, and 2) mutation of the conserved serine residue of the mode III 14-3-3 binding motif (1, 3, 11, 17, 18).

O'Kelly et al. investigated 14-3-3 binding to C-terminal variants of TASK-1 by *in vitro* pull-down experiments from cellular lysates, Rajan et al. employed an alternative approach to investigate 14-3-3 binding to different TASK-derived C-termini (TASK-1, TASK-3 and TASK-5) – Yeast two hybrid analysis (17, 18). Both approaches assess interactions between 14-3-3 and different TASK-derived client proteins qualitatively and obscure 14-3-3 isoform specific differences. Qualitatively, both methods failed to capture interactions of 14-3-3

Discussion

proteins with 14-3-3 binding deficient (TASK-1 S393A, TASK-3 S373A) and truncated TASK-derived substrates (TASK-1 Δ V394, TASK-3 Δ 374).

I quantitatively compared 14-3-3 binding parameters obtained by fluorescence polarization titration (FP), employing 14-3-3 binding deficient C-terminal peptides (TASK-3 S373A and TASK-1 S393A) and a truncated version of each C-terminus (TASK-3 pS373 Δ V374 and TASK-1 pS393 Δ V394). And indeed, for peptides, in which the 14-3-3 binding relevant serine that is part of the mode III 14-3-3 binding motif was replaced with alanine, no 14-3-3 binding was observed. These findings are in agreement with current literature (11, 17, 18), demonstrating that a phosphoserine is required to bind 14-3-3 proteins with high affinity.

Interestingly, 14-3-3 binding to the truncated TASK-1 C-terminus was lost, which is in agreement with previous reports (11, 17, 18), but partially sustained for the truncated TASK-3 C-terminus. Since phosphorylation is essential to detect any 14-3-3 binding, truncated peptides were constitutively phosphorylated at S373 and S393, respectively. These observations indicate that both commonly used manipulations have a distinct effect on 14-3-3 binding, differences between TASK-1 and TASK-3 derived mutants might again be explained by small sequence differences causing a biological relevant effects. The presence of a second serine residue might here as well destabilize interactions between TASK-1 pS393 Δ V394 peptides and 14-3-3 proteins, whereas the presence of K372 in TASK-3 might partially 'rescue' 14-3-3 binding.

Interestingly, binding affinities determined for TASK-3 pS373 Δ V374 were substantially higher than binding affinities determined for TASK-1 WT pS393. Considering that TASK-1 reaches the cell surface more efficiently than TASK-3 pS373 Δ V374, the loss of 14-3-3 binding to the truncated TASK-3 C-terminus cannot satisfactorily explain the biological outcome of this manipulation – accumulation of the reporter protein in internal cellular

compartments – as previously reported by various other workgroups (11, 17, 18, 113).

In context of a phosphorylated mode III 14-3-3 binding motif and in line with a previously reported structure of 14-3-3 σ associated with a TASK-3-derived hexapeptide (107), it was reported that the carboxyl C-terminus of TASK-3 forms only one hydrogen bond with one lysine residue on the inner side of 14-3-3 σ (K122), whereas more intricate interactions are formed by the phosphate group with residues on the inner side of the 14-3-3 binding groove (R56, R129, Y130, E182). Here I provide evidence that the distal valine residue present in TASK-1 and TASK-3 does not substantially contribute to the observed binding affinities determined for TASK-3 WT pS373 or TASK-1 WT pS393.

In summary, I demonstrate that the two commonly and interchangeably used manipulations have distinct effects on 14-3-3 binding. Whereas mutation of the conserved serine residue of the mode III 14-3-3 binding motif to alanine in TASK-3 abolished 14-3-3 binding, deletion of the C-terminal valine residue of TASK-3 did not.

Differences in cell surface expression of TASK-1 and TASK-3 derived reporter-proteins reflect differences in 14-3-3 and COPI binding

A report by Zuzarte et al. illustrated that the mechanism underlying the change of cell surface expression of TASK-1 or TASK-3 could be investigated employing CD8-based reporter proteins, exposing the full-length C-termini of TASK-1 and TASK-3 channels (11). I exploited these findings and generated CD8-based reporter proteins to study the relevance of different 14-3-3 and COPI binding affinities to different TASK trafficking control regions *in vivo*. To directly compare my *in vitro* and *in vivo* findings I generated constructs exposing the last 15 amino acids of the TASK-1 and the TASK-3 C-terminus. Additionally, insertion of a fluorescence probe/fluorophore (CFP) as a linker between CD8 and the TASK C-terminal peptides was particularly useful to

Discussion

identify cells expressing the reporter-protein without relying on antibody detection.

I found that the marked differences in 14-3-3 and COPI binding affinities between TASK-1 and TASK-3 are also relevant *in vivo*. I demonstrated that the TASK-3 WT reporter protein reached the cell surface efficiently, and was mainly localized at the plasma membrane (**Figure 21** and **Figure 22**), whereas the TASK-1 reporter protein reached the cell surface less efficiently and was largely retained in intracellular compartments (**Figure 24, A and B, Figure 25**). These findings are in agreement with observations previously reported by Renigunta et al., showing that TASK-3 is more efficiently transported to the cell surface than TASK-1, while investigating the effect of p11 binding on retention of TASK-1 (66).

Furthermore, I illustrated the importance of S392 present in TASK-1 on cell surface expression of the reporter protein. Mutation of S392 to alanine led to a significant increase in cell surface expression of the reporter protein. I interpret this effect due to increased 14-3-3 binding affinities. Upon mutation, S392, which when phosphorylated leads to a strong decrease in 14-3-3 binding affinity, can no longer be phosphorylated by cellular kinases and is expected to recruit 14-3-3 proteins more efficiently (prerequisite: phosphorylation of S393 by PKA). And indeed, I observed comparable levels of cell surface expression of CD8-CFP-TASK-1 S392A and CD8-CFP-TASK-3 WT (**Table 10, Figure 24 C, Figure 25**). The same effect was observed upon mutation of the ER retention and retrieval motif by replacing K389 with alanine (11, 113). Although, both serine residues are present in this reporter protein and accessible to cellular kinases, in the absence of a functional COPI-interaction motif, 14-3-3 binding to the TASK-1 C-terminus is no longer required for cell surface expression of the reporter protein, therefore the reporter protein reaches the cell surface efficiently, in a 14-3-3 and COPI-independent manner (11). The reduced cell surface expression of the TASK-1 WT construct (CD8-FP-TASK-1 WT) with respect to the change in cell surface

expression of TASK-1 S392A and TASK-1 K369A is consistent with the rationale that both interaction partners, COPI and 14-3-3 proteins, can access the trafficking control region in the steady state. My observations also demonstrate that transient phosphorylation of S392 reduces the efficacy by which 14-3-3 can remove the cargo protein from COPI-mediated ER retention.

Additional experiments carried out with truncated ($\Delta V374$: TASK-3 and $\Delta V394$: TASK-1) and 14-3-3 binding deficient reporter proteins (S373A: TASK-3 and S393A: TASK-1) allowed me to assess the biological outcome of both manipulations *in vivo*. I observed that truncated as well as 14-3-3 binding deficient reporter proteins failed to reach the cell surface efficiently and accumulated partially in COPI positive structures (Kilisch et al., 2016). Although both manipulations have a similar biological outcome, the lack of 14-3-3 binding can only explain the observations made for 14-3-3-binding deficient reporter-proteins CD8-CFP-TASK-3 S373A and CD8-CFP-TASK-1 S393A (**Figure 21**, B; **Figure 22**, 4th Column; **Figure 24**, E; **Figure 25**, 5th Column). A quantitative analysis of 14-3-3 binding to truncated versions of the TASK-3 and TASK-1 C-terminus demonstrated that 14-3-3 proteins associated with the truncated TASK-3 C-terminus (TASK-3 pS373 $\Delta V374$) with calculated binding affinities in the low μM range, however 14-3-3 binding to the truncated TASK-1 C-terminus was lost. In summary, I confirmed the role of 14-3-3 proteins in cell surface expression of TASK-1 and TASK-3 derived reporter proteins (11, 17, 18), I further demonstrated that two commonly used manipulations with similar biological outcome cannot be explained by a loss of 14-3-3 binding.

Truncated TASK C-termini are less efficiently phosphorylated *in vivo*

14-3-3 binding requires previous phosphorylation of a conserved serine or Threonine residue as part of a 14-3-3 binding motif (exceptions are known that bind 14-3-3 proteins in a phosphorylation independent manner, e.g. R18 and the Arg-based ER retrieval signal of Kir6.2). The C-terminal mode III 14-3-3 binding motif featured in TASK-1 and TASK-3 matches the recognition site

Discussion

of multiple cellular kinases (23), such as cAMP-dependent protein kinase A (PKA), protein kinase C (PKC) and ribosomal S6 kinase (RSK). Phosphorylation assays performed by Mant et al. (2011) demonstrated *in vitro* that PKA efficiently phosphorylates a conserved serine residue in TASK-1 and TASK-3, which is part of a mode III 14-3-3 binding motif (23). Additionally it was demonstrated that PKA phosphorylates the second serine featured by TASK-1 (S392) efficiently, *in vitro*. Other kinases tested failed to efficiently phosphorylate either TASK-derived C-terminal peptides, indicating that PKA might also phosphorylate TASK-1 and TASK-3 *in vivo* (23).

Hoffman et al. (1994) reported, by studying the desensitization of acetylcholine receptors with regard to phosphorylation of different subunits of the protein complex, that by introducing single point mutations, the consensus site of a cellular kinase can be altered allowing phosphorylation of a second residue in a mutation-dependent manner (124). A subsequent study by Shabb et al. (2001) elucidated the effect of mutation or truncation on phosphorylation efficiencies in more detail comparing known PKA consensus sites present in various physiological substrates of PKA. For example, the most frequently and efficiently phosphorylated PKA consensus site found is Arg-Arg-X-Ser, which is highly abundant representing more than half of all PKA recognition sites known (125). The PKA consensus site in TASK-1 and TASK-3 perfectly matches this sequence. In comparison, proteins containing an Arg-X-Ser consensus sequence might also serve as a substrate for PKA, although these recognition sites are phosphorylated with less than 10% efficiency (125). The efficiency of phosphorylation of different PKA substrates depends on residues flanking the potential phosphoserine or Threonine residue, as well as the accessibility of the residue in a cellular context. According to Shabb et al. (2001) a C-terminal serine residue will be less efficiently phosphorylated (TASK-1 $\Delta V394$ and TASK-3 $\Delta V374$)(125).

I determined the phosphorylation state of each reporter protein to further explain observed differences in cell surface expression upon mutation or

truncation of TASK-1 and TASK-3 C-termini. I found that the TASK-3 C-terminus was efficiently phosphorylated (**Figure 16**, Lane 1), which is consistent with my observations that the TASK-3 WT reporter protein was mainly localized at the plasma membrane, confirming results reported by Renigunta et al. (2006) that TASK-3 is mainly localizes to the plasma membrane (11, 66). Since cell surface expression of TASK-3 was shown to depend on the ability to recruit 14-3-3 proteins (1, 3, 11, 17, 18, 64), I reason that the phosphorylated TASK-3 C-terminus binds 14-3-3 proteins with high affinity *in vivo* and is therefore efficiently transported forward to the cell surface. Mutation of S373, which is part of a mode III 14-3-3 binding motif, to alanine abolished interactions with 14-3-3 proteins. Consistent with these findings I observed that the 14-3-3 binding deficient reporter protein, CD8-CDP-TASK-3 S373A, failed to reach the surface efficiently and comparable to the truncated reporter protein accumulated in intracellular compartments (64). These observations confirmed previous results reported by O’Kelly et al. (2002), Rajan et al. (2002) and Zuzarte et al. (2009) that efficient transport to the cell surface requires 14-3-3 binding (11, 17, 18). Reporter proteins, in which the non-canonical ER retention and retrieval motif, present at the distal C-terminus (K369A), was mutated, displayed a similar cell surface expression compared to the TASK-3 WT reporter-protein. The reporter protein was as efficiently phosphorylated as the TASK-3 wild type reporter protein and therefore I expected the reporter protein to bind 14-3-3 proteins with high affinity. Major differences in phosphorylation were observed for the truncated TASK-3 reporter protein. Phostag SDS-PAGE revealed that approximately 50% of the truncated reporter-protein was phosphorylated *in vivo*. These observations suggest that either the recognition of the truncated C-terminus by PKA was affected and consequently the truncated C-terminus was less efficiently phosphorylated, or that 14-3-3 binding to the C-terminus only insufficiently protected the truncated C-terminus from dephosphorylation, allowing access to cellular phosphatases. I explored the first possibility further and found that the truncated TASK-3 C-terminus was less efficiently phosphorylated by PKA than the TASK-3 WT C-terminus, *in vitro*,

Discussion

demonstrating that truncation of the TASK-3 C-terminus affects the recognition by PKA as well as 14-3-3 binding. I conclude that the lack of cell surface expression of the truncated reporter protein of TASK-3 can be explained by cooperative effects of less efficient phosphorylation of the client protein and more frequent dephosphorylation of the reporter protein due to the reduced efficacy of 14-3-3 binding.

Mant et al. (2011) reported that both serine residues present in TASK-1 are efficiently phosphorylated by PKA, *in vitro* (S392, S393)(23). I demonstrated that phosphorylation of the second serine residue present in TASK-1 (S392) has a potential inhibitory effect on 14-3-3 binding and therefore affects the forward transport of the reporter protein to the cell surface. Furthermore, I investigated the phosphorylation state of different TASK-1-derived reporter proteins *in vivo* and if S392 could be phosphorylated in a cellular context. Interestingly, the TASK-1 wild-type reporter protein was efficiently phosphorylated, but solely one protein band corresponding to the single phosphorylated protein was observed. Single serine to alanine mutants illustrate that S392 was only weakly phosphorylated *in vivo* in absence of S393. On the other hand S393 was efficiently phosphorylated, in absence of S392. Comparable to observations made for the TASK-3 K369A reporter protein, the analogous TASK-1 K389A reporter protein was phosphorylated efficiently and displayed a protein band corresponding to the single phosphorylated protein. I attribute these observations to differential 14-3-3 binding affinities for different TASK-1 derived reporter proteins. In this model 14-3-3 binding is thought to protect the phosphorylated side-chain of TASK-1 from dephosphorylation by cellular phosphatases (117). Since I have previously shown that phosphorylation of S392 substantially decreased 14-3-3 binding affinities to TASK-1 derived peptides (*in vitro*), reporter proteins in which S392 is accessible to cellular kinases should bind 14-3-3 proteins less efficiently and S392 should consequently be more prone to dephosphorylation by cellular phosphatases.

Figure 28: Proposed mechanism that modulates the cell surface expression of TASK-3. Basal state: Interactions with the COPI vesicle coat mediate the retention of the protein in the early compartments of the secretory pathway. **A:** Phosphorylation of S373 by cellular kinases, potentially PKA (23), leads to the recruitment of 14-3-3 proteins. Low 14-3-3 expression levels permit the rapid association of 14-3-3 and the phosphorylated TASK-3 C-terminus. The absence of 14-3-3 proteins allows for a more frequent access of cellular phosphatase to this trafficking control region. Dephosphorylation of S373 converts the channel into its basal state. **B:** After

Discussion

phosphorylation of the conserved serine residue (S373), which is part of a mode III 14-3-3 binding motif (14, 15), 14-3-3 proteins bind the C-terminus of TASK-3 with high affinity and enable the forward transport of the channel to the cell surface. Low and moderate expression levels will enable immediate masking of the phosphoserine residue, because of the high affinity of 14-3-3 proteins for the phosphorylated TASK-3 C-terminus, thereby limiting the access of cellular phosphatases to the trafficking-control region. The binding equilibrium between association (big arrow) and dissociation (small arrow) of 14-3-3 and the phosphorylated TASK-3 C-terminus is indicated. **C:** Association with 14-3-3 facilitates the forward transport of the channel to cell surface.

CD8-CFP-TASK-1 S392A was phosphorylated efficiently, hence these reporter proteins should bind 14-3-3 proteins with higher affinity than reporter proteins in which both serine residues, or only S392 are accessible to cellular kinases and the phosphorylated side chains (pS393) should therefore be efficiently protected from dephosphorylation by cellular phosphatases. Deletion of the distal valine residue also resulted in a decrease of phosphorylation efficiency of the TASK-1 C-terminus, indicating similar changes in recognition of the phosphorylation consensus site by PKA (125). *In vitro* data suggests that 14-3-3 binding is lost upon truncation of the TASK-1 C-terminus, again, highlighting differences between TASK-1 and TASK-3 C-termini and further emphasizing the role of S392 in TASK-1 protein transport (64). My observations demonstrate that the cell surface expression of TASK-1 can be modulated by other factors, such as phosphorylation of S392 and might thereby render TASK-1 more amenable to regulation. In this study I utilized the last 15 amino acids of either TASK-1 or TASK-3 to simplify the interpretation of our observations, yet I observed distinct effects imposed by minor variations in amino acid sequence. To further appreciate the contribution of other accessory proteins, such as p11 (19, 66, 113), it is necessary to perform experiments with full length TASK-1 and TASK-3 C-termini.

In summary, my observations suggest a mechanism, by which the mutually exclusive binding of 14-3-3 and COPI to the trafficking control regions present in TASK-1 and TASK-3 is regulated by signal transduction events, such as phosphorylation of the client protein by kinases (e.g. PKA), dephosphorylation of the client protein by cellular phosphatases and the expression levels of 14-3-3 proteins in different cell-types and tissues. Furthermore our findings demonstrate that binding events are not competitive as previously assumed (11, 17, 18). The substantially lower affinity of 14-3-3 for TASK-1 WT pS393, compared to TASK-3 WT pS373, and COPI for TASK-1 WT (CT15) allows for a dynamic steady state in which kinases and phosphatases can access and modify the trafficking control region more frequently, than in the case of TASK-3. Phosphorylation of S392 will reduce the efficacy by which 14-3-3 can release the channel from COPI-mediated ER retention, allowing for dephosphorylation by cellular phosphatases. On the other hand phosphorylation of S393 will allow for moderate affinity binding of 14-3-3, protecting the phosphorylated amino acid side chain from dephosphorylation, and therefore facilitating anterograde transport of the channel to the cell surface. For TASK-3 the access of cellular kinases to the trafficking control region present at the distal C-terminus is limited. Upon phosphorylation TASK-3 binds 14-3-3 proteins with high affinity allowing for release of the channel from ER retention. The unphosphorylated C-terminus contains a high affinity COPI binding site and should therefore be retained efficiently. This is exactly what I observed for the 14-3-3 binding deficient reporter protein of TASK-3 (CD8-CFP-TASK-3 S373A). Replacing K369 with alanine did not further increase the amount of reporter protein expressed at the cell surface. Either the reporter protein was sufficiently over expressed and the density of reporter protein at the cell surface reached saturation, or the ER retention activity of the TASK-3 K369A reporter protein was sustained by a second dibasic and canonical ER retention and retrieval motif presented by TASK-3 (RKXX, (8)). For comparison the last six amino acid residues presented by either TASK-3 WT, K³⁶⁹RRKSV-COOH, or TASK-3 K369A, A³⁶⁹RRKSV-COOH.

Discussion

Figure 29: Proposed mechanism that modulates the cell surface expression of TASK-1. Basal state: Interactions with the COPI vesicle coat mediate the retention of the protein in the early compartments of the secretory pathway. The protein shuttles between ER and Golgi. **A:** After the phosphorylation of S392 by cellular kinases, potentially PKA (23), because of the low binding affinities of different 14-3-3 isoforms,

Discussion

14-3-3 binding does not efficiently protect the trafficking control region present at the distal C-terminus of TASK-1 from dephosphorylation, facilitating the access of cellular phosphatase to this trafficking control region. Dephosphorylation of S392 converts the channel into its basal state. **B**: After phosphorylation of the conserved serine residue (S393), which is part of a mode III 14-3-3 binding motif (14, 15), 14-3-3 proteins can bind the C-terminus of TASK-1 with moderate affinity. Low expression levels facilitate the more frequent access of cellular phosphatases to this trafficking control. **C**: Dephosphorylation converts the channel into its basal state. **C**: High expression levels of 14-3-3 allow for a rapid masking of the phosphoserine residue, thereby limiting the access of cellular phosphatases to the trafficking-control region present in TASK-1, enabling the forward transport of the channel to the cell surface. The significantly lower binding affinity of 14-3-3 proteins for the phosphorylated TASK-1 C-terminus might lead to a more dynamic equilibrium between association (upper arrow) and dissociation of 14-3-3 proteins (lower arrow), thereby facilitating the access of cellular phosphatases to the trafficking control region present in TASK-1. Compared to TASK-3, high expression levels of 14-3-3 might be insufficient to saturate available binding sites present TASK-1 pS393, thus this trafficking control region is less efficiently protected from dephosphorylation. **D**: A double phosphorylation of the TASK-1 C-terminus can be achieved by phosphorylation of **A** and **B**. Stimulated activity of PKA might facilitate the double phosphorylation of the channel *in vivo*, thereby uncoupling the cell surface transport of TASK-1 from the antagonistic actions of COPI and 14-3-3. Another possible scenario: The low binding affinities of 14-3-3 do not efficiently protect the channel from dephosphorylation, facilitating the frequent access of cellular phosphatases to the doubly phosphorylated trafficking control region. Dephosphorylation might potentially lead to **A**, **B** or **C**. **E**: Once associated with 14-3-3, the TASK-1 channel is transported to the cell surface.

Curriculum vitae

Personal details:

Name and Surname: Markus Kilisch
Address: Im Hassel 13
37077 Göttingen

Birth date: 05.08.1984
Birthplace: Osterode (Harz)
Nationality: German

Education:

2004 – 2010 Studies at the Faculty of chemistry, Georg-August-University Göttingen

2010 Research work for my diploma thesis in the workgroup of Professor Dr. Claudia Steinem
Title: Impedanzspektroskopische Charakterisierung festkörperunterstützter Membranen in Gegenwart des Transmembranproteins hVDAC1

2011 Graduation from the faculty of chemistry

2012 – 2016 Research work for my PhD thesis in the workgroup of Prof. Dr. Blanche Schwappach at the Institute of Molecular Biology, University Medical School (UMG), Georg-August-University Göttingen

Publication list:

Research topic related publications:

- 2015 Kilisch, M., Lytovchenko, O., Schwappach, B., Renigunta, V., and Daut, J. (2015). The role of protein–protein interactions in the intracellular traffic of the potassium channels TASK-1 and TASK-3. *Pflügers Arch. - Eur. J. Physiol.* 467, 1105–1120.
- 2016 Kilisch, M., Lytovchenko, O., Arakel, E.C., Bertinetti, D., and Schwappach, B. (2016). A dual phospho-rylation switch controls 14-3-3-dependent cell surface expression of TASK-1. *J. Cell Sci.* 129, 831–842.

Method related publications:

- 2013 Lytovchenko, O., Melin, J., Schulz, C., Kilisch, M., Hutu, D.P., and Rehling, P. (2013). Signal recognition initiates reorganization of the presequence translocase during protein import. *EMBO J.* 32, 886–898.
- Pilla, E., Kilisch, M., Lenz, C., Urlaub, H., and Geiss-Friedlander, R. (2013). The SUMO1-E67 interacting loop peptide is an allosteric inhibitor of the dipeptidyl peptidases 8 and 9. *J. Biol. Chem.* 288, 32787–32796.
- 2015 Melin, J., Kilisch, M., Neumann, P., Lytovchenko, O., Gomkale, R., Schendzielorz, A., Schmidt, B., Liepold, T., Ficner, R., Jahn, O., et al. (2015). A presequence-binding groove in Tom70 supports import of Mdl1 into mitochondria. *Biochim. Biophys. Acta - Mol. Cell Res.* 1853, 1850–1859.

2015
