ACKNOWLEDGMENTS

I would like to thank the members of my committee, including Rob Miller for his guidance and patience, Irene Salinas for her incredible support and advice, and Tom Turner and Mike Criscitiello for their help and advice.

Thank you to my lab members Tori Hansen, Bethaney Fehrenkamp, Ben Wheaton, and Gaby Chacon for not only help, but also encouragement and camaraderie.

Thank you to my parents, Joseph and Maria Krasnec, for their guidance and support and for pushing me to challenge my intellectual boundaries. Thanks also to Alex Krasnec, for being the big brother we all need and providing unconditional encouragement.

And my greatest thanks to Sam Golbuff for his unlimited support and love. Sappy platitudes aside, I would have never finished without you.

A Novel Family of Major Histocompatibility Complex Class I Genes in Marsupials and Monotremes

ABSTRACT

The Major Histocompatibility Complex (MHC) class I family of genes encode for molecules that have well-conserved structures, but have evolved to perform a diverse functions. The availability of an opossum genome from the grey, short-tailed opossum, *Monodelphis domestica*, has allowed for analysis of MHC class I genes in a marsupial. Traditional methods for gene discovery uncovered 13 MHC class I genes in the opossum. Utilization of a novel method to search for MHC domain structures discovered a family of 17 novel MHC class I genes. These genes, named *ModoUT1-17*, were located in a cluster on chromosome 1, unlinked to the MHC. *UT* homologues are only found in marsupial and monotreme genomes, consistent with being ancient in mammals yet lost in eutherians.

Twelve of the *ModoUT* loci are transcribed in the opossum thymus. The majority of *UT* transcription is in the thymus or skin, with limited expression in other tissues. Full-

length sequencing of eleven transcribed *ModoUT* genes revealed between five and eight exons, with typical class I gene structure and few alternative splice variants. A survey of *ModoUT* polymorphism in different *M. domestica* populations found low levels of polymorphism. Limited positive selection occurs in any of the *ModoUT* genes, suggesting they may not be under pathogen-mediated pressure.

Also uncovered in *M. domestica* genome search was the presence of two additional loci of the *ModoUA* gene, now designated *ModoUA3* and *ModoUA4*. The *ModoUA* gene is thought to be the class I molecule involved in peptide presentation. These new genes were uncovered in a region of the genome that was expanded and more complete than in earlier genome assemblies. The occurrence of five to six alleles in individual *M. domestica* indicates three loci being transcribed. The *ModoUA1* and *ModoUA3* genes are highly similar and alleles cannot be distinguished, while *ModoUA4* is easily identifiable, although less common and also relatively non-polymorphic and not under positive selection. The use of later assemblies and novel search methods confirmed the existence of three related MHC class I genes in the opossum, making opossums more typical of mammals by having multiple classical MHC class I loci.

THE EVOLUTION OF STRUCTURE-FUNCTION RELATIONSHIPS

The relationship between the structure of a molecule and its function is a fundamental question in both structural and evolutionary biology. Model systems can be used to thoroughly examine how the structure of a molecule affects function. An ideal model system in which to examine this relationship is the Major Histocompatibility Complex class I family. The MHC class I molecules are best defined by the complex structure they all share. However, a striking difference can be seen in how these molecules have evolved to perform a wide variety of functions, indicating the plasticity of molecular structures (Kasahara, 1997, Kelley et al. 2005, Klein et al. 2007).

Examples of other molecules with conserved structures and diverse functions include serpins and lipocalins. Serpins, short for serine proteinase inhibitors, have been found across a vast number of organisms, from humans down to viruses (Silverman et al. 2001). The majority of serpins are comprised of a conserved structure comprised of three β sheets, a minimum of 7 α -helices, and a reactive site loop (RSL) that contains approximately 17 flexible residues that tether two of the β sheets together (Silverman et al. 2001). Researchers have identified serpins that inhibit proteinases, including caspase and cysteine proteinase, while others have been shown to have functions outside inhibition, and serve important roles in hormone transport and blood pressure regulation. Another molecule, lipocalin, shares conserved regions of sequence motifs that result in conserved protein folds resulting in an antiparallel β barrel. Unlike serpins, lipocalin has been found primarily in vertebrates. Lipocalins are involved in diverse functions including ligand binding, binding of receptors for retinol and bilin, along with formation of complexes with macromolecules (Flower, 1996).

THE MHC CLASS I FAMILY AS A RESEARCH MODEL

The MHC class I molecules are encoded by a family of genes that are found in all jawed vertebrates. A number of MHC Class I genes and other important immune and non-immune genes can be found in a cluster together in a region known as the Major Histocompatibility Complex (MHC) region. The MHC class I genes are best defined not by their function, but by their conserved structure. The conserved structure across MHC Class I molecules make them useful for examining the relationship between structure and function of a molecule.

The conserved structure of the MHC Class I molecule is defined by an α chain, comprised of three extracellular domains: $\alpha 1$, $\alpha 2$, and $\alpha 3$ domains, paired with $\beta 2$ -microglobulin (Figure 1). A transmembrane domain and a cytoplasmic tail extend from the $\alpha 3$ domain of the MHC molecule and anchor the molecule to the cell (Yeager and Hughes, 1999). While the $\beta 2$ -microglobulin is not encoded within the MHC region, it is necessary for the proper cell surface expression of most MHC class I molecules (Zijstra et al. 1990). Together, the $\alpha 1$ and $\alpha 2$ domains fold and combine to form a groove comprised of β -sheets with two α helices (Adams and Luoma, 2012). Overall, MHC class I molecules, while having similar structures, have evolved to perform a variety of functions (Table 1). Examples of known functions performed by MHC class I molecules are:

I. Presentation of Lipids to T cells

The groove formed by the $\alpha 1$ and $\alpha 2$ domains in MHC Class I molecules may serve to bind many different antigenic molecules recognized by the immune system. CD1 is an example of a molecule that binds a large array of hydrophobic lipids. CD1 has a

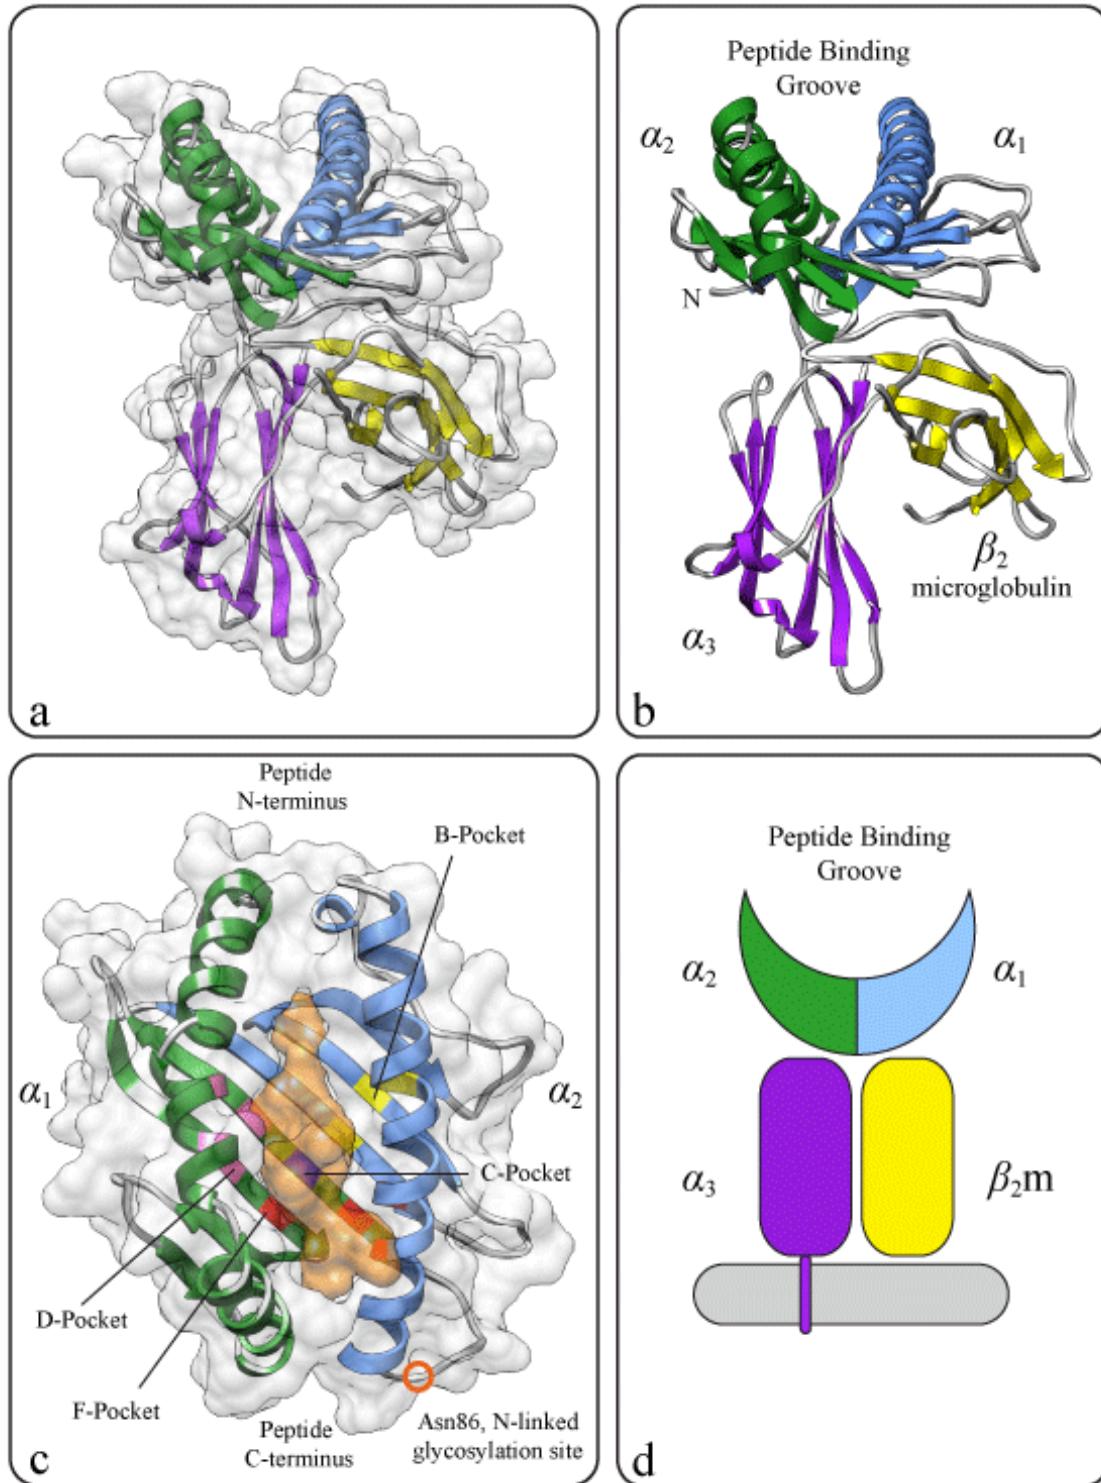

Figure 1: Conserved structure of MHC Class I molecules. Ribbon structure shows the β sheets and the α helices. The groove formed by the α_1 and α_2 domains can also been seen.

Table 1: List of molecules considered to be MHC Class I with functionality, examples and characteristics. Except for M10, these MHC Class I molecules can be found in different species within the vertebrate lineage.

Roles MHC Class I Molecules Have Evolved	Immune/Non-Immune	Examples	Polymorphic	Tissue Specificity
Present antigenic lipids to α/β T cells	Immune	CD1	No	Group 1: cortical thymocytes, Langerhans cells, dendritic cells, B cell subset Group 2: GI epithelium, Bone marrow derived cells
Receptor for transferring maternal IgG to fetus	Immune	FcRn	No	Neonatal epithelium, lung, liver, placenta
Regulation of NK Cells	Immune	All MHC Class I	N/A	Ubiquitously expressed
Binding of Transferrin Receptor	Non-immune	HFE	No	Liver, Gut
Chaperone for Receptor of Pheromones in Rodents	Non-immune	M10	No	Brain
Lipid Catabolization and Fat Storage Reduction	Non-immune	ZAP	No	Adipocytes
Present antigenic peptides to CD8+ T cells	Immune	HLA-A, H2-K	Highly Polymorphic	Ubiquitously expressed

compressed and hydrophobic binding groove, and functions as an antigen presenting molecule by binding self and bacterial lipids for presentation to T cells (Lawton and Kronenberg 2004, Rodgers and Cook 2005, Shawar et al. 1994). In mammals, CD1 is encoded outside the MHC region, while in avian species, CD1 is encoded within the MHC region.

In eutherian mammals, multiple functional CD1 genes exist. An example of this can be seen in humans, who have five CD1 gene isoforms, whereas mice only have one CD1 gene (Brigl and Brenner 2004, Shawar et al. 1994). The presence and/or absence of CD1 genes in non-eutherian and non-mammalian vertebrates, along with being non-orthologous to eutherian isoforms suggests the duplications that generated multiple CD1 groups occurred 170-180 million years ago, after divergence of the eutherian-marsupial lineage (Baker and Miller 2007). CD1 is a pseudogene in the marsupial *M. domestica*, and is encoded outside the MHC region. However, CD1 is functional in other marsupial species (Baker and Miller 2007).

No other molecules that specialize in chaperoning or in loading lipids have been found outside of the CD1 system. This potentially indicates that the antigenic lipid presentation by CD1 molecules may have diverged early from the MHC system in vertebrates, and remains a more primitive system for presentation of antigenic lipids (Hughes 1991, Lawton and Kronenberg 2004). Regardless of the evolutionary divergence, CD1 molecules play an important role in immunity via effector functions for CD1d restricted T cells (NKT cells), pathogenic *Mycobacterium* responses, and presentation of atypical and self lipids (Brigl and Brenner 2004, Rodgers and Cook 2005, Shinkai and Locksley 2000).

II. Transport of Immunoglobulins

Neonatal Fc receptors (FcRn) are a group of MHC class I molecules that do not bind any lipids or peptides, but instead serve as an Fc receptor for IgG. A key difference between FcRn and the other MHC class I molecules structure is the groove is occluded in FcRn and thus cannot bind any molecules (Ghetie and Ward 2000). The occlusion of this binding groove however, does not limit the function of the molecule. FcRn was first discovered as the receptor for transference of maternal IgG to neonate (Story et al. 1994). Subsequent research has shown FcRn is also responsible for maintaining appropriate serum levels of IgG, an indicator that the FcRn molecule is able to transport IgG within and across cells (Ghetie and Ward 2000). Despite the closed binding groove, FcRn binds the IgG on the external surface of the molecule. The FcRn gene is found outside of the MHC region across the mammalian lineage.

IgY is the avian equivalent of IgG, and in avian species, including the chicken, a yolk sac receptor called FcRY plays a similar role to that of FcRn in transferring IgY (West Jr. et al. 2004). However, the chicken FcRY is not homologous in structure to MHC Class I molecules. Instead, the FcRY is homologous to mammalian phospholipase A₂ receptors. This suggests that the use of the MHC Class I molecule FcRn for IgG transport is a recent evolutionary adaptation in mammals, as it is not seen in more distant vertebrates like birds (Roopenian and Akilesh 2007, West Jr. et al. 2004).

III. Regulation of NK Cells

An important mechanism used in innate immunity employs the use of MHC class I molecules and Natural Killer cells (NK cells). NK cells are similar to CD8⁺ cytotoxic T cells, but instead of detecting specific antigenic peptides, they respond rapidly to virally

infected cells or tumor cells that do not express MHC class I on the cell surface (Kärre, 2008). If a cell is detected as lacking MHC class I molecules, cell destruction is initiated via apoptosis by NK cells (Gromm   and Neefjes 2002, Terunuma et al. 2008).

IV. Binding of Transferrin Receptor and the Transfer of Iron

While a number of MHC class I molecules are involved in various immune functions, other MHC class I molecules have evolved roles in non-immune functions. One of these non-immune roles was discovered in individuals with hereditary haemochromatosis (HH), a disease that causes an overload of iron in the blood (Feder et al. 1996). These individuals had defective copies of the HFE gene, a molecule homologous to the MHC class I molecules, that has a narrowed binding groove that cannot bind peptides or lipids (Adams and Luoma 2012, Braud et al. 1999). The role of the HFE molecule is to bind the transferrin receptor, which then reduces the receptor's affinity to load transferrin molecules bound with iron (Lebf  n et al. 1998). Without the HFE molecule reducing the receptor's affinity for iron rich molecules, large deposits of iron can form in organs, leading to organ failure (Braud et al. 1999, Feder et al. 1996). The gene encoding for the HFE molecule is located within the MHC region, despite its non-immune function.

The most common mutation resulting in HH prevents the association of β 2-microglobulin with the HFE α chain, resulting in the molecule not being presented on the cell surface. Defects resulting in the loss of β 2-microglobulin association with the α chain often result in the absence of surface MHC molecules (Braud et al. 1999). The linking of an MHC Class I gene deficiency to a common hereditary disease has brought more focus to the different non-immune roles the MHC class I genes may play.

V. Chaperone for Receptor of Pheromones in Rodents

In rodents, a highly unique MHC class I molecule has been discovered in the vomeronasal organ. The vomeronasal organ serves as the peripheral sensory organ of the accessory olfactory system, and is involved in chemical and pheremone communication (Keverne 1999). The molecule, called M10, is homologous to MHC class I structure and associates with β 2-microglobulin. M10 serves to bind a specialized olfactory receptor V2R in the vomeronasal organ (Adams and Luoma 2012). The M10 molecule and V2R form a multi-molecular complex located at the ends of the vomeronasal neurons, which is the region where pheromone detection occurs (Dulac and Torello 2003). Based on the location of M10 in the vomeronasal organ and the interaction with V2R, it is suspected that it may be a chaperone or co-receptor for the detection of pheromones or receptor localization (Dulac and Torello 2003). The M10 genes are not found in species like humans that lack vomeronasal organs, which is an indicator that they play a highly specific role in pheromone detection (Kumánovics et al. 2003).

VI. Lipid Catabolization and Fat Storage Reduction

Another MHC class I molecule with non-immune functions is the zinc α 2 glycoprotein (ZAG) molecule. ZAG has a more open binding groove, and binds small hydrophobic molecules that resemble fatty acids. This is unlike many of the other MHC class I molecules not involved in peptide binding that have closed or minimal binding grooves (Adams and Luoma 2012, Sánchez 1999). Interestingly, the ZAG molecule functions in the absence of β 2-microglobulin. The expression of the ZAG molecule serves to catabolize lipids and reduce fat stores by breaking down lipids in adipocytes (Sánchez 1999). Because of the role ZAG molecules play in fat depletion, increased

expression of the molecules can be found in patients suffering from cachexia (Adams and Luoma 2012).

VII. Presentation of Peptides Derived from Self & Foreign Antigens to T cells.

A. Discovery, Function, and Evolution

The role of peptide presentation for MHC class I molecules has been left for last because it is the most well studied function. Peptide presentation is the most ubiquitous function and therefore likely the ancestral role of MHC class I molecules. Because peptide presentation was the first function described for MHC class I molecules, they are often referred to in the literature as classical MHC class I.

Peter Gorer discovered the MHC while investigating the genetic basis for tumor rejection and/or survival in mice (Klein 2001). Gorer's (1938) work suggested there were two dominant genes that influence tumor growth or rejection, one of which was linked to a blood group antigen, called antigen-2. Gorer and others began to refer to such loci as histocompatibility loci (H) and the one linked to blood group antigen-2 became known as the H-2 locus. Another researcher, George Snell, began to experiment with mice that differed only by a single H loci. He made the discovery that the H locus was likely a complex of a minimum of two loci, but one locus (H-2) was more critical in the rapid tissue rejection response or for acceptance of transplanted tumors (Snell 1951). Other H loci did not generate tissue rejection so rapidly. The more rapidly responding locus was named the Major Histocompatibility Gene. The region where these loci were uncovered was termed the Major Histocompatibility Complex or the MHC.

The MHC class I genes are best known for their role in encoding for molecules that present antigenic peptides to CD8+ T cells (Lawlor et al. 1990). Presentation of self-derived peptides to T cells allows for cells in the body to be frequently monitored for pathogenic infection. If the peptide presented to the CD8+ T cell is recognized as non-self, apoptosis of the cell presenting the foreign peptide will be initiated. Examples of antigenic peptide presenting MHC class I molecules include HLA-A in humans, H2-k in mice, and ModoUA in the opossum.

A key feature of MHC class I molecules like human HLA-A is that they can be found ubiquitously expressed on all nucleated cells. Another family of MHC molecules exists (MHC class II) that only are expressed on antigen presenting cells, including macrophages and dendritic cells (Rodgers and Cook 2005, Shawar et al. 1994). When intra-cellularly derived non-self peptides are presented to T-cells from MHC class I molecules, an adaptive immune response is generated. This response includes recruitment of macrophages to the area, B-cell activation, and killing of infected cells (Yeager and Hughes 1999). In order for molecules like HLA-A to bind a wide variety of self or non-self peptides, high levels of polymorphism are present in the residues making up the peptide-binding region. Pathogen-mediated selection can act on the genes and stimulate nucleotide changes at sites where peptide binding occurs, resulting in high levels of polymorphism in MHC class I genes (Hughes and Nei 1989, Messaoudi et al. 2002).

The MHC class I genes that encode for peptide-presenting class I molecules are found at a specific chromosomal region where MHC class II genes and antigen processing molecules are also located, known as the MHC region. Many other MHC class I genes, including CD1 and FcRn, can be found entirely outside of this region, and

even on different chromosomes (Shawar et al. 1994). Peptide-presenting MHC class I genes are typically organized with five exons, encode only one mRNA form, and do not contain any unpaired cysteines. Other MHC class I genes that encode for molecules in non-peptide presenting roles may have more atypical gene organization and exon composition that results in features like unpaired cysteines and multiple alternative mRNA forms (Baker et al. 2009, Fujii et al. 1994).

B. Organization of the MHC Region

The genomic organization of the MHC can be highly variable between vertebrates. In eutherians, such as humans and mice, the peptide presenting MHC class I and class II genes are separated by MHC class III with antigen processing and transporter genes found in the MHC class II region (Edwards and Hedrick 1998, Flajnik and Kasahara 2001, Figure 2). The non-eutherian opossum has an MHC region that rivals the length and complexity of eutherian MHC, but is organized more similarly to the MHC of non-mammals. In the opossum, MHC class I and class II genes are interspersed in the genome without separation by MHC class III genes seen in eutherians (Belov et al. 2006, Figure 2). Another feature of non-eutherian MHC organization is that the antigen processing and transporter genes can be found near MHC Class I genes, a trait also seen in frogs and chickens, suggesting the linkage of these genes is the ancestral organization (Baker et al. 2009, Siddle et al. 2009).

C. Evolution and the MHC Class I Genes

Flajnik and Kasahara (2001) postulated that the proximity of the MHC class I genes to antigen-processing or transporter genes is an indicator that these genes evolved their

functions together. However, the co-evolution of these genes could be problematic as it may restrict diversity. If both MHC class I and antigen-processing and transporter genes are in close proximity, Flajnik and Kasahara (2001) predict these genes would then have lower numbers of duplications or deletions, resulting in less diversity within them. Species with unlinked MHC class I and antigen processing/transporter genes (e.g. antigen processing/transporter genes in the MHC class II region) would then have greater levels of duplications and deletions. Because of the separation of these genes in eutherian mammals, one would expect greater level of diversification of the MHC class I and antigen processing/transport genes that have occurred as the result of duplication, deletion, and divergence.

However, the genomes of marsupials, such as the opossum and tammar wallaby, *Macropus eugenii*, reveal that this is not the case. The close proximity of antigen processing/transporter genes to MHC class I genes or the displacement of the antigen processing or transporter genes in these species to outside the MHC region does not hinder the ability of the genes to undergo deletions and duplications necessary for selection (Baker et al. 2009, Belov et al. 2006, Siddle et al. 2009, Siddle 2011). The tammar wallaby has an increased number of transporter and antigen processing genes, some of which are located outside of their core MHC region, while opossums have these genes in proximity to MHC Class I genes (Belov et al. 2006, Siddle et al. 2011). Based upon the overall patterns of MHC gene organization, it is presumed the current form of eutherian MHC organization (Figure 2) occurred after divergence with marsupials, as non-eutherian MHC organization more closely resembles that of non-mammalian species (Miller 2010).

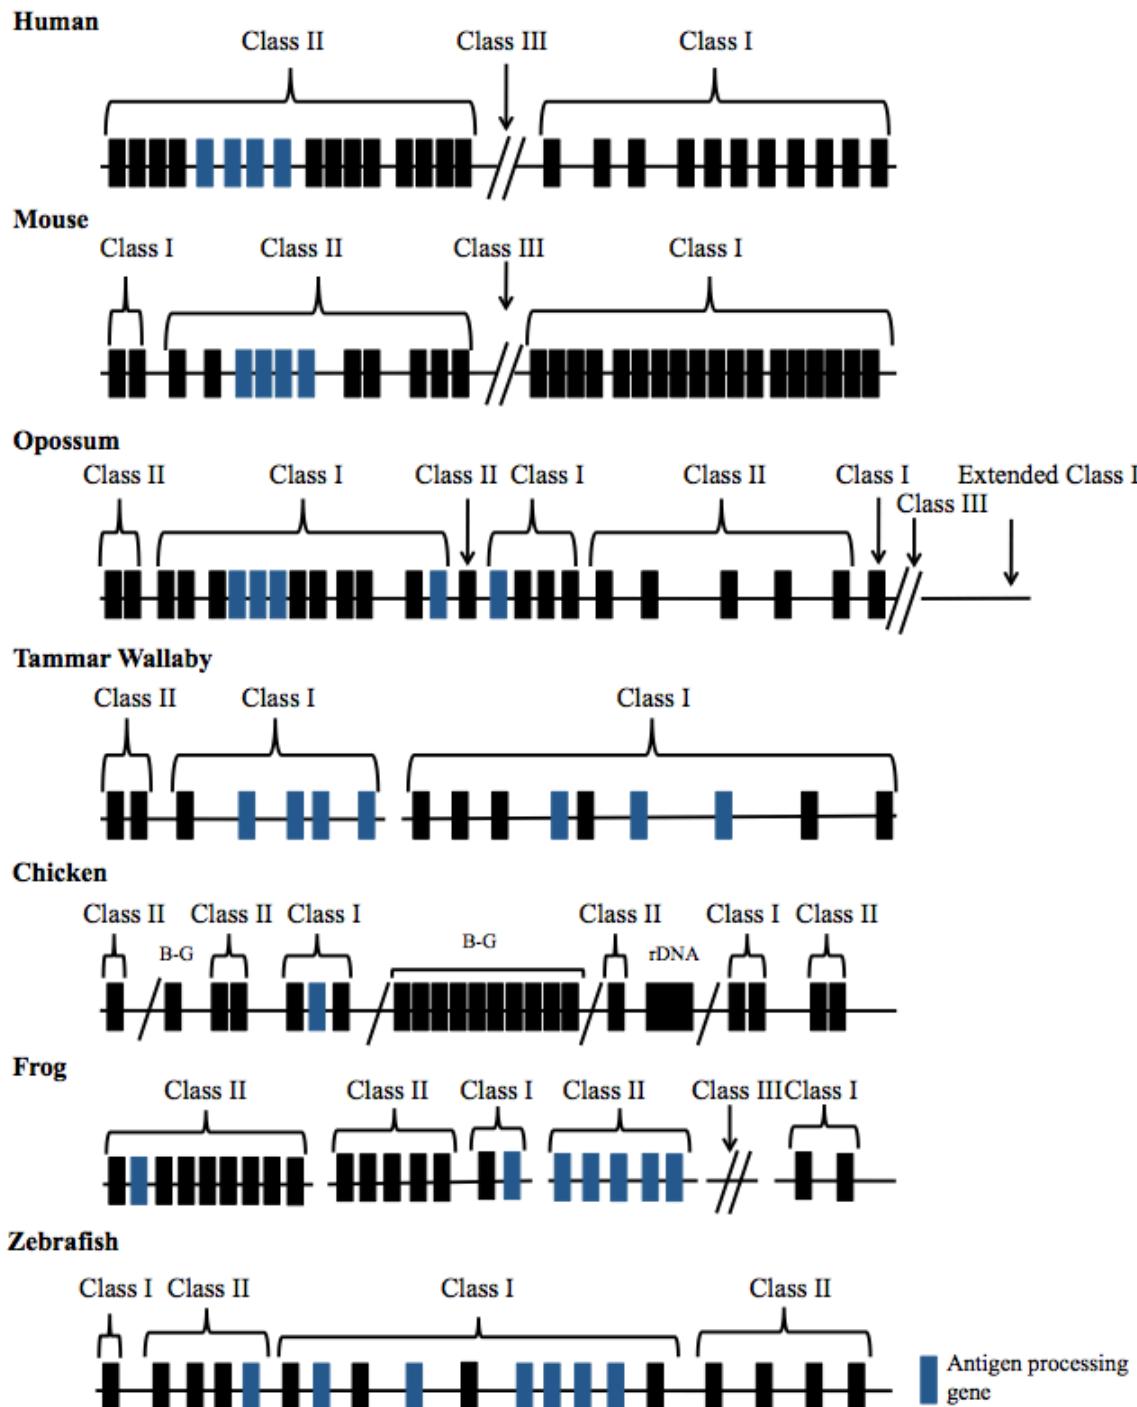

Figure 2: Organization of MHC genes across different species including eutherians, non-eutherians, avian, amphibian, and bony fish. Adapted from Belov et al. 2006, Edwards and Hendrick, 1998, Flajnik and Kasahara, 2001, Lukacs et al. 2007, Ohta et al. 2006, and Siddle et al. 2011.

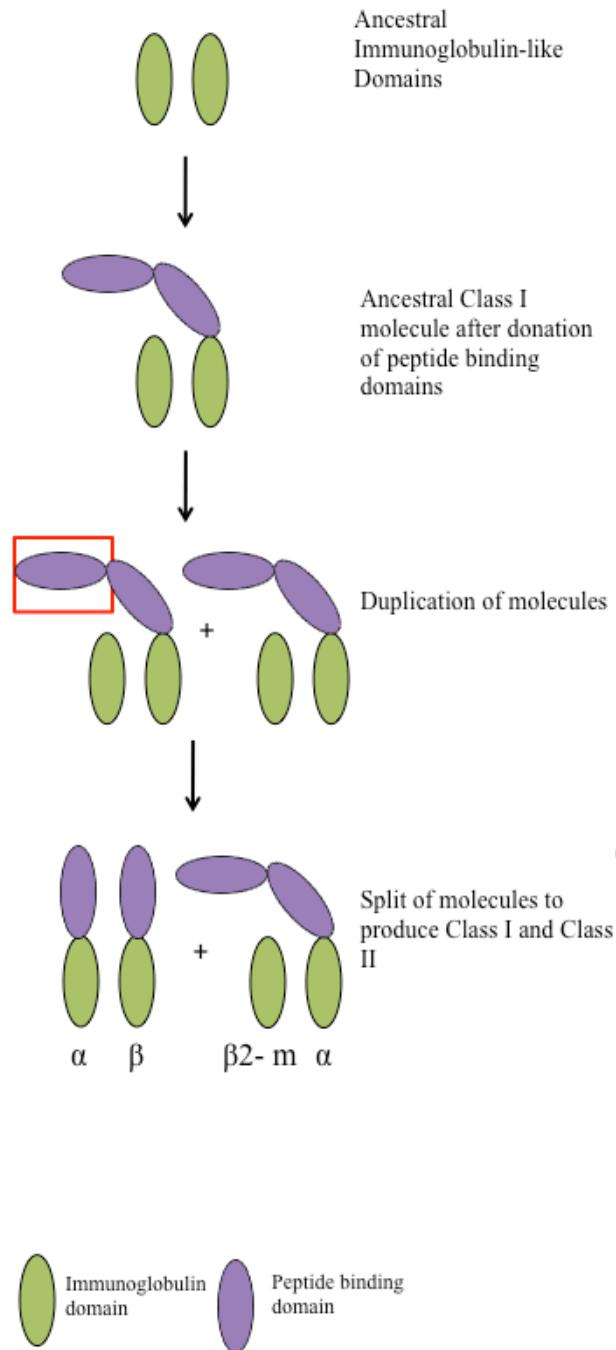

THEORIES ON THE ORIGIN OF THE MHC CLASS I DOMAIN STRUCTURE.

Most of the theories regarding the origin of the unique MHC class I structure are based on its peptide-presenting role for several reasons. The first reason is that peptide presentation is seen as the classical role of MHC molecules, the second being peptide presentation is the most ubiquitous role and therefore believed to be its primordial function.

The evolutionary path and development of MHC Class I and II are debated, but two main hypotheses have been put forward, both involving exon shuffling (Figure 3). The first hypothesis, proposed by Flajnik et al. (1991), posits an ancestral immunoglobulin domain combined with a peptide-binding domain derived from heat-shock proteins to generate an ancestral MHC class I molecule. The ancestral class I molecules comprised of a single α chain containing an immunoglobulin domain and peptide binding domain, and were associated with a $\beta 2$ -microglobulin domain as well. Duplication resulted in multiple ancestral class I and $\beta 2$ -microglobulin genes. An ancestral class I molecule then likely donated an $\alpha 1$ domain onto the $\beta 2$ -microglobulin gene, forming a β chain gene. The remaining α chain from the ancestral class I would readily associate with the newly formed β chain, generating ancestral class II molecules.

The second hypothesis on the origin of MHC class I and II genes was formulated by Klein and O'hUigin (1993) and supports an ancestral immunoglobulin-like domain combined with membrane-anchoring domains and peptide-binding domains to make an ancestral class II molecule. Two instances of whole genome duplication resulted in four ancestral class II molecules. Deletion of the immunoglobulin-like domain and membrane-

Class I First Hypothesis

Class II First Hypothesis

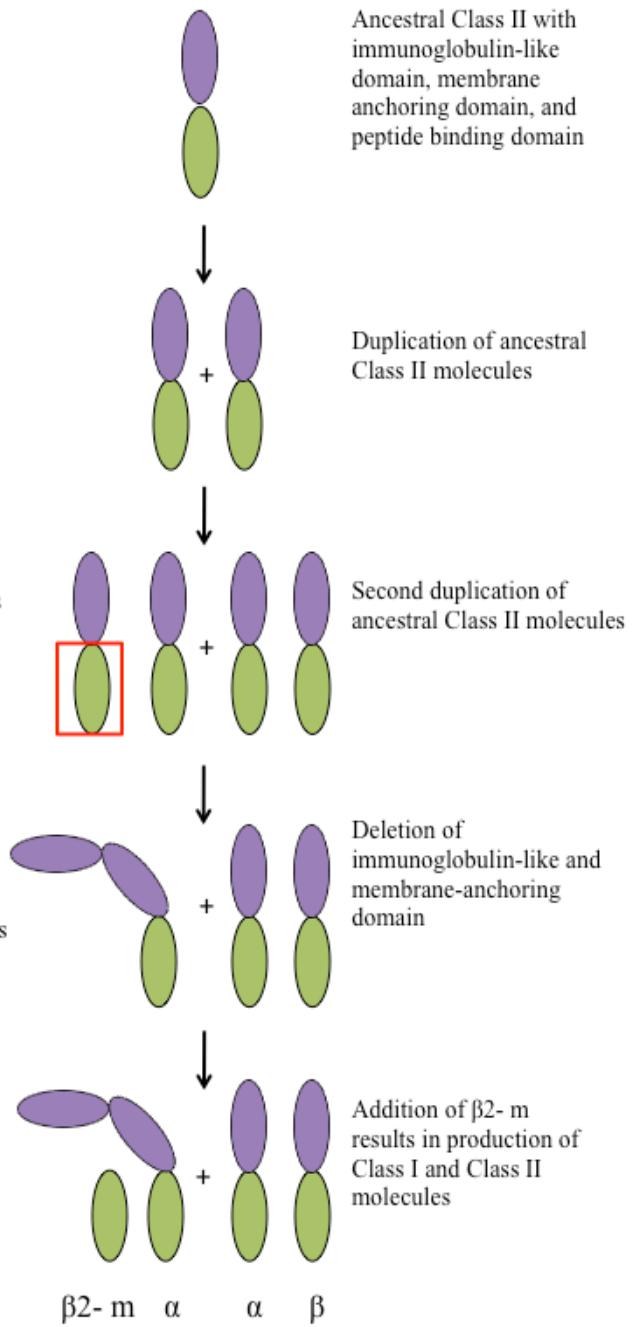

Figure 3: Diagram of the hypothetical evolutionary pattern of MHC. Adapted from Flajnik et al. 1991 (Class I First) and Klein and O'hUigin, 1993 (Class II First)

anchoring domain in one of the class II molecules, along with combining with another ancestral class II molecule resulted in the formation of class I molecules.

While the two presented theories both use exon shuffling for evolution of the genes encoding the MHC class I molecule, the development of MHC region occurred via genome wide duplications that also resulted in the emergence of genes like -classical MHC Class I genes being found in the same region of the genome (Nei and Rooney 2005). However, in 1997, Masatoshi Nei and colleagues developed an alternative hypothesis to explain the diversity generated within the MHC gene family. Phylogenetic analysis of MHC and immunoglobulin genes families resulted in the development of a new evolutionary pattern called “birth-and-death” evolution (Nei et al. 1997, Nei and Rooney, 2005).

THEORIES ON THE ORIGIN AND GENERATION OF MHC CLASS I GENES

Until the early 1990’s, it was hypothesized that the diversity of MHC genes across species was the result of concerted evolution. Concerted evolution can be explained as homologous genes being more similar to their paralogs within a species than of a locus in another species. The genes generated from concerted evolution could be modified or changed if gene conversion occurs. Gene conversion occurs as the result of the transfer of DNA from homologous genes, often by unequal cross-over during meiosis. The conversion of genes could generate polymorphism and differences within these genes (Nei et al. 1997). This view was problematic, because it could not explain how gene conversion could occur between two previously differentiated loci, nor could it resolve the existence of classical and non-classical MHC Class I genes being found in the same region of the genome (Nei and Rooney 2005). However, in 1997, Masatoshi Nei and

colleagues developed an alternative hypothesis to explain the diversity generated within the MHC gene family. The expansion and contraction of these important immunological genes prompted an in-depth phylogenetic analysis of MHC and immunoglobulin gene families. This resulted in the development of a new evolutionary pattern called “birth-and-death” evolution, initially referred to as the accordion model (Klein et al. 1993, Nei et al. 1997, Nei and Rooney, 2005).

In the birth and death model, new genes are generated via gene duplications. Sometimes these duplicated genes may be a functional gene (birth), while others become pseudogenes (death) (Nei and Rooney 2005). Overall, different families or orders of mammals do not have wholly orthologous genes, and instead have different genes or loci due to their birth and death process in individual species (Nei et al. 1997, Nei and Rooney 2005). It is important to note that many MHC genes have survived between species for hundreds of millions of years (e.g. *MICA* and *HFE*), while others (*HLA-A*, *B*, and *C*) have diverged more recently between humans and great apes (Adams and Parham 2002, Nei et al. 1997). The development of high levels of diversity in the MHC region along with the visible differences between MHC across species has been the result of generation, duplication, and loss of MHC genes (Nei and Rooney 2005).

SEARCHING GENOMES FOR MORE MHC CLASS I MOLECULES

Traditionally, novel genes in genomes have been found using *in silico* search methods that rely on sequence identity and similarity to identify new genes. This methodology relies heavily on conserved nucleotide identity or similarity for identification. MHC class I genes offer an ideal model for the new search methods that search using structure rather than sequence. Because nearly all MHC class I genes can be

grouped via their conserved structure consisting of an α chain comprised of three domains and an associated $\beta 2$ -microglobulin, we can utilize new search methodologies that look for the defined protein domain structures of Class I molecules. This method uses a search algorithm that looks for the conserved structure of the MHC Class I molecules rather than sequence homology. Using this novel technique, available full genomes can be searched to see if the algorithm could uncover previously identified MHC class I genes found using traditional search methods or any new Class I genes.

MARSUPIALS AS A MODEL RESEARCH ORGANISM

Because of this ability to search and possibly uncover novel families of MHC class I genes, the genomes of non-traditional organisms must be examined. This includes marsupials and monotremes, including the marsupial species the grey-short tailed opossum, *Monodelphis domestica*.

I. Origins and History of Marsupials

Marsupials are a unique part of the animal kingdom, as they represent the most evolutionarily distant living species of viviparous mammals to eutherians (Cifelli and Davis 2003). Marsupials, or Marsupialia, are a distinct infraclass of mammals that contains nearly 300 different species. While the majority of the known marsupial species are found in Australia and Oceania, many can also be found in the Americas (Wilson and Reeder eds. 2005). South and Central America contain the bulk of the Western Hemisphere's approximately 80 marsupial species. One species can be found in North America, the Virginia opossum, *Didelphis virginiana* (Graves and Westerman 2002). Currently, there are no marsupial species found in Africa, Asia, or Europe. However, a

fossil specimen of a marsupial (*Sinodelphys szalayi*) has been found in China dating to 125 million years ago, along with the earliest placental mammal fossil, indicating that Asia may have been the location where diversification between early metatherians and eutherians occurred (Luo et al. 2003).

II. Unique Birth and Development in Marsupials

Marsupials differ from eutherian mammals in several ways, with the most noticeable difference being the birth of highly altricial or relatively underdeveloped young. The altricial birth state is due to a short gestational period and comparatively less invasive placenta (Graves and Westerman 2002). As the result of these early developmental differences, the overall development of the immune system of marsupials differs from that of eutherians. Marsupial young are born both physically and immunologically underdeveloped and develop some of their lymphoid cells post-natally (Baker et al. 1999, Old and Deane 2000, Wang et al. 2012). However, the pouch environment in which marsupial young enter frequently encounter pathogenic bacteria, and therefore defense mechanisms must be in place for the young to fight microorganisms. As a result, some of the protective mechanisms marsupials have developed to protect altricial young include transfer of immunoglobulins and immune compounds in milk and antimicrobial peptides secreted by the mother in the pouch (Edwards et al. 2012). These characteristics have made marsupials a valuable tool for the study of early immunological development in mammals.

III. Use of the Gray Short-tailed Opossum, *Monodelphis domestica*, in Research

Beginning in 1978, *M. domestica* were imported into the United States from four

sites in Brazil and one Bolivian site for use as a captive laboratory bred marsupial. Since then, *M. domestica* has been used in biomedical research as an animal model for melanoma, corneal cancer, and hypercholesterolaemia (Samollow 2006, VandeBerg and Robinson 1997). Other research, lead by Fry and Saunders (2000), has used *M. domestica* as a model to examine neural fiber regeneration following spinal cord injury. The uniquely altricial development of *M. domestica* allows the species to be used as a model for early neurological and immunological development, while also providing insight about the evolutionary lineage by sharing the last common viviparous ancestor to eutherian mammals. Additionally, *M. domestica* was the first marsupial to have its entire genome sequenced (Mikkelsen et al. 2007), a critical resource for searching genomes.

EARLY IMMUNOLOGICAL RESEARCH ON MARSUPIALS

Early research on the immune systems of marsupials focused on the thymus. It was noted by Johnstone (1898) that some species of marsupials had only a thoracic thymus, as is the case in eutherians, while others had both a cervical and a thoracic thymus. Thymectomy studies done with the quokka, *Setonix brachyurus*, where either the cervical or thoracic thymus was removed suggested that the roles of both of the thymuses were the same, despite their differing locations and development patterns (Stanley et al., 1972). Thymectomy studies on opossum pups a week after birth found a reduction in lymphocytes in lymphatic tissue with an increase of myeloid tissue, confirming that one or both thymuses in marsupials have a critical role in the maturation of T cells and other lymphoid tissues (Miller et al. 1965). Mixed lymphocyte reactions (MLR) of peripheral blood leukocytes (PBL) from two different populations of Virginia opossum failed to

respond and proliferate, but did respond to mitogens (Fox et al. 1976). It was inferred from this that the opossums might lack antigen reactive lymphocytes or may not have MHC, as they could not reject non-self leukocytes from the same species. The application of molecular genetic technologies, however, has confirmed the presence of MHC genes in marsupials.

THE UNIQUE MARSUPIAL IMMUNE SYSTEM

The work done in marsupial immunology has shown that components of immunity have been lost in non-eutherians and found in eutherians and vice versa. In comparisons of the immune systems of eutherians and non-eutherians, the research allows us to see the differences that exist between close relatives. Components of the adaptive immune system, such as immunoglobulins, have been shown to differ between eutherian and non-eutherian mammals. While IgM, IgG, IgE, and IgA have been found in all mammalian species, the marsupial *M. domestica* lacks IgD, which is postulated to be an ancient immunoglobulin in jawed vertebrates (Ohta and Flajnik 2006, Sun et al. 2011, Wang et al. 2009). It is likely the lack of IgD represents a significant gene loss in *M. domestica*, given that IgD can also be found in eutherians, non-eutherians, and other jawed vertebrates (Flajnik 2002, Miller and Belov 2000, Ohta and Flajnik 2006).

All jawed vertebrates have the four T cell receptors (TCR), TCR- α , TCR- β , TCR- δ and TCR- γ . While marsupials and monotremes have all four traditional TCRs, they also have a fifth atypical T cell receptor, TCR- μ (Parra et al. 2007, 2008). Even between marsupials and monotremes TCR- μ differs. In marsupials, pre-joined V genes encode the TCR isoform, whereas the platypus has doubly-rearranging V domains (Miller 2010,

Parra et al. 2007). While the function of TCR- μ and the presumed partner chain remain unresolved, TCR- μ is related to TCR- δ , but remains divergent in both sequence and structure from traditional mammalian T-cell receptors (Parra et al. 2008, 2012). The loss of the immunoglobulin IgD in *M. domestica* and the gain of TCR- μ in marsupials and monotremes have shed new light onto the evolutionary trajectory and development of mammalian immunity.

MHC RESEARCH IN MARSUPIALS

MHC class I genes have been characterized the most in mammalian species such mice and humans, but also have been examined in a more distant group of non-eutherian mammals, the marsupials. Early work on MHC in koalas generated numerous MHC class I gene sequences, and defined MHC class I in the species as a large, multi-gene family (Houlden et al. 1996). In contrast, low levels of polymorphism were found in the MHC class II β chain of tammar wallabies in comparison to eutherians (McKenzie and Cooper 1994). Currently, research on the MHC in marsupials focuses mostly on MHC class I genes.

The model organism for the investigation of marsupial MHC Class I genes is the gray short-tailed opossum, *Monodelphis domestica* (Baker et al. 2006, Baker and Miller 2007, Baker et al. 2009, Belov et al. 2006, Gouin et al. 2006, Miska et al. 2004, Miska and Miller 1999). Using traditional *in silico* search methods, eleven genes encoding the MHC Class I α chain have been uncovered in the *M. domestica* genome, along with three MHC Class I pseudogenes (Baker et al. 2009, Belov et al. 2006, Gouin et al. 2006).

The function and features of MHC class I genes have been fairly well defined in the opossum. Work by Gouin et al. (2006) revealed that a non-classical MHC class I gene, *ModoUG*, can be expressed in three different alternatively spliced mRNA forms. In these forms, a short cytoplasmic tail has been found that does not have traditional phosphorylation sites. In Baker et al. (2009), *M. domestica* MHC class I genes including *ModoUE*, *UI*, *UJ*, *UK*, and *UM* were characterized. These *M. domestic* class I genes had atypical genomic characteristics including alternative mRNA splicing, low polymorphism, and unpaired cysteine residues that could form homodimers. This is indicative that these MHC genes likely do not produce molecules involved in traditional antigenic peptide presentation.

ABSTRACT

Major histocompatibility complex (MHC) class I genes are found in the genomes of all jawed vertebrates. This gene family has evolved to perform immune-related and non-immune functions, including presenting endogenously-derived peptide antigens to cytotoxic T-cells.

Sensitive sequence searches of representative vertebrate genomes using hidden Markov models revealed an extensive, novel sub-family of divergent MHC class I genes, denoted as *UT*, which have not previously been characterized. These genes are found in both American and Australian marsupials and in monotremes, but are absent from non-mammalian genomes and lost from the eutherian lineage. We show that *UT* genes are expressed in immune tissues of the gray short-tailed opossum and several Australian marsupials. Structural homology modeling predicts that *UT* family members have an open, though short, antigen-binding groove. The function of this family is as yet unknown, however their predicted structure may be consistent with being able to present antigens to T-cells.

INTRODUCTION

The major histocompatibility complex (MHC) is a region unique to the genomes of jawed vertebrates and contains genes that are critical to the generation of immune responses. It is the most gene dense and polymorphic region in the genome (reviewed in ¹). The MHC is named for its role in recognition of ‘self’ and ‘non-self’ and was first identified in connection with tumour transplant rejection². Genes in the MHC are also associated with resistance to infectious diseases, autoimmunity, reproductive success, inflammatory response and innate immunity (reviewed in ^{3,4}).

The genes of the MHC are sub-divided into class I, II and III. The MHC class I genes are particularly noteworthy for having undergone gene duplication and divergence, resulting in an extended gene family whose members perform a broad range of functions. The classical role of class I molecules is to present endogenously-derived peptides to CD8⁺ T cells to stimulate cytotoxic responses against virus infected or tumour cells. The class I molecules performing this role are sometimes referred to as classical MHC class I. Examples of classical class I genes include *HLA-A*, *-B* and *-C* in humans and *H2-K*, *H2-D* and *H2-L* in mouse. Classical MHC class I genes are generally broadly expressed in nucleated cells and highly polymorphic. Class I molecules performing other functions, collectively known as non-classical MHC class I, generally have low polymorphism, may have tissue-specific expression and in some cases have evolved functions other than antigen-presentation, including immuno-regulatory and non-immune roles. Examples of non-classical class I genes include *HLA-E*, *-F* and *-G* in human, *B1* and *Qa1* in mouse, as

well as *MIC*. The function of non-classical molecules is not limited to the immune system. The *HFE* gene, for example, serves as part of the transferin complex involved in iron storage (reviewed in ⁵). Others, such as the neonatal Fc receptor, *FcRN*, that transports maternal IgG to fetal or neonatal mammals, has a role in the immune system that is distinctly different from conventional class I (reviewed in ⁶). Typically, classical and some non-classical genes are located in the MHC, although many of the non-classical are located elsewhere in the genome⁷.

In humans, the MHC is located on chromosome 6p¹. Additionally, there are three regions of the genome that are paralogues of the MHC, indicative of the two rounds of whole genome duplication thought to have occurred in early vertebrate evolution⁸. These paralogous regions are located on chromosomes 1q, 9q, and 19p. They contain additional non-classical class I genes, including the *CD1* gene family, *MR1* and *FCGRT*. Other non-classical class I genes are found on chromosome 20 (*PROCR*), chromosome 7 (*AZGP1*) and chromosome 6q (*ULBP* and *RAET* families), suggesting that duplication and translocation have acted to further distribute MHC class I genes throughout the genome.

In some species, similar processes have acted to spread class I genes from the MHC. Two tightly linked, classical class I-like genes (*UB* and *UC*) in the opossum, *Monodelphis domestica*, for example, were translocated outside the MHC although they remain syntenic to the MHC on chromosome 2^{9,10}. In a more extreme example, in the tammar wallaby, *Macropus eugenii*, the classical class I-like genes have been completely translocated out of the MHC and are distributed across multiple chromosomes¹¹.

Both classical and non-classical class I molecules have a conserved and distinctive protein domain structure. MHC class I genes typically have 5-9 exons encoding proteins with well-defined domain organization (Figure 1A and 1B). The first exon encodes a signal peptide. Exons 2 and 3 encode the α_1 and α_2 domains, which together make up the antigen-presenting domain (APD). An immunoglobulin domain (Ig or α_3) is encoded by exon 4. Additional exons may encode one or more transmembrane domains and the final exon contains a conserved cytoplasmic domain at the C-terminus of some MHC class I genes. The α_1 , α_2 and Ig domains are the hallmark of MHC class I genes. However, different isoforms of some MHC class I genes exist. These may splice out some of these domains to produce other membrane bound versions of the protein or secreted forms. Additionally, the UL16-binding protein (*ULBP*) and retinoic acid early transcript (*RAET*) families, known in eutherians, are MHC class I-related genes that lack immunoglobulin domains and may utilize a GPI-anchor rather than a transmembrane domain¹²⁻¹⁵.

To better understand the evolution of MHC class I genes, particularly in mammals, we undertook to catalogue the class I genes. Here, we describe a sensitive comparative genomic analysis of MHC class I genes spanning the vertebrates. This was achieved using a novel approach based upon combining profile hidden Markov models (HMMs), which represent the separate domains characteristic of MHC class I genes. Our results reveal a new sub-family of MHC class I genes in marsupials and monotremes, which are not found in non-mammals and have been lost from the eutherian lineage. We show that these genes are transcribed in immune tissues in the gray short-tailed opossum, tammar

wallaby, brushtail possum and Tasmanian devil. Structural homology mapping is used to begin to investigate the function of these genes.

Materials and Methods

Collection of annotated protein sequences

Predicted MHC class I proteins were identified and extracted from the Ensembl genebuilds (Release 75) of a selection of species spanning the gnathostomes, a jawless vertebrate, 2 invertebrate species, and a fungus. Protein sequences from human³³, mouse³⁴, dog³⁵, cow³⁶, opossum³⁷, wallaby³⁸, Tasmanian devil¹⁹, platypus³⁹, chicken⁴⁰, zebra finch⁴¹, turkey (The Turkey Genome Consortium), green anole lizard⁴², *Xenopus tropicalis*⁴³, zebrafish⁴⁴, pufferfish⁴⁵, lamprey⁴⁶, sea squirt⁴³, fruitfly⁴⁷ and yeast⁴⁸ were searched using profile hidden Markov models (HMMs) representing the MHC class I APD (PFAM:PF00129 and SUPFAM:0045513), C1-type Ig domain (PFAM:PF07654) and MHC class II β domain (PFAM:PF00969) using HMMer version 2 (fs and ls) and HMMer version 3 (PFAM models only). The separate domain searches were integrated and MHC class I proteins predicted using a simple heuristic: proteins were annotated as predicted MHC class I proteins if they had a significant match to the MHC class I APD (E-value<10⁻⁵) or a weak match to the APD (score>0) and a significant match to the Ig domain model (E-value<10⁻⁵) in the correct order, with the additional requirement that the MHC class I APD model score is higher than the MHC class II β domain model score. Where a gene had multiple isoforms, the longest protein was selected as representative. The most sensitive approach (based on the number of proteins matched) used the SUPFAM MHC class I APD model, the PFAM Ig domain and HMMer2 in fs-mode. ULBPs and RAETs, which do not possess immunoglobulin domains, were identified by searching with the MHC class I APD HMM only.

Sensitive genome search

The predicted MHC class I proteins were used to construct custom profile HMM models in HMMer2. The 6-frame translations of the human (hg19), mouse (mm9), dog, cow, opossum (mondon5), wallaby (Meug_1.0), Tasmanian devil (assembly 7), platypus (OANA5), chicken, zebra finch, turkey, green anole, *Xenopus tropicalis*, zebrafish, tetraodon, lamprey, sea squirt, fruitfly and yeast genome sequences (Ensembl Release 75) were searched using profile HMMs representing the MHC class I APD (PFAM:PF00129, SUPFAM:0045513 and a custom model), C1-type Ig (PFAM:PF07654 and the custom model), C-terminal (PFAM:PF06623) and MHC class II β (PFAM:PF00969) domains with HMMer (version 2) with an E-value threshold of 10. Local alignment models (fs) were used.

The coordinates of predicted domains in the 6-frame translation were then transformed back to genomic coordinates. Genomic regions matching the first half of the MHC class I domain model were annotated as α_1 domains, while features matching the second half were annotated as α_2 domains. Regions also matching MHC class II β domains were removed if the class II match scores were greater than the class I match scores.

Genomic regions containing matches to the α_1 , α_2 , Ig and C-terminal domains with the correct orientation and order and intron-like separation were identified by aligning a model representing the canonical domain architecture of class I genes to the predicted domains (Figure 1). The alignment algorithm was implemented using dynamic programming. It used weighted HMMer scores as match scores. The weights were

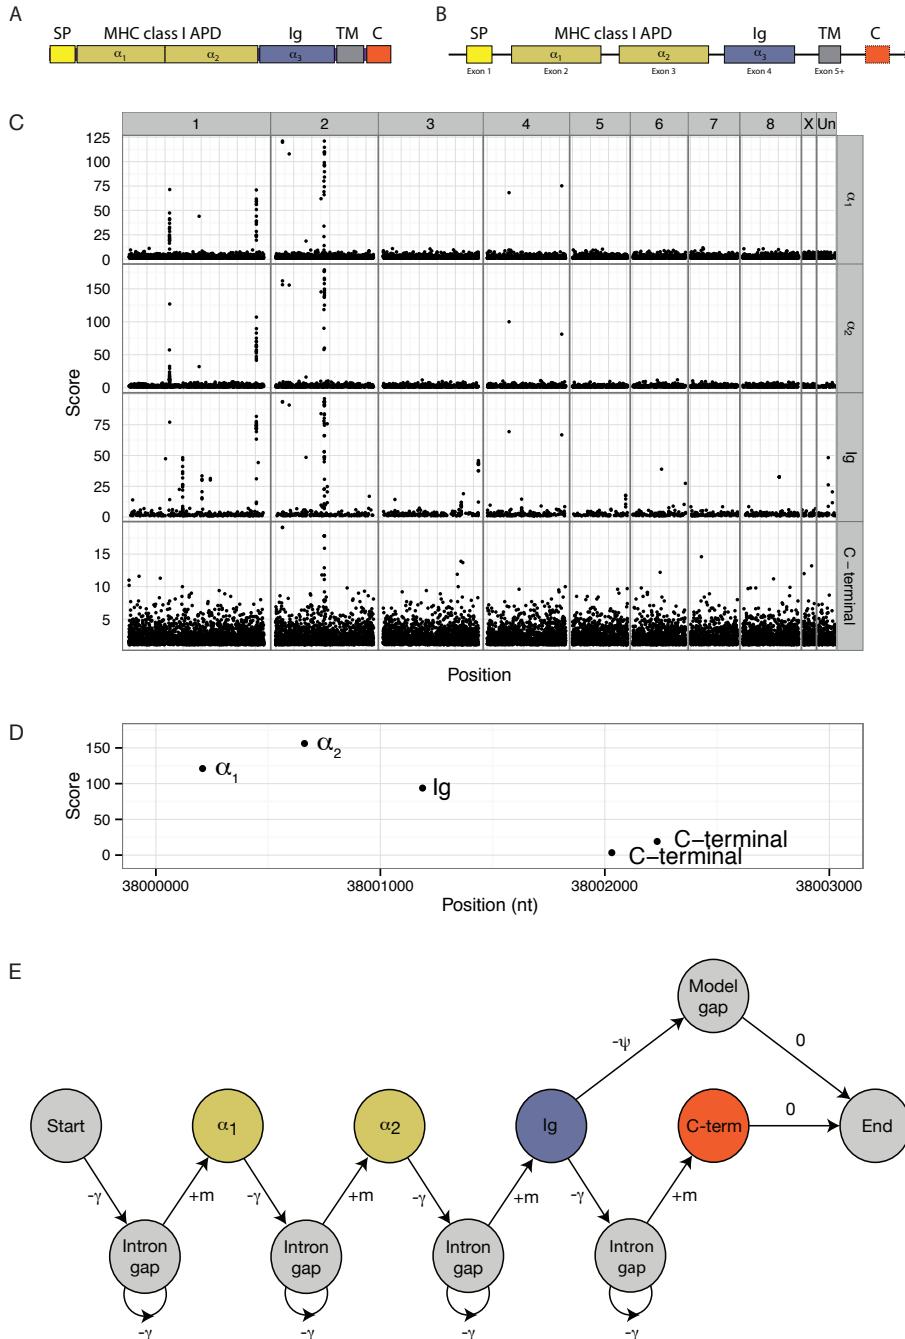

Figure 1. Sensitive pan-genome search for MHC class I genes. The canonical domain structure of MHC class I (A) proteins and (B) genes. (C) The location in the opossum genome and score of matches to profile hidden Markov models representing the antigen-presenting domain (split into α_1 and α_2 regions), C-type immunoglobulin domain and C-terminal domain. (D) Example of a high-scoring run of α_1 , α_2 , Ig and C-terminal domains in the opossum genome. (E) Finite state automata of the alignment algorithm to search for runs of α_1 , α_2 , Ig and C-terminal domains, taking domain score and distance between domains into account. The nodes (circles) show match states. Symbols on edges show scores/penalties: $+m$ is the match score, which is based on the HMM match score; $-\gamma$ is a distance-dependent affine gap penalty, which models introns and allows the alignment to skip over matches that interrupt a run of domains; $-\psi$ is a constant penalty for dropping the C-terminal domain.

selected to approximately normalise the contributions from each domain (weights were α_1 : 1, α_2 : 1, Ig: 2, C-terminal: 20). An affine gap penalty was used to model introns with gaps shorter than 5000nt penalty-free and calibrated so that a 20,000nt gap gets a penalty of 300. Mismatches are effectively disallowed by applying a very large mismatch score (-20,000), but the affine gap function can skip over mismatching domains. Parameters were selected to have maximum sensitivity on the well-annotated human MHC class I genes and then tested on the mouse (positive control) and lamprey and sea squirt genomes (negative controls).

The workflow is summarized in Supplementary Figure 5 and code is provided in the Supplementary Materials and Methods.

Phylogenetic analysis

Multiple sequence alignments of predicted peptide sequences were generated using Clustal Omega^{49,50} and edited in jalview⁵¹.

The phylogeny of the 449 predicted MHC class I genes identified in the representative jawed vertebrates was inferred using the JTT model⁵² in BEAST2⁵³. A discrete Gamma distribution with 4 categories was used to model evolutionary rate differences among sites. Four Markov chains were run for 3,000,000 steps each starting from random trees. Trees were output every 1000 steps. The consensus tree was estimated from the last 500,000 steps of the 4 chains.

To infer the evolutionary history of 30 selected human, mouse, marsupial and monotreme MHC class I genes, and the gene tree of the 46 *UT* family members, the best phylogenetic model was first selected using PROTTEST3⁵⁴. In both cases, the best model based on AIC was the JTT method⁵² with invariant sites, gamma rate distribution, and empirical amino acid frequency. Phylogenetic trees were estimated using the maximum likelihood method with MEGA5⁵⁴. The bootstrap consensus tree inferred from 500 replicates was taken to represent the evolutionary history of the genes analyzed. A discrete Gamma distribution was used to model evolutionary rate differences among sites with 4 categories. The rate variation model allowed for some sites to be evolutionarily invariable. The *UT* gene tree and the species tree were reconciled using NOTUNG⁵⁵ to identify gene duplication and loss events.

BAC library screening

Overgo probes representing each of the wallaby and platypus novel class I genes were designed from genomic sequence using the Overgo Maker program. The specificity of the resulting overgos was judged by using the 40bp probe sequence to BLASTN search the tammar wallaby or platypus genomes. All overgoes used to screen the BAC libraries are listed in Supplementary Table 6. Overgos were radioactively labelled, pooled and hybridised to tammar wallaby (Me_KBa; Arizona Genomics Institute) or platypus (Oa_Bb, Clemson University Genomics Institute) BAC library filters as previously described¹¹. Positive BACs from this initial screening were spotted onto Hybond N+ and subjected to a further round of screening with individual probes as previously described⁵⁶.

Fluorescence in situ hybridisation

BAC DNA from each positive BAC clone was directly labelled with either SpectrumOrange dUTP or SpectrumGreen dUTP (Abbott Molecular Inc., Des Plaines, IL, USA). Labelled BACs were hybridised to male metaphase chromosomes spreads, visualised and imaged as previously described⁵⁶.

RT-PCR of predicted transcripts in opossum

Coding sequences of *mdUT* genes were amplified by targeted PCR with primers designed based on predicted exon 2 and 3 gene sequence, using a cDNA library constructed from opossum thymus mRNA (Supplementary Table 7). The PCR was done using Advantage HF 2 PCR kit (Clontech, Mountain View, CA), with the following parameters for all primers: 94°C for 1 minute, 35 cycles of 94°C for 30 seconds and 61 to 65.1°C gradient for 4 minutes, and 68°C for 5 minutes. The amplified DNA was then ligated into the pCR4-TOPO TA vector, transformed into One Shot Chemically Competent TOP10 *E. coli*, and incubated with 250µL LB medium at 37° while shaking for 1 hr (Invitrogen, Carlsbad, CA). A total of 120 µL of the transformed cells were then plated on ampicillin agar plates and incubated between 12-18 hours at 37°C. A minimum of 8 clones per plate were chosen, and plasmid DNA were generated using the boiling lysis method. Both the forward and reverse strands were sequenced with BigDye Terminator v3.1 Cycle Sequencing Kit (Invitrogen, Carlsbad, CA) Analysis of the sequences was done using Sequencher 5.0 (Gene Codes, Ann Arbor, MI).

Searching marsupial immune tissue transcriptome data

To find support for the expression of UTs in several marsupials, sequencing data from the following immune tissue cDNA or EST libraries were downloaded: Roche 454 sequencing data from tammar wallaby, *Macropus eugenii*, thoracic and cervical thymus cDNA libraries (NCBI SRA accessions: SRX019250 and SRX019249)⁵⁷; Roche 454 sequencing data from Tasmanian devil, *Sarcophilus harisii*, spleen and lymph node cDNA libraries (NCBI SRA accession: TBA); Roche 454 sequencing data from the opossum, *Monodelphis domestica*, thymus cDNA libraries (Katina Krasnec and Robert Miller, unpublished data); 17,818 ESTs from brushtail possum, *Trichosurus vulpecula*, spleen, lymph node and stimulated splenocytes (NCBI EST: LIBEST_019237); and a small set of 1319 ESTs from a northern brown bandicoot, *Isoodon macrourus*, thymus ESTs (GenBank accession: EE743888-EE745206) ENREF_41⁵⁸.

Reads from each library were aligned to predicted tammar wallaby UTs, or Tasmanian devil UTs, in the case of the devil spleen and lymph libraries, using BLASTN. An E-value threshold of 10^{-5} was used and only a single best hit was recorded.

Structural homology modelling

Structure prediction used the I-TASSER method²⁰. Structural similarity or divergence was evaluated by a pairwise root mean square deviation (RMSD) value upon superposition of the backbone C α trace from the two groups of structurally equivalent atoms in MHC class I α_1 and α_2 domains. Structure visualization and the RMSD calculation are using Pymol (<http://pymol.sourceforge.net/>).

Results

Sensitive peptide searches for MHC class I proteins

We first set out to identify all annotated MHC class I proteins in 15 representative species sampled from across vertebrate life. The selected species comprised human, mouse, dog, cow, three species of marsupials with sequenced genomes, platypus, three avian species, a lizard, a frog, and two fish species. Additionally, we selected 4 eukaryotic species known to lack MHC class I genes as negative controls (lamprey, sea squirt, fruitfly and yeast). Predicted protein sequences from these species were obtained from Ensembl and searched using profile HMMs representing the MHC class I APD and the C1-type Ig domain, which are characteristic of MHC class I genes, and the MHC class II β domain, with HMMer. The separate domain searches were integrated and MHC class I proteins predicted using a simple heuristic: proteins were annotated as predicted MHC class I proteins if they had a significant match to the MHC class I APD or a weak match to the APD and a significant match to the Ig domain model in the correct order, with the additional requirement that the MHC class I APD model matched with higher score than the class II β domain model. MHC class I genes frequently encode multiple isoforms; in these cases, we selected the longest protein as the representative protein. A variety of HMMs were tested (e.g. PFAM, SUPFAM and iteratively constructed custom models; see Methods for details) and the most sensitive combination was adopted.

Our search identified 348 MHC class I proteins across the 15 jawed vertebrate species searched (summarized in Table 1). This included all 24 known human and 41 mouse

Table 1. Summary of the number of MHC class I genes across species. The number MHC class I genes identified in each species by searching annotated proteins using customized models and by sensitive genome search.

Species	Number of predicted MHC class I genes		
	Protein search	Genome search	Merged total
Human	24	26	33
Mouse	41	49	55
Dog	19	21	24
Cow	47	39	55
Opossum	28	40	47
Tammar wallaby	17	35	41
Tasmanian devil	22	23	25
Platypus	19	10	21
Chicken	24	21	26
Zebrafinch	11	3	11
Turkey	7	3	7
Green anole	25	19	26
Frog	26	31	32
Zebrafish	28	31	33
Tetraodon	10	10	13
Lamprey	0	0	0
Sea squirt	0	0	0
Fruitfly	0	0	0
Yeast	0	0	0
	348	361	449

MHC class I proteins with no false positives. Searches of several negative controls—lamprey, sea squirt, fruitfly and yeast—did not identify any MHC class I proteins. Aligning all PFAM-A domain models to the set of predicted MHC class I proteins using hmmpfam showed that for each protein the strongest matches consisted only of the MHC class I APD, Ig and in some cases the conserved MHC C-terminal domains, with no other unexpected high quality matches. MHC class II genes were never misidentified as class I genes in the searches of any jawed vertebrate protein databases. Taken together these observations indicate the approach has high sensitivity and specificity.

Sensitive genome searches for MHC class I genes

Next, we set out to identify any unannotated MHC class I genes in these genomes using a highly sensitive search method designed to take advantage of the conserved exon/domain organisation of MHC class I genes (Figure 1A). Profile HMMs representing the MHC class I APD, C1-type Ig, MHC C-terminal, and MHC class II β domains were used to search the six-frame translation of each genome. The domain matches in the 6-frame translation were transformed back to genomic coordinates and the α_1 , α_2 , Ig and C-terminal domains within the model matches were identified. In each species, we found thousands of matches to these domains (summarized in Supplementary Table 1). For example in the opossum genome, we found 2127 matches to the α_1 domain, 3571 matches to the α_2 domain, 5028 matches to the Ig domain and 5546 matches to the MHC C-terminal domain. The majority of these matches had low scores. However, both isolated and clustered high scoring matches were also apparent (Figure 1B). Genomic features matching the expected structure of an MHC class I gene, that is a chain of α_1 , α_2

and Ig domains and optionally a C-terminal domain on the same strand and at intron-like distances (for example Figure 1C) were identified by aligning a canonical model of an MHC class I gene, taking match score and the gaps between domains into account (Figure 1D and methods for details). Once again, a variety of HMMs were tested (e.g. PFAM, SUPFAM, and custom models based on the protein search results; see Methods for details). The custom models were adopted as the most sensitive.

From the 388,409 domain matches across all species, the genome search identified 361 genomic features possessing the MHC class I gene structure (summarized in Table 1; Supplementary Table 2 for details). These included 26 putative MHC class I genes in the human genome, 49 in mouse, and 40 in the opossum. Again, searches of the negative controls identified no MHC class I genes, as one would expect. These genomic features included annotated genes and both annotated and unannotated pseudogenes. Merging the protein and genome searches produced a total of 449 MHC class I genes and proteins across the species searched (Supplementary Table 3), including a total of 33 in human, 55 in mouse and 47 in the opossum.

The most dramatic differences between the results of searching annotated class I proteins and an unbiased search of the whole genome arose in the marsupials and monotremes. The annotation of the opossum genome (Ensembl Release 75) contains 28 MHC class I genes, but 40 putative MHC class I genes (genomic features with structural similarity to MHC class I genes) were identified in the sensitive genome search results. Seven of the annotated proteins were missed in the genome search, as the corresponding loci lack Ig

domains. Fifteen of the loci identified by the genome search were unannotated. Five of these contained in-frame stops, including opossum *CD1*, *UH*, and a *MIC*-like gene. These in-frame stops may be due to sequencing errors in the draft opossum genome, polymorphisms in the individual sequenced or the fact that our model does not take splice sites into account and may erroneously include short segments of intronic sequence in the domain matches, resulting in the genomic feature going out of frame. Consequently, we retained these genes in our analyses. Thus, a total of 47 putative MHC class I genes were identified. A similar pattern emerged in other marsupial and monotreme genomes.

Phylogenetic analysis

To annotate these genes and understand the evolutionary relationship between them, we inferred the phylogenetic relationships between all MHC class I genes identified in the selected vertebrates using a Markov Chain Monte Carlo (MCMC) method on the JTT+IGF model. Four MCMCs were run (see Supplementary Figure 1 for traces of posterior probability) and the consensus tree from the last 500 steps of each run was taken to represent the evolutionary history of the genes (Figure 2A). Additionally, a smaller phylogeny consisting of just human and opossum class I genes and the mouse *Mill* genes was also inferred by maximum likelihood (Supplementary Figure 2).

While support in parts of the trees is low, the phylogenies provide a number of insights into the evolution of MHC class I genes in vertebrates. The large tree provides additional evidence for the previous observation that the non-classical MHC class I gene family *MR1* is found only eutherians and marsupials¹⁶. Similarly, it suggests that the *FCGRT*,

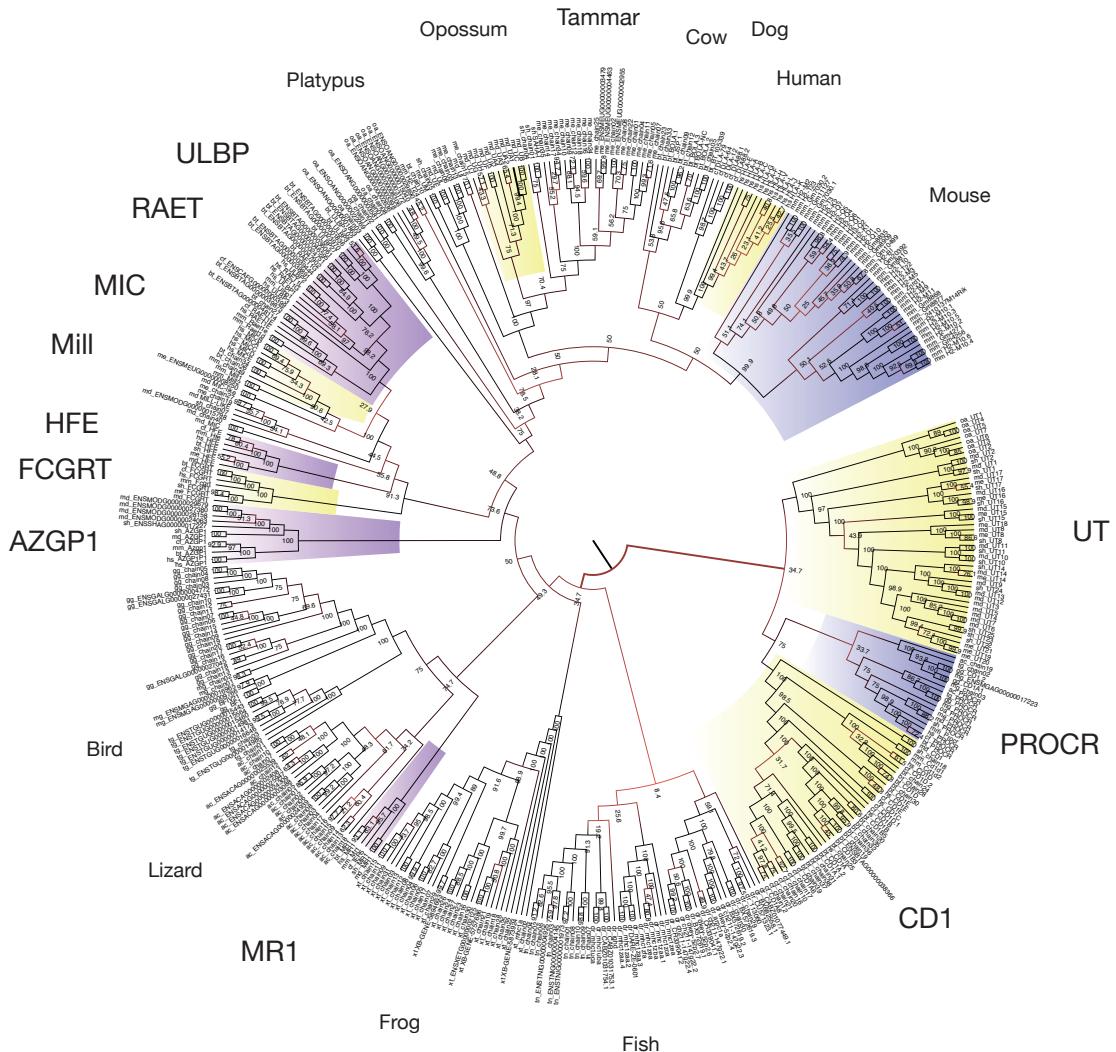

Figure 2. Phylogeny of class I genes predicted in representative species spanning the jawed vertebrates estimated by MCMC on the JTT+IG model. Numbers at nodes represent the frequency with which that split is observed. Gene families are labelled around the outside. The species label shows the location of classical MHC class I for each species or group of species. Key gene families or species' classical class I genes are highlighted in colour.

HFE and *AZGP1* gene families are specific to eutherians and marsupials. It demonstrates that the *PROCR* gene family is found across the amniotes. It suggests that MIC is duplicated in opossum (md_chain40), though this contains in-frame stops. The small tree supports the previous observation that marsupials may have a member of the *ULBP* gene family (ENSMODG00000015798)¹⁷. It identifies a possible expansion of *AZGP1* in opossum (ENSMODG00000024063, ENSMODG00000027380, ENSMODG00000028158, and ENSMODG00000029679). The phylogenies also reveals two new opossum MHC class I genes that are located in the MHC, but have not previously been identified, which we have denoted *UA3* and *UA4*. These appear to be closely related to *UA1* and *UA2*.

Strikingly, the phylogenetic tree identifies an extensive and entirely novel clade of MHC class I genes in marsupials and monotremes, which we have named *UT*. There are 17 *UT* family genes identified in the opossum genome, 9 in tammar wallaby, 13 in the Tasmanian devil and 7 in the platypus. The numbering of *UTs* is based on location in the gene cluster in the opossum and clear orthology, or lack of it in other marsupials. Platypus *UTs* are numbered independently as these appear to form a distinct clade. This is highlighted by the *UT* gene tree (Supplementary Figure 3), which was estimated using maximum likelihood with the JTT+IGF model and reconciled with the species tree using NOTUNG. No *UTs* were identified outside of the marsupials and monotremes in our searches.

Chromosomal location

The *UT* family of MHC class I genes is encoded in a gene cluster on chromosome 1 in the opossum genome (Figure 3). This region is approximately 460 kilobases in size. Interestingly, the cluster is located at an evolutionary breakpoint and is flanked by genomic regions that share synteny with different chromosomes in human (chr2 and chr20) and mouse (chr6 and chr2). The tammar wallaby genome assembly (Meug1.0) is highly fragmented and scaffolds are not mapped to chromosomes. Fluorescence In-Situ Hybridization (FISH) shows that the *UT* gene cluster is also located on chromosome 1 in the tammar wallaby genome (Figure 4), as predicted by conserved synteny between the tammar and opossum¹⁸. Interestingly, the FISH also shows a signal on the tammar Y chromosome. As all marsupial genomes sequenced were female, this locus was not detected in genome-wide searches and the significance of this signal is not yet understood. Based on the digital karyotype of the Tasmanian devil¹⁹, the *UT* gene family is also located on chromosome 1. In platypus, the *UT* genes are located on unmapped scaffolds and we were unable to map them using FISH.

Sequencing and gene expression

Of the 17 putative opossum *UT* genes, the expression of 8 genes, consisting of *UT4*, *UT5*, *UT6*, *UT8*, *UT9*, *UT10*, *UT15*, and *UT17*, was confirmed in opossum thymus using RT-PCR (Supplementary Figure 4). Predicted sequences obtained from our sensitive search method were confirmed using RT-PCR to obtain amplicon sequences from within exons 2 and 3 (Supplementary Table 4). A further 4 *UT* loci, *UT2*, *UT3*, *UT7*, and *UT16*, were

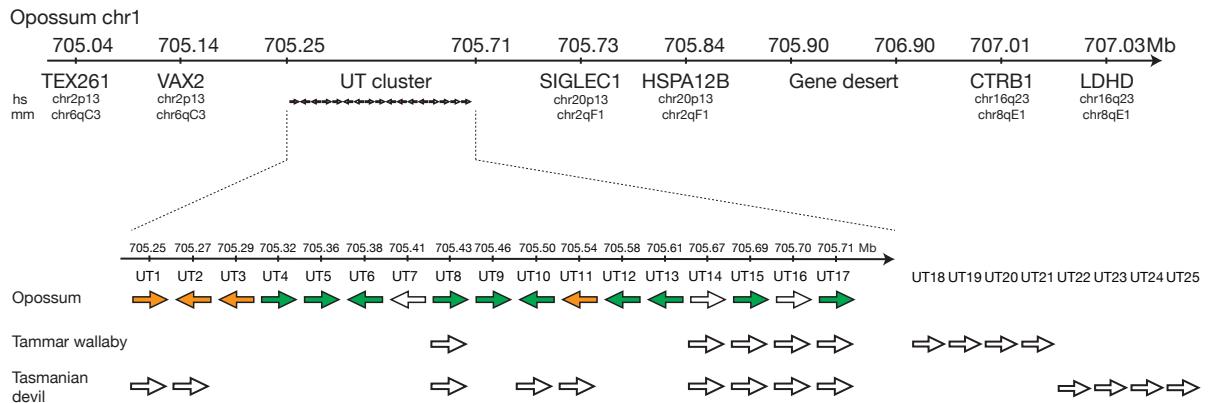

Figure 3. Comparative map of the *UT* cluster. (A) Genomic region containing the *UT* cluster in opossum showing the non-synteny of flanking genes between the opossum and human/mouse genomes. (B) Comparative map of *UT* cluster in opossum, tammar wallaby and Tasmanian devil. Green arrows represent *UT* genes found transcribed, orange for genes not transcribed, and white for unknown transcription

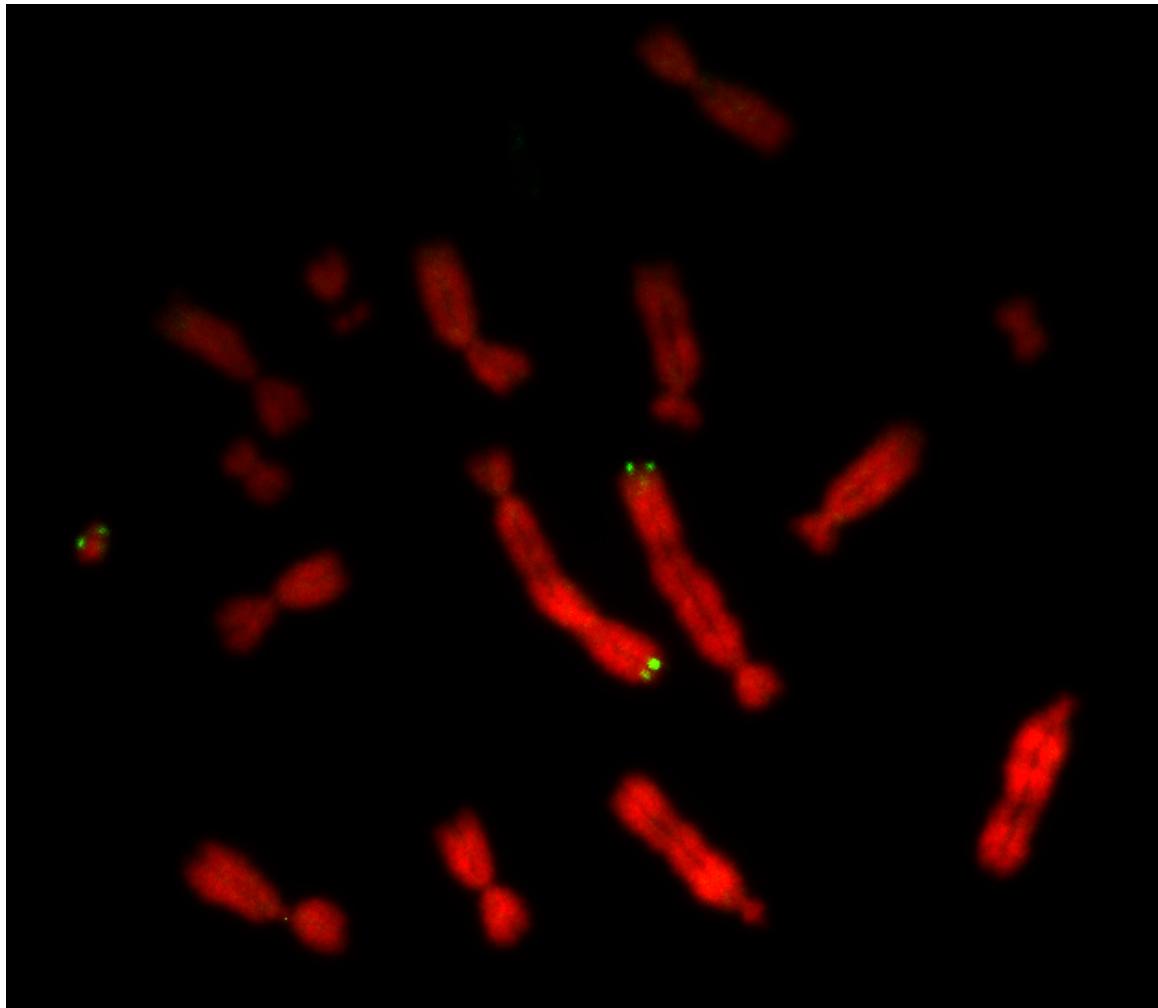

Figure 4. Fluorescence In-Situ Hybridisation showing location of *UT* cluster on chr1 in the tammar wallaby. A signal is also observed on the Y chromosome.

confirmed as expressed in Roche 454 sequencing data from an opossum thymus cDNA library (data not shown).

Transcription of tammar wallaby *UT1*, *UT2*, *UT3*, *UT4*, *UT5*, and *UT8* was confirmed in 454 data from thoracic and cervical tammar thymus cDNA libraries. There was support for Tasmanian devil *UT2*, *UT8*, and *UT11* in 454 cDNA data from devil spleen, but no *UTs* were detected in a lymph node library.

Limited transcriptome sequence data is available from immune tissues of other species of marsupial. An EST (id: 161106CS44009845FFFF) from brushtail possum immune tissues with homology to *meUT2* was also identified, providing support for the existence of functional *UTs* in the possum. No *UT* transcripts were detected in BLASTN searches of a small bandicoot thymus EST library. No platypus immune tissues transcriptome data was available.

Homology mapping

To investigate the function of *UT* family members we predicted the protein structure of selected *UTs* (opossum *UT4*, *UT5* and *UT8*) using homology modeling with the I-TASSER method²⁰. Protein structures from the Protein Data Bank (PDB) that were closest to the predicted models comprised both classical and non-classical MHC class I genes from chicken, cow, mouse and human (Supplementary Table 5; Figure 5A for an annotated sequence alignment of 7 of the top matches). The structure of the classical chicken MHC class I protein B21 (3BEV²¹) was the best match for *UT8* and appeared in

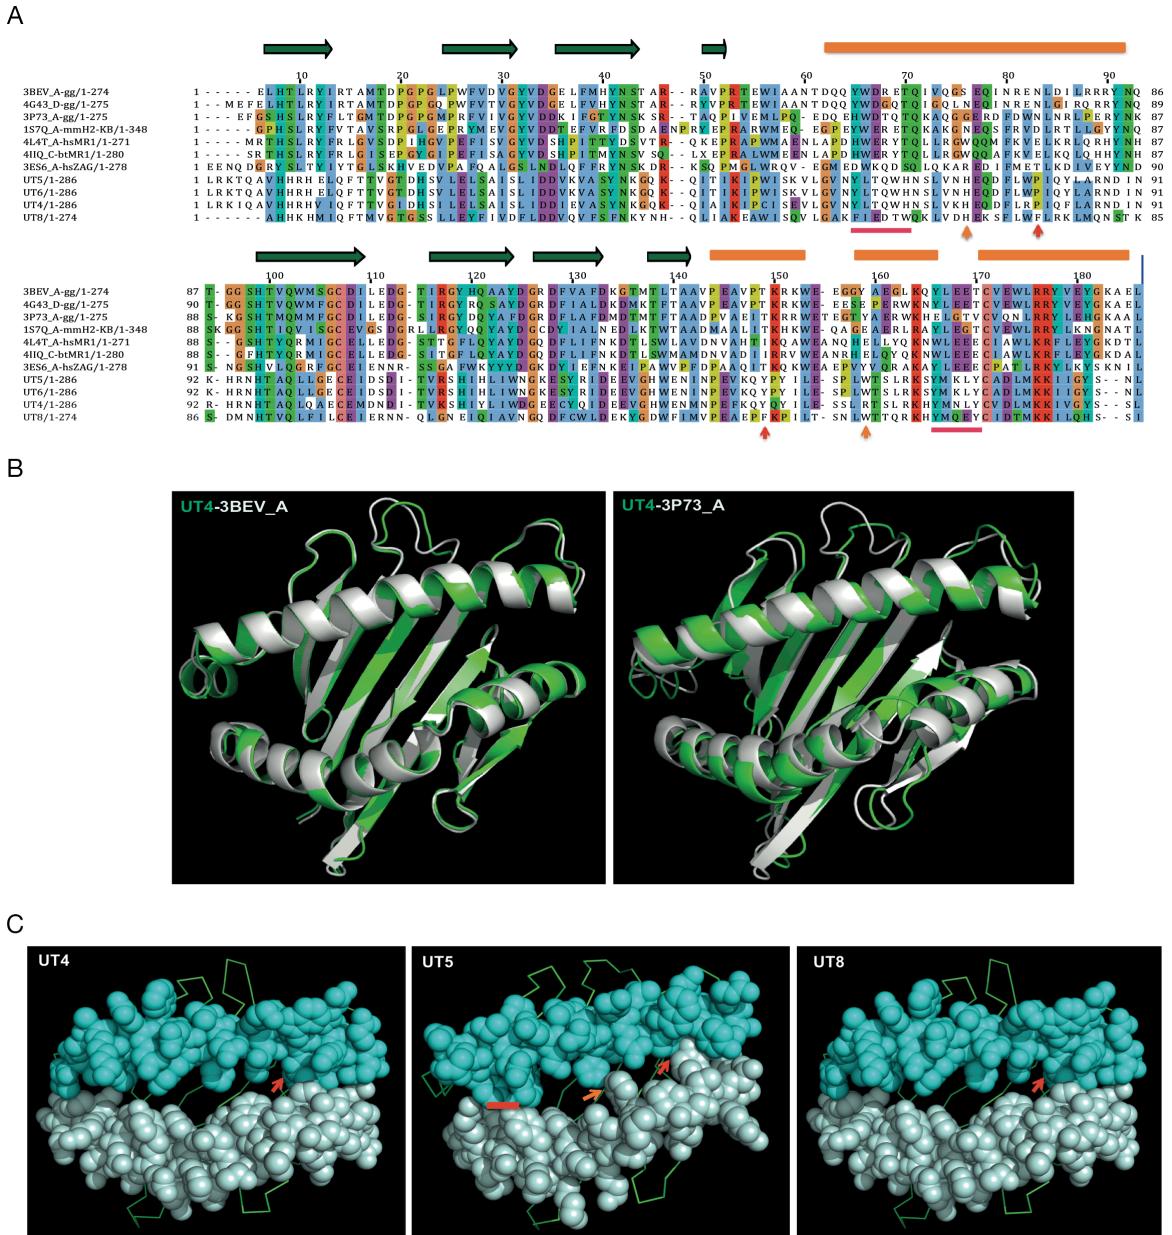

Figure 5. Predicted structure of UT proteins. (A) Sequence alignment of the α_1 and α_2 domains of *UT4*, *5*, *6*, *8* with 7 of the top 10 structural analogs from Protein Data Bank (PDB) identified by I-TASSER. Orange bars show α -helices. Green arrows highlight β -strands. Major differences between the *UTs* and templates are indicated by arrows, or red lines, and the consequence of these on the protein structures are shown in Figure 5C. (B) Overlay of the backbone of the peptide binding groove of *mdUT4* with its top 2 structural analogs, 3BEV_A (ggB21) and 3P73_A (ggYF1).

(C) Superposed model structures of *mdUT4*, *5* and *8* with the *B21* template shows the antigen-binding groove is open, but possibly short. Filled sphere view shows the α -helices and ribbons show the β -sheets of the peptide-binding platform on the modeled protein structures. The residues indicated with arrows in Figure 5A cause the binding grooves to be short or narrow (e.g. *UT4*: the distance between Pro81 C γ to Tyr144 OH is 3.0 \AA ; *UT5*: the distance between Pro81 C β to Tyr144 OH is 2.9 \AA , and a close hydrophobic contact between $^{64}\text{LTQW}_{67}$ and $^{161}\text{MNL}Y_{154}$; *UT8*: the distance between Phe75 C ϵ to Phe138 C ζ is 2.9 \AA).

the top 5 templates for all *UT*s examined. The backbone structural alignment of *UT4* with 3BEV and 3P73²², the top 2 structural analogs for *UT4* and *UT8*, are shown in Figure 5B. The peptide-binding grooves of *UT4*, 5 and 8 are shown in Figure 5C.

Discussion

MHC class I molecules have been historically defined by their function. The classical MHC class I typically presents peptide fragments derived from antigens to CD8⁺ cytotoxic T lymphocytes. This particular function is ubiquitous across the jawed vertebrates and is likely the primordial function of the class I protein. However it is clear that members of the MHC class I family have evolved to perform other functions, often in lineage specific ways. Therefore, a more appropriate definition of an MHC class I molecule is its unique structure which is a heterodimer of an α -chain paired with β 2-microglobulin. The MHC class I α -chain is composed of three extracellular domains. The α_3 domain is an immunoglobulin domain, a protein fold that predates the origin of jawed vertebrates in evolution. The origins of the α_1 and α_2 domains that make up the antigen-binding groove are more enigmatic and appear unique to the MHC molecules. Searching the genomes of jawless vertebrates and invertebrates failed to uncover genes encoding α_1 - and α_2 -like domains, shedding no light on their evolutionary origin.

The diversity of functions that MHC class I molecules have evolved to perform demonstrate the plasticity of this protein structure. For example, FcRN, which functions as an IgG receptor in mammals, does not bind the Fc region using the antigen-binding groove. Rather that groove is fairly closed and the IgG binds to a combination of the outer face of the α_2 and β 2-microglobulin domains²³. Such functional plasticity of a protein structure leads to the question of what other roles these molecules may have evolved to perform and how divergent they may have become. The results presented here

demonstrate that highly divergent genes, based on nucleotide sequence can encode proteins that fold to produce the MHC class I α -chain structure. This is not to say that the *UT* genes are a product of convergent evolution. Indeed, the phylogenetic analyses place them squarely within the extended MHC class I family. The phylogenetic position of these genes, close to *CD1* and *PROCR*, suggests they are non-classical MHC class I genes, but diversity and expression also need to be assessed.

The presence of the *UT* family of MHC class I genes in both marsupials and monotremes is consistent with their being ancient and present in the last common ancestor of all living mammals. The marsupials and eutherians (placental mammals) most recently shared a common ancestor approximately 165 million years ago²⁴. It appears that after the divergence of these two lineages the *UT* family was lost in the eutherians, likely prior to the radiation of the modern eutherians. Without knowing the function of *UT* genes it is difficult to speculate on why they were dispensable in the eutherians. However this is not the first case where mammal specific immune system genes have been lost in the eutherians. Both marsupials and monotremes have orthologues of a uniquely mammalian T cell receptor called TCR μ , however this locus has been lost in the eutherian lineage^{25,26}. Given the classical role of MHC class I molecules interacting with TCR it is an intriguing possibility that there is a functional connection between the UT molecules and TCR μ , whereby UT present antigen to TCR μ^+ T cells. Hence the loss of one may have resulted in the loss of the other in eutherians. While possible this would not be consistent with current models of how TCR μ chains interact with antigen in an MHC independent manner²⁷. Similar to *UT* loci, the TCR μ cluster is located in a region of the mammalian

genomes that have a break in synteny between marsupials and monotremes²⁸. It may be these gene families were independently lost due to being in regions of the genome subject to instability or rearrangement.

Other working hypotheses on the function of UT molecules are based on models predicting the structure of the region corresponding to an antigen-binding groove. Structurally, the UT proteins are most similar to the chicken B21 MHC class I molecule (3BEV), which binds peptide promiscuously²¹. The presence of some hydrophobic residues in the α -helices may make the effective binding size short or narrow. This may suggest the UTs present small peptide fragments, but is also consistent with a structure where the space between the α_1 and α_2 domains is relatively closed or alternatively, UT molecules may be involved in presenting hydrophobic antigens such as lipids. Marsupials have a homologue of the CD1 molecule that is normally involved in the presentation of glycolipids and lipoprotein antigens²⁹. However, the marsupial gene is single copy and not orthologous to any of the known *CD1a*, *b*, *c*, *d*, or *e* genes found in eutherians³⁰. Furthermore, in the opossum *M. domestica* *CD1* is a pseudogene³⁰. It is possible that there has been less pressure to retain or diversify the *CD1* family in marsupials due to some functional overlap with the *UT* genes.

The region of chromosome 1 containing the *UT* cluster does not correspond to one of the four MHC paralogous regions. These paralogous regions are the remnant of the two rounds of whole genome duplication that occurred during vertebrate evolution³¹. In humans these regions are located on chromosomes 1, 6, 9, and 19, with chromosome 6

containing the *bona fide* MHC region. In the opossum they are located on chromosomes 1, 2, and 3, with two paralogous regions on chromosome 2, one being the MHC proper³². The paralogous region on opossum chromosome 1 corresponds to human chromosome 9 and is syntenic to, but not identical to, the opossum *UT* region. Therefore, the extant *UTs* are the product of the novel expansion of diverging MHC class I genes in the marsupials and monotremes and likely originate from the duplication of an MHC class I gene in the ancestral mammal.

Conclusion

Using a novel, boutique method to search the annotated proteins and genomes of a selection of species spanning vertebrate life for MHC class I genes with high sensitivity, we identified a new class I gene family, the *UTs*. *UT* family members are encoded in gene clusters on chromosome 1 of the opossum, tammar wallaby and Tasmanian devil genomes, and are present but have not been mapped in platypus. The region is located in a synteny break between marsupial and the human genome. Homology modeling suggests *UT* genes have an open but short antigen-presenting groove, raising the possibility that they may present peptide epitopes or non-peptide fragments.

Abstract

Recently a new family of Major Histocompatibility Class I genes was discovered in marsupial and monotreme mammals. These loci were designated the *UT* genes. Seventeen *UT* loci were identified as a tandem array on chromosome 1 of a model marsupial species, the gray short-tailed opossum *Monodelphis domestica*. Of these 17 genes, 12 are transcribed, with most having restricted tissue distribution. Tissues where *ModoUT* genes were most frequently found are the thymus and skin. The *ModoUT* genes have limited polymorphism and little evidence of positive selection. One of the loci, *ModoUT8*, was chosen for further analysis due to its conservation amongst marsupials and generic characteristics. *ModoUT8* transcription is limited to developing $\alpha\beta$ thymocytes, while being absent from mature peripheral $\alpha\beta$ T cells in lymphoid tissues. The overall characteristics and features of *ModoUT* genes including low polymorphism and limited distribution make it likely that the molecules encoded by *ModoUT* genes perform a function other than antigen presentation.

Introduction

The Major Histocompatibility Complex (MHC) class I gene family encodes cell surface proteins that share a unique, well-conserved structure. The typical MHC class I molecule is a heterodimer of an α chain paired with $\beta 2$ -microglobulin [1]. The α chain contains three extracellular domains ($\alpha 1$, $\alpha 2$, and $\alpha 3$), along with a transmembrane domain and a cytoplasmic tail [2]. The $\alpha 1$ and $\alpha 2$ domains form a structure unique to MHC class I proteins by combining to form a groove comprised of β -sheets with two α helices [3]. The $\alpha 3$ domain is an immunoglobulin superfamily type domain. So far, genes encoding MHC class I α chains have only been found in the gnathostomes [4].

In spite of the conserved domains, molecules sharing the MHC class I structure perform a diverse set of functions. The initial role uncovered for MHC class I proteins was in the presentation of antigenic peptides to cytotoxic, CD8 $^+$ T cells [5]. Antigenic peptides derived from proteolysis of self or pathogen derived proteins can be bound in the groove created by the $\alpha 1$ and $\alpha 2$ domains and "presented" to CD8 $^+$ T cells by forming a ligand for the T cell receptor (TCR) [6]. Because this was the first role discovered for MHC class I molecules it is usually termed their "classical" role. Peptide presentation is the most ubiquitous role for MHC class I molecules in gnathostomes and is likely their ancestral function [7]. MHC Class I molecules involved in peptide presentation, such as human HLA-A and -B, are usually highly polymorphic and ubiquitously expressed [8].

Some MHC Class I molecules have evolved to present non-peptide antigens to T cells. One example is the CD1 molecules that present glycolipids to T cells [9]. Even more

wide ranging roles for MHC class I molecules have evolved such as the neonatal Fc receptor (FcRn) that binds and transports IgG. FcRn transports IgG across the placenta in some mammals, and is expressed in the mammary tissue in others for depositing IgG in milk [10]. Although maintaining the traditional MHC class I domain structure, FcRn is unable to bind peptides and the groove formed by the $\alpha 1$ and $\alpha 2$ domains is occluded and does play a role in binding IgG [11, 12]. Other examples of divergent MHC class I roles include the HFE molecule that associates with the transferrin receptor, reducing the receptor's affinity to load transferrin molecules bound with iron, and the murine M10 molecule that binds and serves as a chaperone for vomeronasal organ olfactory receptors [13, 14]. In contrast to MHC class I genes encoding molecules that present peptides, those encoding "non-classical" molecules such as M10, FcRn, and CD1 are typically less polymorphic and often have tissue specific patterns of expression.

The gray short-tailed opossum, *Monodelphis domestica*, is among the more established model marsupial species, and the first to have a sequenced genome [15, 16]. Many of the MHC class I genes in the genome of *M. domestica* have been annotated [17-22]. Using traditional homology based *in silico* search methods, eleven genes encoding the class I α chain have been uncovered in the *M. domestica* MHC region, along with two clear MHC class I pseudogenes [17, 19, 20, 23]. There are three presumed peptide-presenting MHC class I genes in *M. domestica*; *ModoUA1*, *UA3*, and *UA4*. *ModoUA1* and *UA3* display many traits common to peptide presenting MHC genes, such as ubiquitous expression throughout tissues and high levels of polymorphism, *ModoUA4* has lower levels of polymorphism but remains ubiquitously expressed [19, 23]. Many of the other known

opossum MHC class I genes encode molecules likely to have non-classical functions. *ModoUG*, for example, can be expressed in three different alternatively spliced mRNA forms [20]. In these forms, a short cytoplasmic tail has been found that does not have traditional phosphorylation sites. *ModoUJ* and *UM* also have several alternative mRNA isoforms, including one possible *ModoUJ* soluble isoform [17]. A majority of the opossum class I genes had limited polymorphism consistent with possible non-classical function.

The functional plasticity of the MHC class I structure makes these molecules good models to study the evolutionary relationship between structure and function. The availability of whole genome sequences from a variety of gnathostome lineages provides the information needed to discover new MHC class I genes and potentially new roles for these molecules. Recently, a new family of MHC class I loci called *UT* was found, and appears to be restricted to marsupials and monotremes [24]. The phylogenetic distribution is consistent with having emerged early in mammalian evolution and subsequently lost in the eutherian lineage. A more in-depth analysis of these genes revealed that some were transcribed in immune tissues of the opossum, tammar wallaby, brushtail possum and Tasmanian devil. The goal of this study was to characterize the *UT* genes in opossum, *M. domestica*, further.

Materials and Methods

Tissue Transcription of ModoUT

ModoUT gene transcription was examined using the Illumina generated transcriptome data from of 19 adult *M. dometica* tissues, publically available at OpossumBase (<http://opossumbase.org>). Tissues included kidney, liver, lung, spleen, colon, skin (ear pinna), intestine, stomach, diaphragm, heart, skeletal muscle, tongue, pancreas, thyroid, brain, eye, adipose, testes, and ovary. In addition, a thymus transcriptome was generated using the Roche 454 sequencing platform. BLAST searches of the databases were performed using the predicted nucleotide sequence of exons 2, 3 and 4 that encode the regions corresponding to the $\alpha 1$, $\alpha 2$, and $\alpha 3$ domains from all *ModoUT* genes identified previously [24]. Sequences in the assembled RNA databases that were over 180 bp and 98% or greater nucleotide sequence identity to a known *UT* gene were scored as transcripts of that gene. In order to verify the accuracy of the transcription sites, any transcripts of *ModoUT* genes uncovered using BLAST search were aligned to all the previously identified predicted sequences. Alignments were then assembled into a phylogeny using MEGA 5.0 and a maximum-likelihood tree was generated for basic identification of transcripts to a specific *ModoUT* in order to avoid incorrect sites of transcription due to sequence identity between the *ModoUT* genes [25].

Isolation of full-length coding sequences

Two methods were used to isolate full-length coding sequences of transcribed *ModoUT* loci: Rapid Amplification of cDNA Ends (RACE) polymerase chain reactions (PCRs)

and assembly using available transcriptome sequence databases. The latter included OpossumBase and the opossum thymus 454 transcriptome. This approach allowed for assembly of a *ModoUT* gene in the absence of obtaining the full 3' end via RACE PCR, or to assemble without PCR amplification and sequencing. Full-length coding sequences for *ModoUT4, 5, 6, and 8* were isolated entirely using the RACE method, while *ModoUT9* and *10* were obtained using a combination of sequences generated by RACE and from the transcriptome databases. RACE PCR were performed using the SMARTer RACE cDNA Amplification Kit (Clontech, Mountain View, CA) with Advantage HF-2 high-fidelity Taq polymerase (Clontech, Mountain View, CA) following the manufacturer's recommended protocol. PCR parameters for all primers were 94°C for 30 seconds, followed by 72° C for 3 minutes, repeated 5 times, then 94°C for 30 seconds, 70° C for 30 seconds, and 72° C for 3 minutes repeated 5 times, followed by 94°C for 30 seconds, 68° C for 30 seconds, and 72° C for 3 minutes, repeated 25 times. If no PCR products were visible on an agarose gel, a secondary PCR amplification was done by an additional 5 cycles at 94°C for 30 seconds, 68° C for 30 seconds, and 72° C for 3 minutes. The primers were designed within either the predicted exon 2 to amplify the 5' end or exon 3 to amplify the 3' ends [24]. If it was not possible to design both 5' and 3' primers according to guidelines of the amplification kit, the same sequence was used for the forward and reverse primers. The PCRs were performed on cDNA made from total thymus RNA extracted from a 6-week-old male *M. domestica*. The 5' and 3' RACE PCR was performed in a single step for *ModoUT4, 5, 9, and 10* with specific primers (Table 1), or as a nested PCR for *ModoUT6* and *ModoUT8* using additional nested specific primers. PCR products were cloned, and sequenced using BigDye Terminator v3.1 Cycle

Sequencing Kit (Invitrogen, Grand Island, NY). Any sequences obtained that did not span the full length of the 3' end were supplemented using 454 transcripts. The nucleotide sequences from the 5' and 3' ends were then aligned against the MonDom5 opossum genome assembly (GenBank accession number AAFR03000000) to identify the exons present in each sequence [15].

Full-length coding sequences for *ModoUT2, 3, 15, 16, and 17* were determined using transcripts from tissues transcribed from OpossumBase or from thymus 454. Transcribed *ModoUT* loci were assembled and aligned against the opossum genome in Sequencher 5.0 (Gene Codes, Ann Arbor, MI). In some instances, full-length genes could be found from a single transcript from the transcriptome, while others required multiple transcripts to generate a contig that covered all of the exons. Accession numbers for full-length RNAs encoding the class I α chains of *ModoUT2, 3, 4, 5, 6, 8, 9, 10, 15, 16, and 17* including alternative mRNA splice variants are KP125495-KP125507.

Polymorphism Analysis

Polymorphism was determined only for the *ModoUT* genes that are transcribed in the thymus. Genomic DNA was isolated from *M. domestica* liver or spleen tissue that was provided by the Southwest Foundation for Biomedical Research (SFBR, San Antonio, TX) and the Museum of Southwestern Biology (MSB), University of New Mexico [17, 20]. DNA was extracted using a standard phenol/chloroform extraction protocol. The SFBR tissues were from captive-bred animals of Brazilian populations 1 and 2 [26]. Tissues from the MSB were from wild-caught *M. domestica* collected from five different

sites in Bolivia. These samples and their origins have been published previously [17, 20]. PCR products using primers listed in Table 1 were amplified using the Advantage HF 2 PCR kit (Clontech, Mountain View, CA), with the following parameters for all primers: 94°C for 1 minute, 33 cycles of 94°C 30 seconds and 62°C for 4 minutes, followed by a 7 minute extension at 68°C.

For loci where intron 2 was less than 400 bp (*ModoUT2, UT3, and UT5*), exon 2, intron 2, and exon 3 were amplified as a single product with primers placed at the start of exon 2 and end of exon 3. For loci where intron 2 was greater between 800 and 1400 bp (*ModoUT4, UT6, UT7, UT8, and UT15*), exon 2, intron 2, and exon 3 were amplified as two overlapping fragments with primers nested within intron 2. Three loci (*ModoUT9, UT10, and UT17* had intron 2 greater than 3Kb and exons 2 and 3 were amplified separately.

PCR products were cloned for sequencing using the TOPO TA cloning kit (Life Technologies, Grand Island, NY). A minimum of five clones per individual per locus were isolated and sequenced using the illustra TempliPhi kit (GE Life Sciences, Pittsburgh, PA) and BigDye Terminator v3.1 Cycle Sequencing Kit (Life Technologies, Grand Island, NY), respectively. Sequences were analyzed and edited using Sequencher 5.0 (Gene Codes, Ann Arbor, MI) and BioEdit [27]. Accession numbers for novel allele sequences reported are: *ModoUT2*, KP174147-KP174156; *ModoUT3*, KP221763-KP221785; *ModoUT4*, KP174157-KP174166; *ModoUT5*, KP221786-KP221799; *ModoUT6*, KP174167-KP174180; *ModoUT7*, KP221744-KP221762; *ModoUT8*,

Evidence of selection on the ModoUT loci was determined using a maximum-likelihood estimation of the dN/dS ratio using the CODEML module of the Phylogenetic Analysis by Maximum Likelihood (PAML) package [28]. The regions encoding the $\alpha 1$ and $\alpha 2$ domains of all *ModoUT* alleles obtained from the polymorphism study were analyzed for evidence of positive selection by looking at non-synonymous/synonymous substitution ratios. This was done using an initial Maximum Likelihood phylogenetic tree of sequences which was then analyzed with four site-specific models, M1a – nearly neutral, M2a – positive selection, M7 - β , and M8 - β , and ω , in CODEML. A Bayes Empirical Bayes analysis was performed on each model to infer the location of the codons under selection and the ω values for each of these sites [29].

Fluorescent In-situ Hybridization (FISH)

Thymus and spleen tissue from six-week old opossums were collected for cell suspensions. The tissues were manually separated into single cell suspensions that were washed and resuspended in RPMI 1640 media with HEPES (Sigma-Aldrich, St. Louis, MO). Erythrocytes were removed by Ficoll gradient centrifugation. Lymphocytes were resuspended in 1X PBS (Sigma-Aldrich, St. Louis, MO) and counted on a hemocytometer. Cells at a concentration of 2×10^6 /ml were deposited on non-coated Shandon Cytoslides using a Cytospin (Thermo-Fisher Scientific, Waltham, MA) and used

immediately or stored frozen at -80°C. Custom Stellaris FISH probes (Biosearch Technologies, Petaluma, CA) were designed using the constant regions of T cell receptors (TCRs) and untranslated region (UTRs) for T cell identification. The slides were probed and hybridized with a set of 48 singly labeled oligonucleotide probes, each 20 nucleotides in length that were designed from the full-length sequences of *ModoUT8*. A Quasar® 570 fluorophore was used for *ModoUT8* and a Quasar® 670 fluorophore for TCR α or TCR β , following the Stellaris FISH protocol for frozen tissue (Stellaris, Biosearch Technologies, Petaluma, CA)[30]. Slides were then stained using wash buffer consisting of 5 ng/mL of DAPI dilactate (Sigma-Aldrich, St. Louis, MO) and mounted using Vectrashield® Mounting Medium (Vector Labs, Burlingame, CA). Slides were imaged on a Nikon Ti Eclipse inverted fluorescent microscope using the 100x oil immersion lens. Z-stacks images of each fluorophores were merged together and edited using NIS-Elements Imaging Software (Nikon Instruments, Melville, NY).

Results

Analysis of ModoUT Transcription

To investigate transcription of *ModoUT* genes in a variety of tissues, public transcriptome data from the OpossumBase public database was downloaded and searched. This database contains transcriptome profiles of 19 different tissue types. Since OpossumBase lacked information on the thymus, a good candidate tissue for immune gene expression, a separate thymus transcriptome database was generated using the Roche 454 platform.

The initial analyses focused on the diversity of *ModoUT* loci transcribed in each tissue type. Of the 17 *ModoUT* genes, the most common sites for transcription are the thymus and the skin (Figure 1). Twelve out of 17 *UT* loci are transcribed in the opossum thymus, and eleven out of 17 are transcribed in the skin. For all other adult tissues, the colon and thyroid contained the greatest variety of transcribed *ModoUT* genes with four each. In contrast, the testes, eye, lung, diaphragm, skeletal muscle, pancreas, stomach, and heart each only transcribe a single *ModoUT* locus. Brain and kidney were the only adult tissues investigated that lacked any *ModoUT* transcripts.

Next the breadth of transcription of each *ModoUT* locus among the various tissues was examined. Most of the *ModoUT* genes demonstrated restricted tissue transcription patterns. *ModoUT1*, *11*, and *14* were each found transcribed in only a single tissue, the testes, liver, and skin, respectively. Similarly, *ModoUT2*, *6*, and *16* were only transcribed

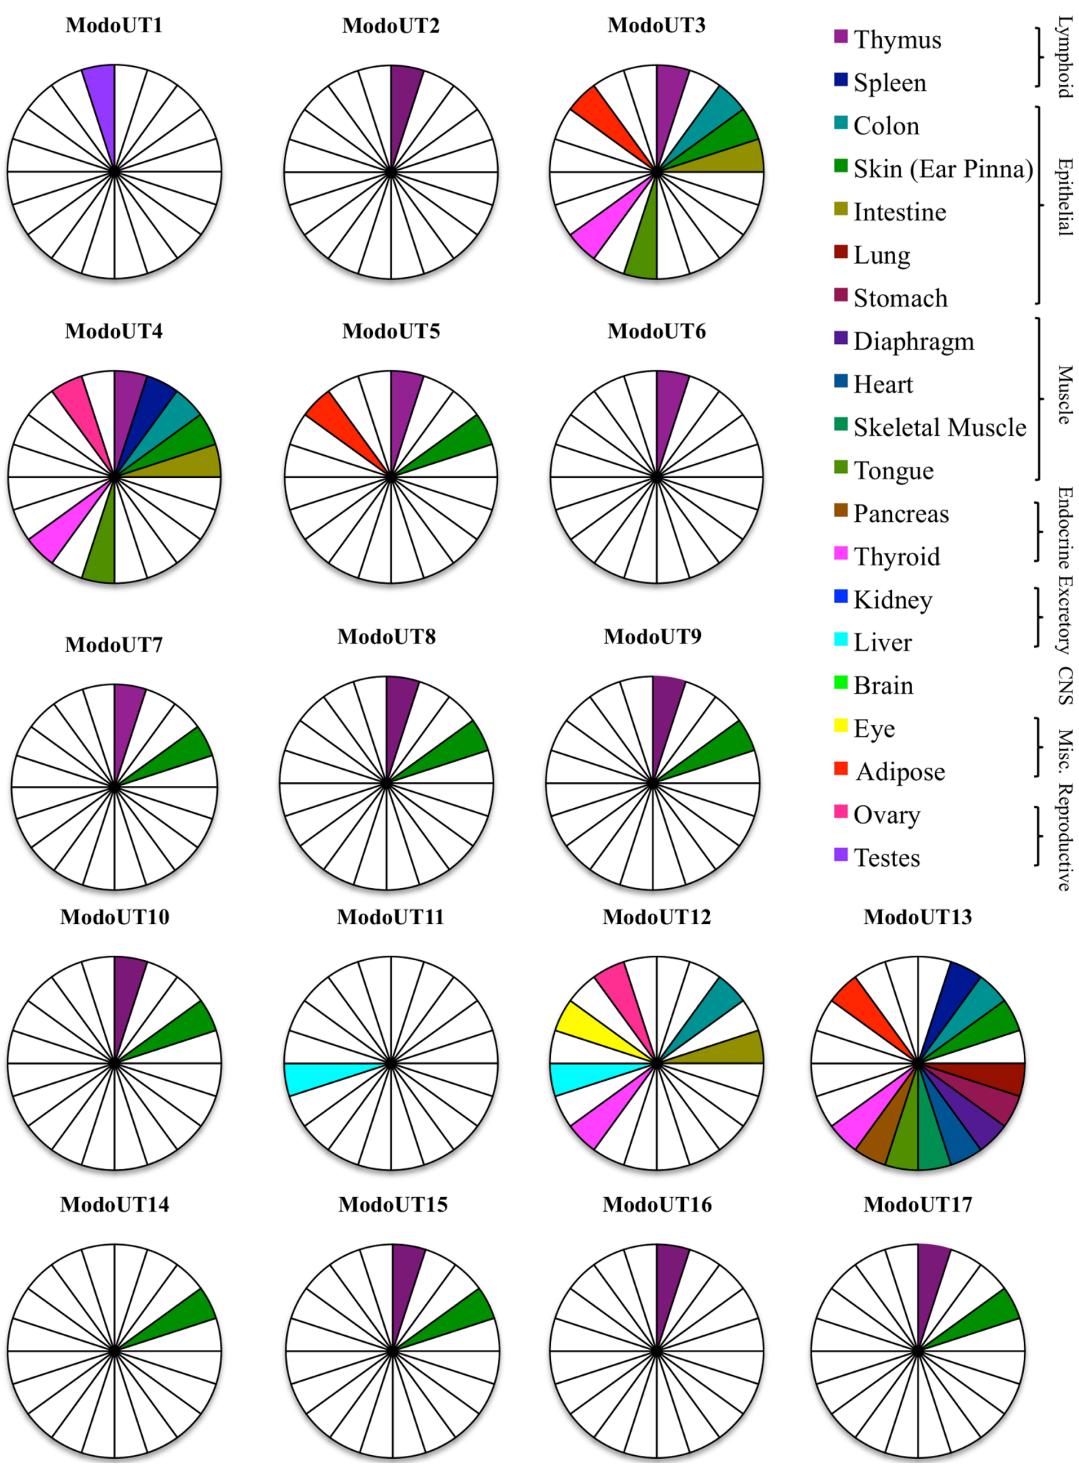

Figure 1: Differential expression of *ModoUT* genes across 20 different tissue types. Filled pie wedges represent the detection of a *ModoUT* transcript in either a Roche 454 dataset or from Illumina sequences found at www.OpossumBase.org with a 99% sequence identity at 180 or more base pairs. Tissue types examined included lymphoid, epithelial, muscle, endocrine, excretory, reproductive, CNS, and miscellaneous that included the eye and adipose.

in the thymus. In contrast, *ModoUT13* was found most broadly transcribed in 16 different tissues (Figure 1). Of the 17 known *UT* loci in the opossum genome, only *ModoUT7* is thought to be a pseudogene due to an in-frame stop codon near the beginning of exon 3. In spite of being a putative pseudogene, it is transcribed in both thymus and skin.

ModoUT Gene Organization

To determine the complete structure of *ModoUT* genes, a combination of RACE PCR and the sequence from the Illumina and Roche 454 databases was utilized. Sequences from all sources were aligned to the opossum whole genome and contigs representing full-length mRNA sequences for the twelve *ModoUT* genes transcribed in the thymus, allowing for the determination of gene boundaries and alternative splice variants (Figure 2). The size range of the full-length *ModoUT* genes ranged from 5,453bp (*ModoUT6*) to 16,053bp (*ModoUT9*). *ModoUT2, 4, 6, and 16* have similar lengths (5,453-7,484bp) while *ModoUT3, 5, 8, 9, 10, 15, and 17* are larger in size from 9,672bp to 16,053. As is typical of MHC class I loci, the number of exons per locus varied between five and seven (Figure 2). The variation in gene size does not correlate with phylogenetic relationship based on coding sequence, as highly related groups like *UT3, UT4, UT5, UT6, and UT7* range from 5,453bp to 12,219bp [24].

Previous work in *M. domestica* has revealed that a majority of the MHC class I loci within the MHC region were transcribed to generate alternative splice variants with open reading frames (ORFs) [17, 20]. Only *ModoUT2* and *UT16* generated variants with

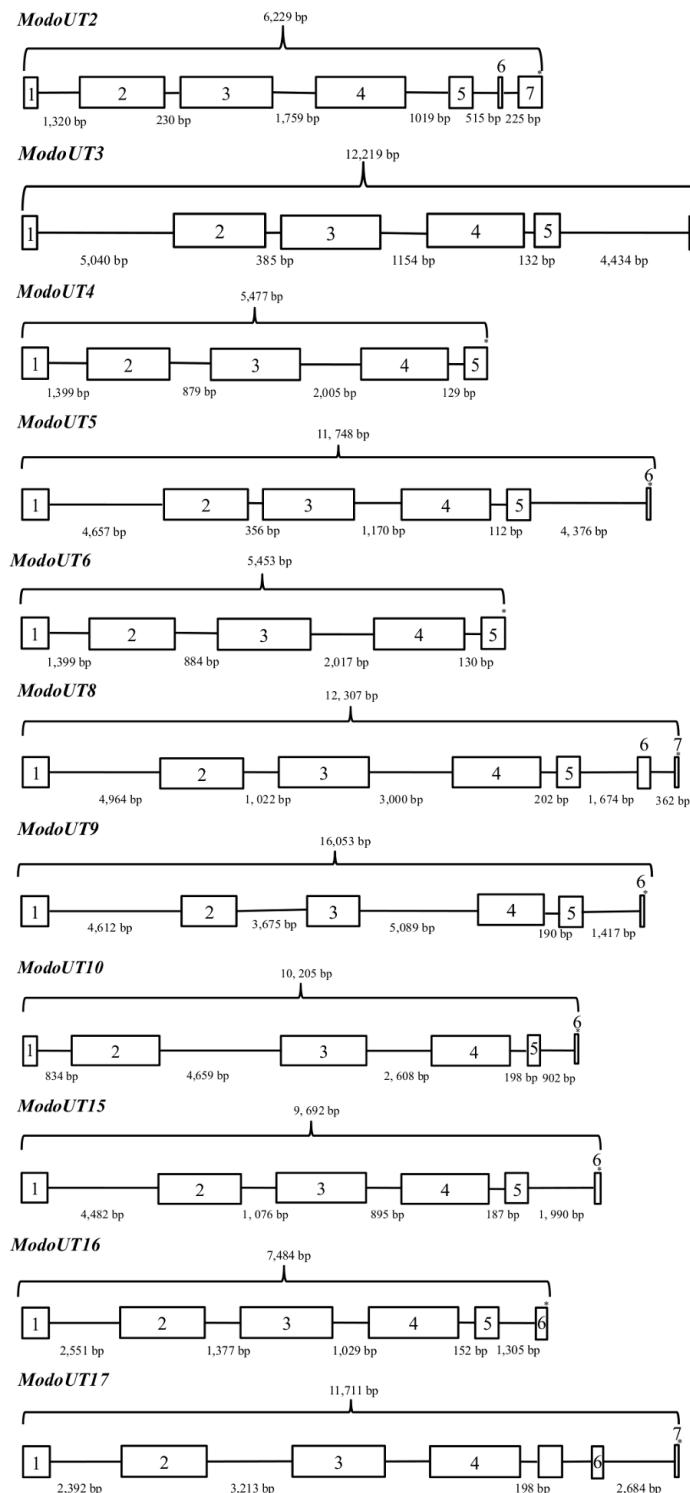

Figure 2: Gene organization and exon composition of *ModoUT2*, *UT3*, *UT4*, *UT5*, *UT6*, *UT8*, *UT9*, *UT10*, *UT15*, *UT16*, and *UT17* mRNAs. Asterisks indicate relative location of stop codons.

ORFs other than the full length (Figure 3). The *ModoUT2* splice variant would encode a truncated $\alpha 3$ domain due to using an alternative splice site within exon 4, whereas the *ModoUT16* variant would be translated without an $\alpha 3$ domain due to splicing out exon 4 altogether.

Polymorphism and Evidence of Positive Selection

Levels of polymorphism in the *ModoUT* genes were investigated using both captive bred animals from Brazilian stock as well as wild caught Bolivian animals. MHC class I genes typically have the highest level of polymorphism in exons 2 and 3, which encode the $\alpha 1$ and $\alpha 2$ domains, respectively. Genomic DNA was amplified for exon 2, intron 2, and exon 3 from eight captive bred Brazilian *M. domestica* and 19 wild caught individuals from Bolivia. Alleles were counted for all nucleotide variants, whether in coding or non-coding regions of the gene. The number of nucleotide alleles for each of the *UT*'s varied substantially in comparison with previous polymorphism studies on MHC Class I genes in *M. domestica*, as they had consistently greater numbers of genomic alleles found [17, 20] The lowest number of alleles were found in *ModoUT9* and *ModoUT10*, with three and four alleles respectively (Supplemental Table 1). *ModoUT3* and *ModoUT7* had the greatest number of alleles, with 23 and 19, but much of the variation was found in the intron. No individual was found with more than two alleles at any locus lending validity to the genotyping. The majority of the alleles for each locus were unique to either the Brazilian or Bolivian populations, with the exception of one

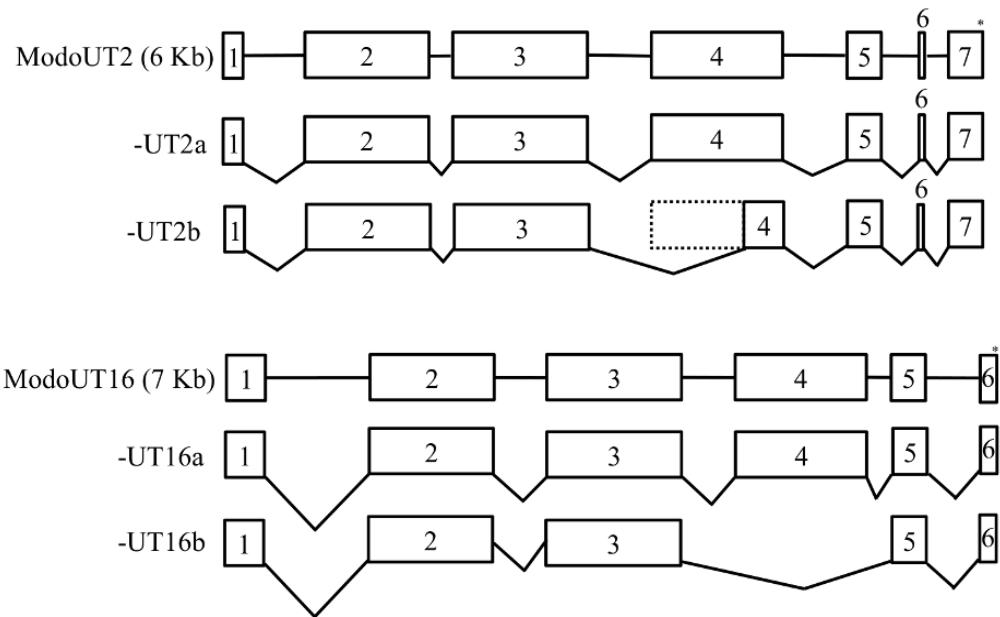

Figure 3: *ModoUT2* and *ModoUT16* are transcribed into alternatively spliced isoforms that differ with the loss or truncation of exon 4. Asterisks indicate relative location of stop codons.

allele in both *ModoUT7* and *ModoUT10* that were found in both populations. When examining alleles at the protein level, the numbers dropped 3 to 4-fold, indicating that a majority of the nucleotide diversity at each of the loci was found in intron 2 or were synonymous mutations in exons. The number of protein alleles ranged between one and six for exons 2 and 3, with an average of 3.4 alleles for exon 2 and three for exon 3. Most of the polymorphism found in *ModoUT* genes was limited to one to five amino acid changes between alleles. The exception to this is *ModoUT5*. While some of the alleles found in *ModoUT5* do not differ substantially to the sequence found in the reference genome, ten of the alleles contain an additional insertion of three nucleotides in the intron, and another allele, *ModoUT5.08*, has a 26 base pair long insertion in the intron (not shown). No insertions were seen in the exons of the *ModoUT5* alleles, but substantial polymorphism between the alleles was seen. A large 23 base pair insertion and two base pair insertion were also seen in intron 2 of two *ModoUT7* alleles. Premature stop codons were found in one allele of *ModoUT5* in exon 2 and two alleles in exon 3, as well as all alleles of exon 3 in *ModoUT7* and one allele of *ModoUT17*.

Heterozygosity was common across the UT genes and most frequently seen in the wild-caught Bolivian individuals. Of the captive Brazilian animals, those from Population 2 were homozygous in two-thirds of the ModoUT genes analyzed for polymorphism. The high percentage of homozygosity in captive-bred is likely the result of some partial inbreeding [26]. Only four and six animals respectively were found to be homozygous at *ModoUT3* and *ModoUT5*, while *ModoUT9*, *ModoUT10*, and *ModoUT15* had twenty or more animals that were homogyzous. For most of the *ModoUT* genes, approximately half

of the animals were heterozygous. Animals collected from the Porvenir region of Bolivia displayed the greatest amount of heterozygosity, with the highest numbers in *ModoUT3*, *ModoUT5*, *ModoUT6*, *ModoUT7*, and *ModoUT8*.

Overall, there is amino acid conservation across the different *ModoUT* genes. The conservation can be seen across the $\alpha 1$ domain, at a leucine in position 54 and glutamic acid in position 71 are shared across all alleles (Supplemental Figure 1). Similar levels of conservation are seen across all alleles in the $\alpha 2$ domain. A shared threonine and glutamine are seen at positions 7 and 9, a cysteine at position 14, a glycine at position 32, and a proline at position 50. (Supplemental Figure 2) A comparison of the number of hydrophobic amino acids using all the *ModoUT* alleles to CD1 and other MHC class I genes was made. Analysis reveals nearly double the number of hydrophobic amino acids across the *ModoUT* $\alpha 1$ and $\alpha 2$ domains with 41 sites, when compared to classical MHC class I from both eutherians and marsupials, which had approximately 21. The number of hydrophobic sites in *ModoUT* genes was comparable to those of CD1 from both eutherians and marsupials.

Positive selection was inferred for the $\alpha 1$ and $\alpha 2$ domains of all *ModoUT* alleles individually with the Pairwise Analysis of Maximum Likelihood method to determine which sites were under selection [28]. Only *ModoUT5* had more than a single site with evidence of being under positive selection, and these were all in the $\alpha 1$ domain (Figure 4). *ModoUT6* had a single site in the $\alpha 2$ domain that appeared to be under selection (not

ModoUT5

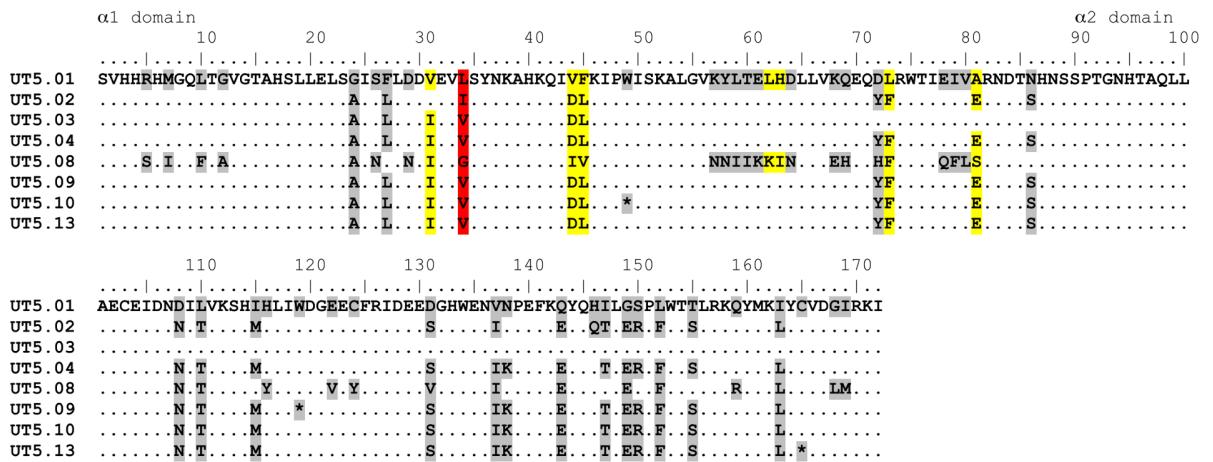

Figure 4: Sites of positive selection in the α_1 and α_2 domains of *ModoUT5*. Gray shading represents sites of polymorphism that are not significant, yellow shading has significance at $p < 0.05$, and red shading is significant at $p < 0.005$. Of 52 sites of non-synonymous substitutions across both the α_1 and α_2 domains, only one was highly significant, and seven were significant.

shown). All other *ModoUT* loci revealed no evidence of positive selection acting on their evolution.

Expression of ModoUT8 in thymic but not peripheral αβ T cells

ModoUT8 was chosen as a model *UT* for further expression analysis as it was the first *ModoUT* uncovered, it demonstrates a limited transcription pattern like most opossum *UT* genes, it has clear orthologues in other marsupial species, and has the greatest structural similarity of all *ModoUT* molecules to the chicken MHC class I protein [24]. To detect mRNA transcription of *ModoUT8* in specific cell lineages, fluorescent in-situ hybridization (FISH) was performed utilizing opossum thymus and spleen. *ModoUT8* and T cell receptor β chain (TCRβ) mRNA were imaged simultaneously, allowing the visualization of the location of each of the *ModoUT8* or TCR mRNA molecules within a cell. In the thymus, *ModoUT8* co-localized with TCRβ (Figure 5) and TCRα (not shown), demonstrating that it is transcribed in αβ thymocytes. Consistent with the transcriptome databases (Figure 1) and RT-PCR experiments (not shown), *ModoUT8* transcripts were not detected in mature, splenic αβ T cells (Figure 5).

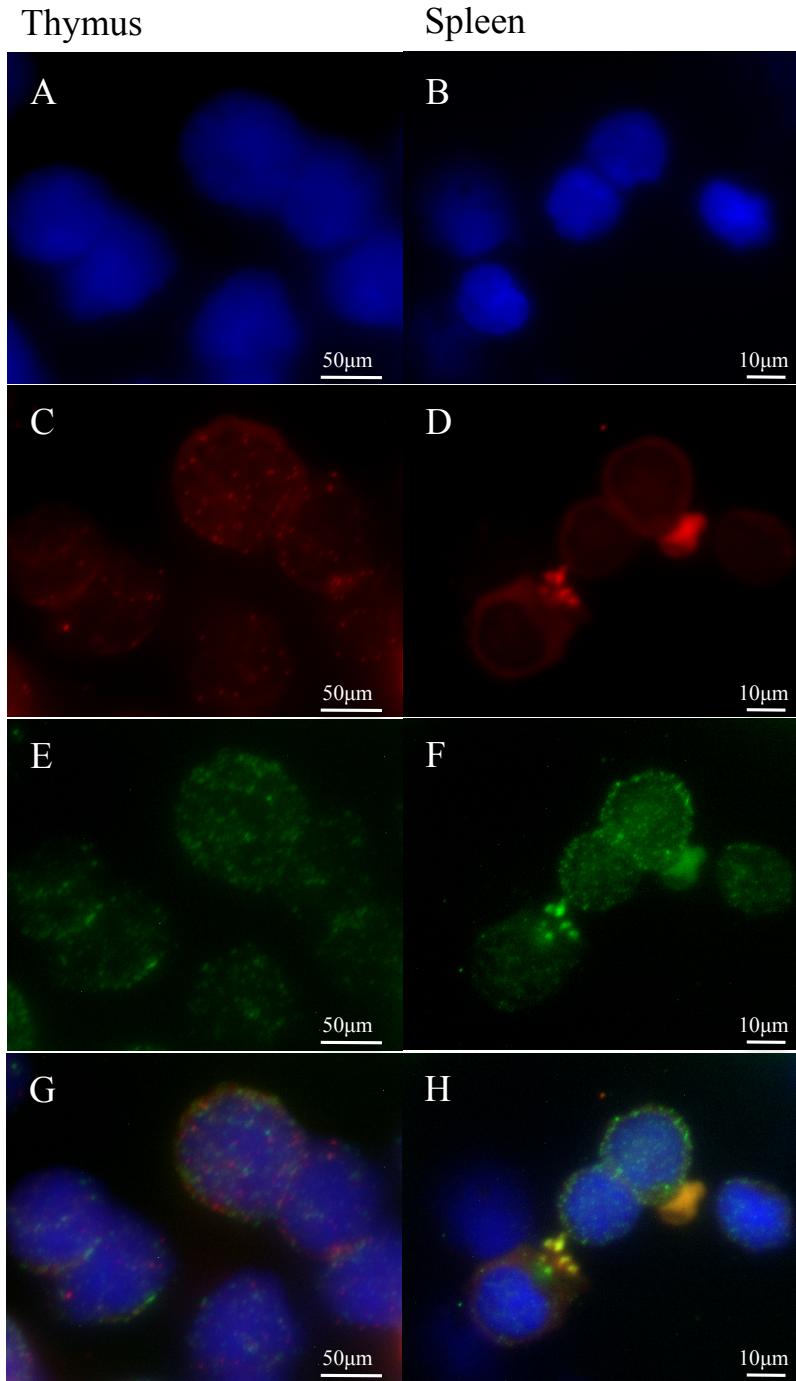

Figure 5: Fluorescent *in-situ* hybridizations of *ModoUT8* with TCR α or TCR β in the spleen and thymus. **A&B:** DAPI nuclear staining in the spleen and thymus allows visualization of lymphocytes. **C&D:** *ModoUT8* probes hybridizes to the thymus but not the spleen. Red points indicate evidence of transcription in the cell. Large areas of fluorescence are background and associated with binding of probes to dead cells. **E&F:** TCR β probes bind to cells in both the spleen and thymus. **G&H:** Merged images of DAPI, *ModoUT8*, and TCR β give no evidence of *ModoUT8* transcription in the spleen, while *ModoUT8* co-localized with TCR β in the thymus.

Discussion

An unexpected result to emerge from the analyses of marsupial and monotreme genomes was the presence of immune related genes that are absent from eutherian genomes. One example is the *UT* family of MHC class I genes [24]. Another was a non-conventional TCR locus, *TCRμ* [31]. Both *UT* and *TCRμ* genes are present in marsupial and monotreme genomes, consistent with their presence in the last common ancestor of all living mammals [24, 32-34]. Neither of these gene families has been found in any eutherian mammal or non-mammalian genome to date, consistent with their being unique to mammals but lost in the eutherians [24, 32]. Why genes such as the *UT* family or *TCRμ* have been lost in the eutherian lineage is a matter of speculation and can only be understood when their function in the species where they are found is determined. Towards this end, this study was convened to further characterize the *UT* family in a model marsupial.

The opossum *UT* family of genes can be generally described as having limited tissue expression, low levels of polymorphism, and little evidence for positive selection. *ModoUT5* is an exception in that it had several sites under selection in the α1 domain. These characteristics are usually indicative of MHC Class I molecules that have non-classical roles. The genes that encode the *ModoUT* molecules do not have the ubiquitous pattern of expression like the polymorphic *ModoUA1* locus in *M. domestica*. *ModoUA1*, along with its nearest related genes *ModoUA3* and *UA4*, is likely involved in peptide presenting functions based on its similarity to classical MHC class I loci. Thirteen of the

ModoUT genes are transcribed in three or less tissue types, indicative of a restricted transcription pattern. It is noteworthy that two of the *ModoUT* genes, *ModoUT12* and *ModoUT13*, have six or more sites of transcription, but do not have transcription in the most common tissue, the thymus. This may indicate that the *ModoUT12* and *ModoU13* loci may be playing a different role than the *UT* loci that are found transcribed in the thymus and skin. The majority of *ModoUT* genes are found in the thymus and skin, and thus may have other roles than those found across more numerous tissues. All *ModoUT* loci do have numerous hydrophobic residues in the binding groove as well as structurally resembling the chicken B21 MHC class I molecules, which binds peptides promiscuously [24]. The hydrophobic residues as well as the possibility of non-specific peptide binding due to structure suggest they may be able to present small peptides within the relatively closed binding groove, or they bind hydrophobic antigens such as lipids. A more specific role for *ModoUT* in the thymus may be for T cell selection and maturation. Alternatively, *ModoUT* genes may also just be ectopically expressed in the thymus for negative selection against self-molecules and not serve in T cell selection.

The role of *ModoUT* in skin is less clear. The high levels of *ModoUT* expression in the skin may be the result of the *UT* molecules playing a role in innate immunity. The skin serves as not only a barrier against many pathogens, but both cells within the skin and secreted molecules can protect against pathogens. Potentially, *ModoUT* molecules may also play a protective role in development. The altricial birth and development of marsupials and monotremes can leave the developing young immunologically immature and susceptible to pathogens. The presence of the *UT* molecules on the surface of the skin

of undeveloped young may help to provide protective benefits in a pathogen-rich environment. Close examination of the other epithelial tissues beyond skin did not find a correlation between epithelial tissues and transcription of *ModoUT*'s. Therefore, the abundance of expression of *ModoUT* genes in the skin is likely not the result of high levels of *ModoUT* transcription of the genes in epithelial cells, but rather, *ModoUT* transcription in skin cells only for potentially serving a protective role after altricial birth.

Except for *ModoUT2* and *UT16*, there was no evidence for alternative splice variants generated by the *ModoUT* loci. This is in contrast to the non-classical MHC class I loci encoded within the opossum MHC where alternative splicing was a common characteristic [17, 20]. Unfortunately, this result provides little insight into the function of the *ModoUT* gene products other than they are likely to be expressed in a form with all three extracellular α -domains and there does not appear to be secreted or soluble forms of the molecules.

Minimal polymorphism and little evidence for positive selection on the *ModoUT* genes follows a similar pattern as other *M. domestica* non-classical MHC class I genes. The lack of polymorphism is consistent with *ModoUT* molecules likely having a function other than peptide presentation. In examination of the *in-situ* hybridizations, *ModoUT8* cannot be found in the spleen, but does co-localize with TCR α and TCR β in the thymus. This suggests that perhaps the mature α/β T cells found in lymphatic tissues like the spleen do not express *ModoUT8*, but *ModoUT8* is transcribed in immature α/β T cells in the thymus, perhaps indicating that it may play a role in T cell maturation.

The sequencing of the $\alpha 1$ and $\alpha 2$ domains of the *UT* genes revealed a high degree of hydrophobic residues, nearly double that of other marsupial and eutherian MHC class I, but comparable to CD1 [24]. This characteristic remained intact with the analysis of additional *UT* alleles. Some instances of polymorphism did occur at hydrophobic sites, but the majority of the hydrophobic sites were highly conserved across all of the *UT* loci. This likely indicates a need for conservation of the hydrophobic sites, potentially serving as invariant sites for binding lipids.

The characterization of the *UT* genes in *M. domestica* contributes new insights into genes that are being uncovered using novel methods, but also provides greater knowledge into the evolution and development of marsupials and their immune system and how they differ from eutherian mammals. Future work done on *ModoUT* genes will possibly allow for the identification of the function of this large family of genes and the immune or non-immune role they may play in marsupials.

Abstract

The gray short-tailed opossum *Monodelphis domestica* is one of the few marsupial species for which a high quality whole genome sequence is available and the Major Histocompatibility Complex (MHC) region has been annotated. Previous analyses revealed only a single locus within the opossum MHC region, designated *Modo-UA1*, with the features expected for encoding a functionally classical class I α -chain. Nine other class I genes found within the MHC are highly divergent and have features usually associated with non-classical roles. The original annotation however was based on an early version of the opossum genome assembly. More recent analyses of allelic variation in individual opossums revealed too many *Modo-UA1* sequences per individual to be accounted for by a single locus found in the genome assembly. Analyses of a later generation assembly, MonDom5, revealed the presence of two additional loci, now designated *Modo-UA3* and *UA4*, in a region that was expanded and more complete than in the earlier assembly. *Modo-UA1*, *UA3* and *UA4* are all transcribed, although *Modo-UA4* transcripts are rarer. *Modo-UA4* is also relatively non-polymorphic. Evidence presented support the accuracy of the later assembly and the existence of three related class I genes in the opossum, making opossums more typical of mammals by having multiple apparent classical MHC class I loci.

Introduction

The Major Histocompatibility Complex (MHC) is among the most gene dense and polymorphic regions of the vertebrate genome (Beck et al. 1999; Gaudieri et al. 2000).

The MHC encodes molecules involved in the processing and presentation of antigens to T cells and has been associated with disease resistance, transplant rejection, and reproductive success (Kumánovics et al. 2003). Classical MHC class I molecules, such as human HLA-A and B, are typically responsible for peptide presentation to cytotoxic CD8⁺ T cells. They are generally polymorphic and ubiquitously expressed on most nucleated cells. Non-classical class I genes, on the other hand, are often less polymorphic, restricted in their tissue expression, and have evolved to perform a variety of roles (Hofstetter et al. 2011).

The study of distantly related species has provided important insight into the evolution of the MHC. Marsupials represent a lineage of mammals that diverged from the eutherians (placental mammals) over 150 million years ago and have provided insights into the evolution of mammalian MHC (Baker et al. 2009; Belov et al 2006, Gouin et al. 2006).

The gray short-tailed opossum (*Monodelphis domestica*) is arguably one of the better-developed model marsupial species and has been useful for comparative immunology and biomedical research (Samollow 2008). *M. domestica* is used as a model for melanoma, developmental biology, spinal cord injury, and genetics of cholesterol regulation (Samollow 2008). Significantly it is one of the few non-eutherian mammals for which a well-annotated whole genome sequence is available (Mikkelsen et al. 2007).

The opossum MHC, a 3.95 Mb region on chromosome 2, is as gene rich and complex as that of mouse and human (Belov et al. 2006). However its organization differs from that of eutherians in that the class I and II genes are interspersed at one end of the MHC, rather than being separated by the class III region (Belov et al. 2006). Eleven class I loci were identified within the opossum MHC region (Belov et al. 2006). One, *Modo-UA1*, appeared to be highly polymorphic and ubiquitously transcribed and likely involved in peptide presentation (Miska and Miller 1998; Gouin et al 2006; Belov et al. 2006; Baker et al. 2009). *Modo-UA1* also appeared to account for all the known MHC class I transcripts known at the time (Miska and Miller 1998). Six of the class I loci (*Modo-UE*, *UI*, *UG*, *UJ*, *UK*, and *UM*) are transcribed but have features of genes encoding molecules with non-classical functions (Baker et al., 2009). *Modo-UF* and *UL* have complete ORF but transcripts have yet to be identified in any tissue tested. A gene designated *Modo-UA2* due to its similarity to *UA1*, along with *Modo-UH*, are pseudogenes due to incomplete open reading frames (Belov et al., 2006). Two other loci, *Modo-UB* and *UC*, appear related to *Modo-UA1* but are located outside MHC (Miska et al. 2004, Belov et al 2006).

The number of classical MHC class I loci can vary between species and vertebrate lineages. Chickens and *Xenopus*, for example, only have a single classical class I locus each (Flajnik et al. 1999; Gunther and Walter 2001; Kaufman 1999; Renard et al. 2001; Shiina et al. 1999). Mammals, however, tend to have multiple classical MHC class I loci. Therefore the presence of only a single classical class I chain locus in the opossum seemed unusual. Unfortunately, the previous analysis was based on an early version of

the opossum genome assembly, MonDom2, and gaps in the area containing corresponding to the MHC were present (Belov et al 2006).

Recent genotyping studies of both captive bred and wild caught *M. domestica* uncovered too many *Modo-UA1* "like" sequences per individual to be accounted for by a single locus (Table 1). Here we reexamined the opossum MHC genomic region using a later assembly than that used for the earlier annotation (Belov et al 2006; Mikkelsen et al. 2007).

¹Genomic DNA sequences confirmed with targeted PCR on splenic cDNA from same animals

²Genomic DNA sequences confirmed with 454 sequencing on RNA from same animals

Materials and Methods

Whole genome sequence analysis

Sequence analyses were performed using the MonDom5 *M. domestica* genome assembly available (GenBank accession number AAFR03000000) (Mikkelsen et al. 2007). Homology searches using the BLAST algorithm and *Modo-UA1* cDNA sequences (accession number AF125540.1) were performed. Intron-exon boundaries were identified by determining splice sites using cDNA sequences and with the GENSCAN 1.0 algorithm (Altschul et al. 1997; Burge and Karlin 1997; Miska and Miller 1999).

RNA and DNA extraction and cDNA synthesis

Opossum adult spleen tissue or whole embryonic tissues were collected from captive-bred *M. domestica* and stored overnight at 4°C in RNALater (Invitrogen, Carlsbad, CA). RNA was extracted using the Trizol protocol (Invitrogen, Carlsbad, CA) and stored at -80°. Complementary DNA was synthesized from RNA using the SuperScript III First-Strand Synthesis System for RT-PCR (Invitrogen, Carlsbad, CA). Genomic DNA was extracted from spleen or liver tissue from six captive-bred adult animals with the DNeasy Blood & Tissue Kit (Qiagen, Valencia, CA). Genomic DNA was also isolated from liver and spleen tissues from one Brazilian and three wild-caught Bolivian animals provided by the Division of Genomic Resources, Museum of Southwestern Biology (MSB) at the University of New Mexico. All live animal protocols were approved under the University of New Mexico Institutional Animal Care and Use Protocol No. 10-100413-MCC.

PCR and sequencing

The region of *Modo-UA1*, *UA3*, and *UA4* loci corresponding to exon 2, intron 2, and exon 3 were amplified from genomic DNA by PCR using the primers 5'-AGGGAGAGCTGCCCTGAGCC-3' and 5'-AGTCTTCCTCTCTGCGATGCT-3' which flank the exons and the Advantage HF 2 PCR kit (Clontech, Mountain View, CA). PCR conditions were 94°C for 1 minute, 33 cycles of 94°C for 30 seconds and 62°C for 4 minutes, followed by a 7 minute extension at 68°C. The sequences of full-length transcripts were determined from overlapping clones amplified from a *M. domestica* thymus library using primers (5'-ATTAACCCTCACTAAAGGGA-3' and 5'-TAATACGACTCACTATAAGGG-3') flanking the cloning site in the Uni-ZAP XR vector paired with primers in exons 2 and 3 (*Modo-UA1*-F, 5'-CGACCAGCAGTTCGTGCCT-3'; *Modo-UA1*-R, 5'-CACTCTCTGCGAAGCTCCTCTC-3'; *Modo-UA3*-F, 5'-GCGGCCTGGATGGACAAGATGG-3'; *Modo-UA3*-R, 5'-AGTCTTCCTCTCTGCGATGCT-3'; *Modo-UA4*-F, 5'-GGCGGCCTGGATGGACAAG-3'; *Modo-UA4*-R, 5'-ATCTCTGCGATGCTCCTCTG-3'). Targeted PCR were performed on splenic cDNA from one genotyped Brazilian animal with two primer pairs in exons 2 and 3 (5'-GATATTGCCACACTACCATGTCCCC-3' and 5'-TGCAGGTACTTCTCAGCCACTGC-3'; 5'-TTTCCACACTGCCATGTCCCC-3' and 5'-GCCACTGCAGGCAGGTCTCC-3').

All PCR products were cloned using the pCR4-TOPO TA kit following manufacturers recommended protocol (Invitrogen, Carlsbad, CA). Clones were sequenced with Big Dye Terminator v3.1 Cycle Sequencing Kit (Invitrogen, Carlsbad, CA) (Holmes and Quigley 1981). Sequences were analyzed and edited using Sequencher 5.0 (Gene Codes, Ann Arbor, MI). Sequence identity was determined by BLAST comparison and nucleotide alignment with the MonDom5 assembly. Exon and intron structures were determined via the GENSCAN algorithm (<http://genes.mit.edu/GENSCAN.html>).

Sequence analyses

Phylogenetic analyses were performed based on nucleotide alignments corresponding to exons 2 and 3 of MHC class I genes from *M. domestica* and other representative vertebrate species. Nucleotide sequences were first translated into protein and aligned using ClustalW in BioEdit (Hall, 1999) to preserve codon positions. Aligned sequences were then converted back to nucleotides for tree construction using MEGA 5.05 (Tamura et al. 2011). The tree was constructed using neighbor joining statistical method using the Tajima-Nei Model with 1000 bootstrap replicates. Accession numbers for sequences used in the phylogenetic analyses were: Human *HLA-A* (U03862.1), *HLA-B* (X91749.1), *HLA-Cw* (U06487.1), *HLA-F* (BC009260.2), *HLA-G* (M32800.1), FcRn (NM_004107.4), HFE (NM_000410.3), MICA (NM_000247.1), and MICB (AK314228.1); mouse *H-2K(b)* (U47328.1), and FcRn (D37874.1); Grey short-tailed opossum *Modo-UB* (NM_001079820.1), *Modo-UC* (NM_001079819.1), *Modo-UE* (NM_001171835.1), *Modo-UG* (DQ138606.1), *Modo-UI* (NM_001171837.1) *Modo-UJ* (NM_001171836.1), *Modo-UM* (NM_001171834.1), *Modo-I* (AF135040.1), *Modo-3* (AF125540), *Modo-10*

(AF125542), and *Modo-16* (AF125543); Northern brown bandicoot *Mhc-1* (DQ927302.1); brushtail possum *Trvu-UB* (AF359509.1), and FcRn (AF191647.1); Red-necked wallaby, *Maru-UA* (L04950.1), and *Maru-UB* (L04952.1); Rhesus macaque *Mamu-A* (AF157401.1), and *Mamu-B* (NM_001048245.1).

Divergence time between *Modo-UA1*, *Modo-UA3*, and *Modo-UA4* was estimated using the Jukes-Cantor model in MEGA5 (Jukes and Cantor 1969; Tamura et al. 2011). The number of substitutions between *Modo-UA1* and *Modo-UA4* across introns 1-5 was estimated at 0.0390 substitutions/site (over 2642 sites) divided by the marsupial-specific rate of neutral nucleotide substitution of $6.8\text{--}8.9 \times 10^{-9}$ substitutions/site/year based on previous analysis of opossum class I loci (Miska et al. 2004)

Evidence of selection was performed using exon 2 and 3 sequence of the alleles from *Modo-UA1*, *UA3*, and *UA4* (GenBank Accession No. JX661062-JX661088). Sequences were aligned using Clustal X (Larkin et al. 2007) and analyzed using MEGA (Tamura et al. 2011) where a maximum likelihood tree was generated. The alignment and tree were input into the Phylogenetic Analysis through Maximum Likelihood (PAML) program (Yang, 2007) for maximum likelihood analysis of to determine sites of positive selection. The analysis used both Naïve Empirical Bayes and Bayes Empirical Bayes to determine sites of positive selection, and any site determined to be under selection had p values of 0.05 or lower.

Sequence deposition

Sequence data for *Modo-UA1*, *Modo-UA3*, and *Modo-UA4* described in this paper have been deposited in GenBank (<http://www.ncbi.nlm.nih.gov/Genbank>) under accession numbers JX661062 through JX661088.

Results & Discussion

This reanalysis revealed two additional loci encoding MHC class I α chains along with a previously unrecognized *TAP2A* gene. These were located in a 390 Kb region flanked by the non-classical class I *Modo-UJ* and class II *DXA* genes (Fig. 1). The two additional class I genes are located in gaps in the earlier MonDom2 assembly and were designated *Modo-UA3* and *UA4*. The *Modo-UA1* locus retained its original designation. In comparing the full-length sequences of each of the genes with each other, *Modo-UA1* and *Modo-UA3* have the greatest levels of sequence identity at 93.09%, while comparing *Modo-UA1* to *Modo-UA4* is 88.39%. A comparison of *Modo-UA3* to *Modo-UA4*, there is a sequence identity of 89.77%, indicating that *Modo-UA4* is the most different of the three.

Confirmation of *Modo-UA1*, *UA3*, and *UA4* loci presence in the genome of *M. domestica* was made using genomic DNA to ensure discovery was not another assembly artifact. Genomic DNA from eight opossums, five of which were from a captive colony with Brazilian founders and the remaining three were wild-caught Bolivian animals (Baker et al. 2009). Primers located in intron 1 and exon 3 were used to amplify a 734 bp product containing exon 2, intron 2, and most of exon 3 by PCR. PCR products were then cloned and sequenced from each individual. Five or six unique alleles were amplified from six of the eight individuals, consistent with there being at least three *UA* loci, supporting the later genomic assembly (not shown).

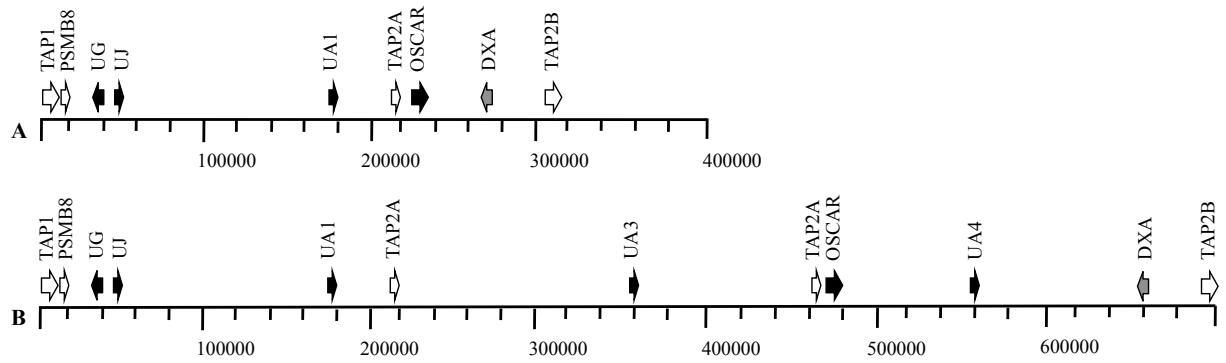

Figure 1. A: *Monodelphis domestica* MHC map derived from Belov et al. 2006. B: *M. domestica* updated MHC map derived from coordinates relative to opossum build 2.2 (MonDom5) base pair 270,288,868 on chromosome 2. Black arrows represent Class I genes, grey arrow are Class II genes, and white arrow are antigen presenting genes.

RACE-PCR was performed on the thymic cDNA library to investigate the complete gene structure for *Modo-UA1*, *Modo-UA3*, and *Modo-UA4*. Transcripts that correspond to all eight exons for each locus were amplified. Overall, the *Modo-UA1*, *UA3*, and *UA4* loci have similar intron/exon structure that is typical of MHC class I genes (Figure 2). While the exon length was constant between loci, the intron lengths varied considerably, notable was the variation in intron 1 length. Alignment of full length *Modo-UA1*, *UA3*, and *UA4* cDNA sequences reveal substantial similarity between the *Modo-UA* loci and other MHC class I genes (Figure 3).

Phylogenetic analyses using marsupial and eutherian class I sequences revealed *Modo-UA1*, *UA2*, and *UA3* form a single clade sister to that containing *Modo-UB* and *UC* (Figure 4). Three of MHC class I cDNA sequences, Modo-3, 10 and 16, reported previously and thought to be from *Modo-UA1*, are actually more related to *Modo-UA3* (Miska and Miller, 1999). Another cDNA, Modo-1, appears to be transcribed from *Modo-UA1*. The topology of the *Modo-UA* clade is consistent with *Modo-UA1* and *UA3* being a more recent gene duplication and the duplications that gave rise to the three *Modo-UA* genes having occurred after the divergence from the locus that duplicated to form *Modo-UB* and *UC*. These interpretations are also supported by the divergence times estimated for the three *UA* loci. Using estimates of divergence rates for opossum MHC class I genes established previously (Miska et al. 2004), the *Modo-UA1* and *Modo-UA3* duplications estimated as 6.35-8.31 million years ago (MYA) (0.0564 substitutions/site), whilst that for *Modo-UA3* and *Modo-UA4* is 7.56-9.89 MYA (0.0672 substitutions/site).

Figure 3. Alignment of protein translation of *Modo-UA1*, *Modo-UA3*, *Modo-UA4*, and select opossum and human MHC genes. Dashes indicate sequence identity, dots indicate gaps, and asterisks represent stop codons. Accession numbers for sequences used are Modo-UB, Modo-UC, and Modo-UA2, AAFR03000000 ; Modo-UE, NM_001171835.1; Modo-UI, NM_001171837.1; Modo-UK, EU886706.1; Modo-UM, EU886712.1; HLA-A, AAA03603.

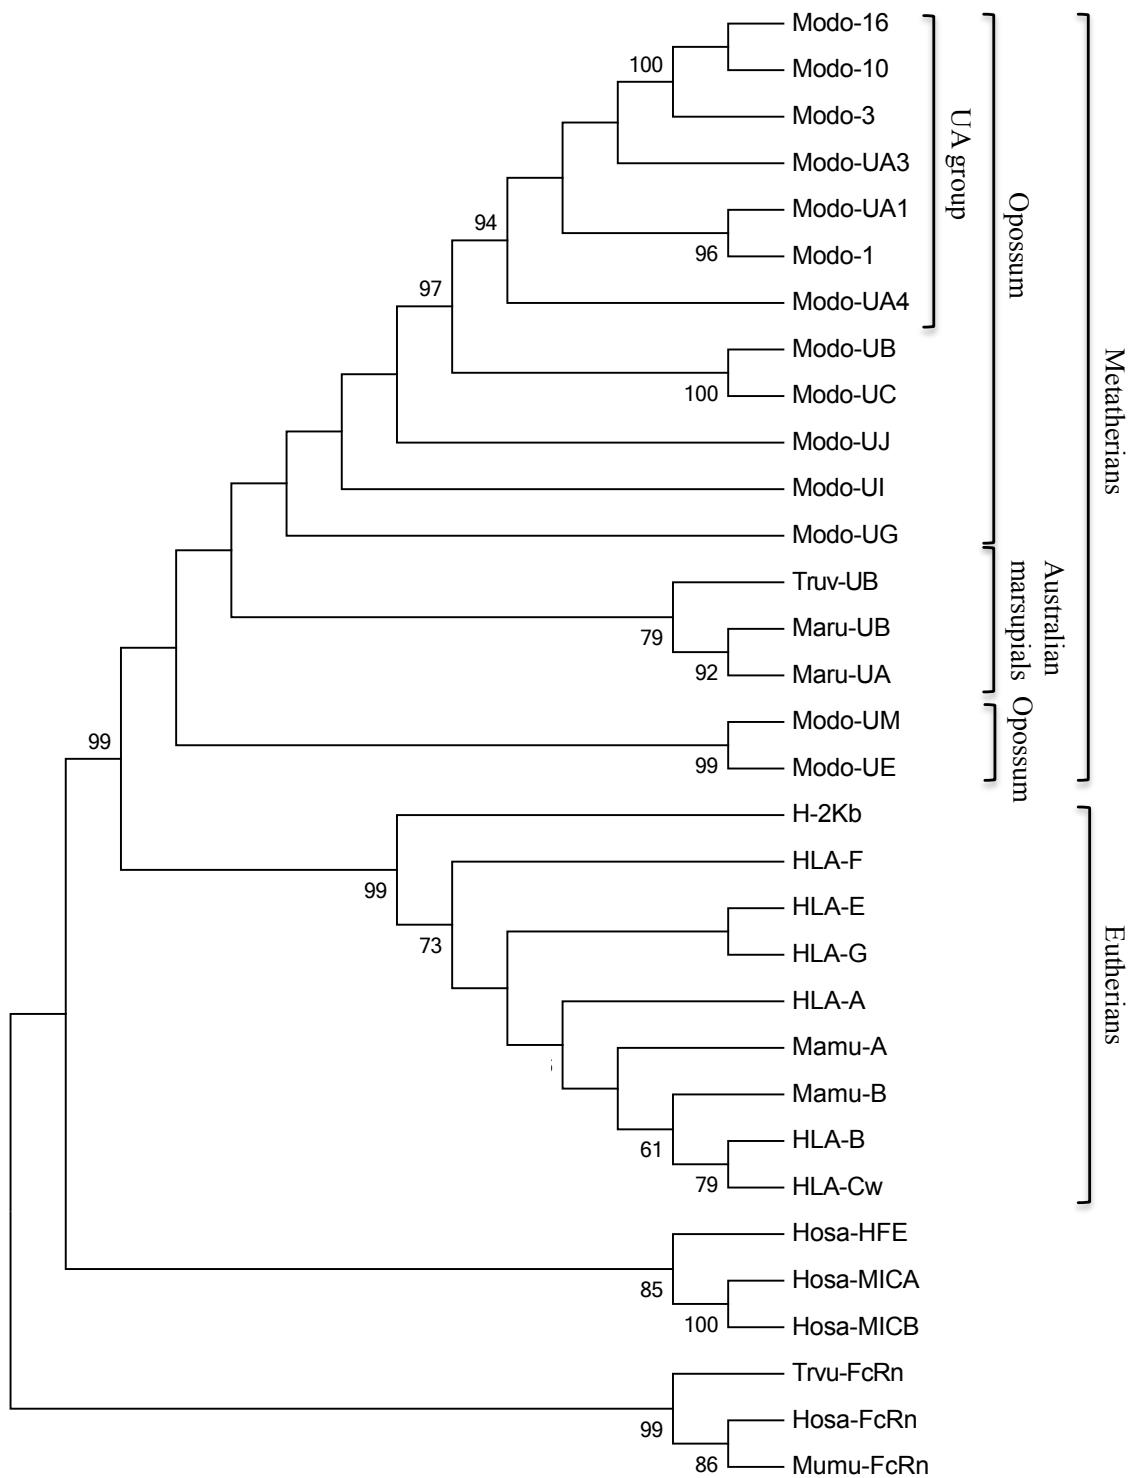

Figure 4. Phylogenetic relationship among MHC loci. Phylogenetic tree based on nucleotide alignments corresponding to exons 2 and 3 of MHC class I from *M. domestica* (Modo) and representative vertebrate species. The tree was constructed using neighbor joining statistical method using the Tajima-Nei Model with 1000 bootstrap replicates using MEGA 5.05 (Tamura et al. 2011).

By comparison, the duplication that gave rise to *Modo-UB* and *UC* occurred less than 6 MYA.

Previously, it was thought that the *Modo-UA1* locus was highly polymorphic (Gouin et al 2006). It is likely that the polymorphism identified was due by the presence of multiple related loci. Sequencing of the *Modo-UA* loci from eight individual *M. domestica* from both captive-bred Brazilian animals and wild-caught animals from Bolivia revealed that *Modo-UA1* and *UA3* alleles are too similar to be distinguished from one another. *Modo-UA4* is sufficiently divergent from both *Modo-UA1* and *UA3* that alleles for this locus could be distinguished. A total of six different *Modo-UA4* alleles were uncovered from both the captive and wild-caught, while a total of 22 *Modo-UA1/UA3* alleles were identified. An analysis of the *Modo-UA4* $\alpha 1$ and $\alpha 2$ domain sequence, which could be analyzed independently, revealed no evidence of sites under positive selection (data not shown).

In summary, a reanalysis of the *M. domestica* MHC genomic region using a later whole genome assembly revealed that a majority of the gene content and gene order remained unchanged from what was published previously (Belov et al 2006). The region differed substantially due to an additional 390 kb of sequence not present in the original assembly, located in a region between the TAP1 and TAP2B genes. Present were three additional genes, two encoding class I α chains, designated *Modo-UA3* and *Modo-UA4*, and one encoding a second TAP2A. *Modo-UA3* and *Modo-UA4* were so named in recognition of their sequence homology to *Modo-UA1* and the pseudogene *Modo-UA2*. Phylogenetic

analyses place the three loci in a clade with *Modo-UA2* and the MHC class I-like genes *Modo-UB* and *UC*, located outside of the MHC (Miska et al. 2004). As with other rapidly-evolving class I genes, these genes are nested within a larger *M. domestica* clade and are not orthologous to other species' class I genes (Belov et al. 2007; Miska and Miller 1999). Previous annotations and analyses of the opossum genome depicted the MHC as more akin to nonmammalian vertebrates' genomes, with only a single classical class I gene (Flajnik and Kasahara 2001; Kulski et al. 2002). This revisiting of a marsupial MHC reveals a class I gene organization more akin to eutherian mammals' multilocus class I system.

ABSTRACT

One hundred and thirty four Little Penguin (*Eudyptula minor*) carcasses found since 2004 in south west Australia were necropsied. The livers and spleens from ten of the penguins exhibited varying degrees of multifocal, randomly scattered areas of necrosis and varying numbers of parasites were associated with these areas. Hepatomegaly and splenomegaly were noted in many of these ten cases. Necrosis and parasites were also observed in the cardiac muscle of four of the cases and in the lung tissue in one of the penguins. Using PCR, the parasites were positively identified in four of the cases as *Haemoproteus* spp. and morphologically identical tissue stage parasites associated with histopathological changes were observed in all ten dead penguins. This is the first study to demonstrate both the *in situ* presence of the *Haemoproteus* parasite in any member of the Spheniscidae family and mortality due to its presence. We postulate the involvement of anomalous environmental conditions in a potential increase in local vectors.

1. Introduction

The largest colony of Little Penguins (*Eudyptula minor*) in Western Australia, found on Penguin Island, has the highest conservation status of all the major Little Penguin colonies in Australia and New Zealand (Dann et al., 1996). However, they face an increasing range of natural and anthropogenic threats, such as reduction in food resources, collisions with watercraft, hyperthermia, pollution, and introduced predators (Cannell, 2004). These threats, along with parasites and infectious diseases, are

known causes of mortality for Little Penguins throughout Australia and New Zealand (Obendorf and McColl, 1980; Harrigan, 1992; Norman et al., 1992; Clarke and Kerry, 1993; Hocken, 2000a; Cannell unpubl. data).

The prevalence of the haemosporidian parasites of the genera *Plasmodium*, *Haemoproteus* and *Leucocytozoon* is generally low in seabirds (Peirce, 2005; Quillfeldt et al., 2011), and worldwide, penguins appear to be more likely to be infected by *Plasmodium* than by species of *Haemoproteus* or *Leucocytozoon* (Levin et al., 2009; Quillfeldt et al., 2011). Infections of avian malaria, caused by *Plasmodium relictum*, *P. elongatum* and *P. cathemerium*, have been observed in many captive populations of penguins, often resulting in high mortality (Fleischman et al., 1968; Bennett et al., 1993a; Clarke and Kerry, 1993; Graczyk et al., 1994; Jones and Shellam, 1999a; Valkiunas, 2005;

E-mail addresses: B.Cannell@murdoch.edu.au, belindacannell@bigpond.com (B.L. Cannell).

Bueno et al., 2010). *Haemoproteus* spp. in penguins have only been reported so far in a study of haemoparasites of Galapagos penguins (*Spheniscus mendiculus*), where a single individual, out of 362 tested, was positive (Levin et al., 2009). *Leucocytozoon* spp. have been observed in Fiordland crested penguins (*Eudyptes pachyrhynchus*), African penguins (*Spheniscus demersus*) yellow-eyed penguins (*Megadyptes antipodes*), and Macaroni penguins (*Eudyptes chrysolophus*) (Valkunas, 2005; Peirce et al., 2005) and were associated with increased regional chick mortality with evidence of severe, disseminated megaloschizont formation in multiple tissues in the latter species (Hill et al., 2010). Haemoparasites have rarely been observed in Little Penguins (Jones and Shellam, 1999a,b), though a “malaria-like parasite” was noted to have caused the mortality of two wild Little Penguins from New South Wales in 2000 (Rose, 2001) and *Leucocytozoon takawi* was transferred from a Fiordland crested penguin into a juvenile Little Penguin (Allison et al., 1978).

Avian haemosporidians have a sexual phase that develops in a vector, a blood-sucking dipteran, and an asexual phase in birds (Valkunas, 2005). The abundance and geographic range of vectors and hence vector-borne disease may be impacted by climate change (Jones and Shellam, 1999b; Harvell et al., 2002), while migratory birds are an important factor in the distribution of parasites and diseases (Jourdain et al., 2007) due to their movement over large areas. In addition to this normal large scale movement, the geographic range of many bird species is also affected by changes in climate. In Western Australia, tropical birds have moved into areas that once were the domain of temperate birds (Dunlop and Wooller, 1986; Wooller et al., 1991), and haemosporidian parasites have been reported in a greater number of species of tropical compared to temperate seabirds (Quillfeldt et al., 2011). The expansion of tropical seabirds onto temperate islands such as Penguin Island could therefore result in the introduction or rise in prevalence of such parasites in endemic species.

Since 2004, 134 necropsies have been performed on many of the Little Penguins found dead on the Southwestern Australian coastal foreshores as well as Penguin Island itself. It is extremely rare to find wild birds that have died of haemoparasitic infections (Valkunas, 2005), as most dying birds are predated upon (Bennett et al., 1993b; Ladds, 2009). In this paper, we report on the first known cases of haemoproteosis caused by *Haemoproteus* spp. in wild Little Penguins in Western Australia, and describe the pathology and pathogenicity.

2. Materials and methods

2.1. Specimen collection and gross examination

Necropsies were performed on 10 dead Little Penguins found on Penguin Island, Western Australia ($32^{\circ}18' S$, $115^{\circ}41' E$) or at various locations in the southwest of Western Australia (Fig. 1) between November 2006 and May 2012. Eight of the dead penguins were frozen for 10–90 days prior to necropsy (following an unspecified interval between death and the discovery of the carcase), and two were necropsied within 24 h of discovery and

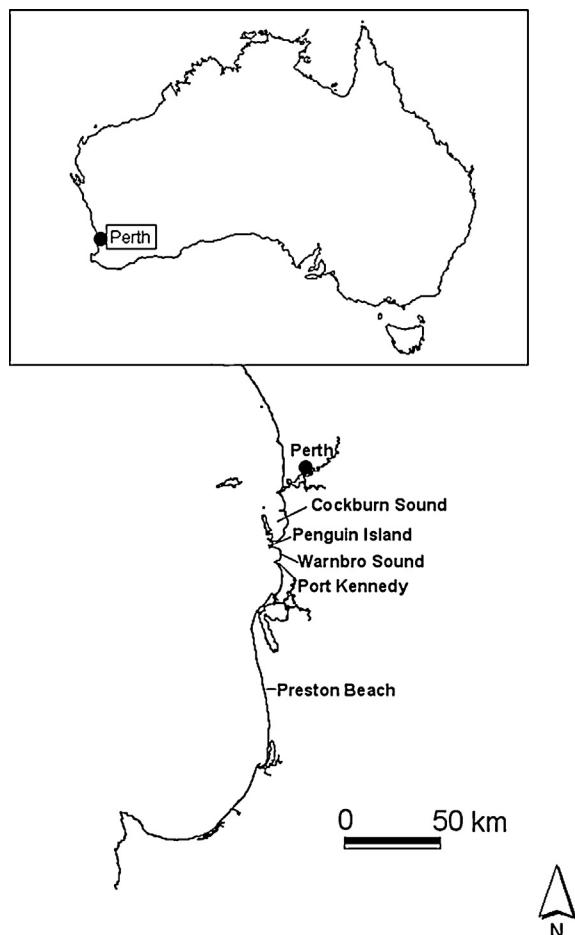

Fig. 1. The location of dead penguins in Western Australia: on Penguin Island and the foreshores of Cockburn Sound, Warnbro Sound, Port Kennedy and Preston Beach. Penguin Island is approximately 50 km south of Perth, the capital city of Western Australia.

subsequent refrigeration, though the post-mortem interval was unknown. Gross external and internal examinations were performed and the body was weighed in all but one case. The liver and spleen were weighed in eight of the cases and abdominal fat pad in seven cases. The bodies were weighed using an Avery platform scale (resolution 10 g) and internal organs were weighed using an A&D EK-410i scale (resolution 0.01 g). The mass of each of the organs was compared with that reported for Little Penguins from New Zealand (Hocken, 2000b). However, penguins from the Penguin Island colony are known to be larger than those from New Zealand (Wienecke, 1993; Dann et al., 1996), and as Hocken (2000b) found a consistent organ-to-body mass ratio in penguins, the liver to body mass ratio was used to demonstrate hepatomegaly. The ratio of abdominal fat to body mass was also used to demonstrate the body condition of the penguins. Histopathology was performed on various organs, providing autolysis did not preclude such examination; all carcases were scored according to their degree of autolysis.

2.2. Screening of organs for tissue stages of haemosporidians

Tissue samples from the lung, spleen, liver and heart were fixed in formalin, cut into 4 µm thick sections and stained with haematoxylin and eosin. 2 µm thick sections stained with Martius Scarlet Blue were used to obtain photomicrographs of the organisms, which appeared more prominent using this technique. The samples were examined using light microscopy, including 1000× magnification with oil immersion. Impression smears were made for cytological examination of the liver and spleen in the final case, by rolling the cut surface of the fresh tissues onto glass slides, air drying, then staining with Wright–Giemsa.

2.3. Molecular screening for haemosporidians and sequence analysis

DNA was extracted and purified from the liver of each bird using a Qiagen DNeasy Blood and Tissue Kit. Using polymerase chain reaction (PCR) a fragment of approximately 480 bp of the mitochondrial cytochrome-*b* (cyt-*b*) gene was targeted for *Plasmodium* and *Haemoproteus* using a nested PCR strategy. For each bird, at least three independent PCR amplifications were performed before being declared negative. Avian blood samples known to be positive for either *Haemoproteus* or *Plasmodium* were used as positive controls for the PCR. Samples were first amplified using the primers HaemNF (5'-CATATATTAAGAGAATTATGGAG-3') and HaemNR2 (5'-AGAGGTGTAGCATATCTATCTAC-3') described in Waldenström et al. (2004). A second nested PCR was performed using HaemNF1 (5'-CATATATTAAGAGAA-ITATGGAG-3') [I=a universal base, inosine] and HaemNR3 (5'-ATAGAAAGATAAGAAATACCATTTC-3') (Hellgren et al., 2004). PCR were set up as 15 µl reactions containing 50 ng template DNA, 0.75 units of AmpliTaq Gold (Applied Biosystems, Carlsbad, California), 1.5 µl of MgCl, 0.2 mM of each dNTP, and 0.5 mM of each primer. The HaemNF and HaemNR2 PCR were run using a programme of 94 °C for 8 min followed by 35 cycles of 94 °C for 30 s, 50 °C for 30 s, and 72 °C for 45 s, and a final extension at 72 °C for 10 min. The conditions for HaemNF1 and HaemNR3 are identical except for an annealing temperature at 52 °C. An additional positive control to assess DNA quality was performed using avian-specific cyt-*b* primers as described in Cicero and Johnson (2001).

PCR products were cloned using the pCR4-TOPO TA kit following the manufacturers recommended protocol (Invitrogen, Carlsbad, CA). Cloning rather than direct sequencing of PCR products was performed initially to avoid problems that may arise due to presence of mixed infection. Multiple clones from each positive PCR amplification were sequenced using the BigDye Terminator v3.1 Cycle Sequencing Kit (Invitrogen, Carlsbad, CA). Sequences from independent clones obtained from the same bird were always identical indicating absence of variation due to PCR and/or cloning artefacts. Sequences obtained were viewed and manually edited using Sequencher ver 5.0 (GeneCodes, Ann Arbor, MI) and aligned using ClustalX (Larkin et al., 2007). Sequences were compared to

those in the GenBank database using the BLAST algorithm (<http://www.ncbi.nlm.nih.gov>). Novel sequences generated in this study have been deposited in GenBank under accession numbers KC121053–KC121056.

Parameters for phylogenetic analysis and rooting were based on that of Outlaw and Ricklefs (2011). A maximum likelihood phylogeny was generated using MEGA 5.0 (Tamura et al., 2011) and a GTR+ gamma model of nucleotide substitution with 1000 bootstrap iterations, and was rooted between mammalian *Plasmodium* and avian *Plasmodium*. Accession numbers for additional sequences used in the phylogenetic analyses are: Avian *Haemoproteus* spp.: *Spheniscus mediculus*, JX679087 and KC121057; *Heteromyias albuspecularis*, AY714147; *Turdus merulus*, DQ630013; *Sylvia atricapilla*, GU784854; *Malimbus rubricollis*, HQ386243; *Quelea quelea*, EF117230; *Fringilla coelebs*, DQ368340; *Phylloscopus trochilus*, AF254972; unknown avian host, EF032812. Avian *Parahaemoproteus* spp.: *Dumetella carolinensis*, GU252002; *Vireo olivaceus*, GU252005; *Falco sparverius*, GQ141558. Avian *Plasmodium* spp.: *Sciurus aurocapillus*, HM222481; *Parus major*, DQ658590 and JQ778277; *Passer domesticus*, AF069611. Mammalian *Plasmodium* sp.: *Gorilla gorilla*, GU045322; *Grammomys surdaster*, DQ414646; *Mandrillus sphinx*, JF923750.

3. Results

3.1. History and body condition of penguins cases

Three of the ten cases were adults that had previously been banded or microchipped. These marked penguins had been observed 11–45 days prior to being found dead (Table 1). Of the other seven cases, one was an unmarked fledgling and six were unmarked adults, none of which had previously been observed (Table 1). Penguin 11/624 had just completed rearing two chicks, which were last observed in the nest on 14th September 2011, i.e. approximately 2 months prior to 11/624 being found dead.

The body condition of the penguins was variable; however none were in poor condition, all having an appreciable layer of subcutaneous adipose tissue and a reasonable to adequate intra-abdominal fat pad. The penguins of known ID were all lighter than their average body mass, however the body mass of 11/624 had actually increased from the time it was last observed alive (Table 1).

3.2. Gross pathological findings

3.2.1. Liver

Hepatomegaly with rounded lobar edges was evident in several of the penguins. The livers were weighed in eight penguins and ranged from 58.6 to 79.7 g (Table 2), with an average of 65.8 ± 4 g for males and 65.7 ± 3.3 g in females. This is notably greater than that of healthy Little Penguins in New Zealand (males: 42.4 ± 14.6 g, females: 34.2 ± 10.9 g; Hocken, 2000b). The liver mass, as a percentage of body mass, averaged 5.3 ± 0.5 for males and 5.5 ± 0.3 in females (Table 3). In this study, the ratio of liver to body mass for all penguins (5.4 ± 0.3) was substantially greater than that obtained by Hocken (2000b) for healthy Little Penguins (3.67 ± 0.8). Thus, all eight

individuals in which the liver was weighed had demonstrable hepatomegaly. Pinpoint flat white to off-white spots were disseminated over the hepatic capsular surfaces in 11/626, 11/627, 11/628, and 12/362 (Fig. 2). A focal area of metallic yellow speckling was noted on the capsular surface of the right liver lobe of 08/1075 (interpreted as urate precipitate).

3.2.2. Spleen

The spleen was enlarged in all cases (8/10) in which it was measured (Table 2). The average for both males (6.1 ± 1.0 g) and females (5.2 ± 1.2 g) was notably greater

than that found by Hocken (2000b) for healthy males (1.5 ± 1.0 g) and females (1.2 ± 0.7 g). Pinpoint white to off-white spots were scattered throughout the splenic parenchyma and over its capsular surface in the case of 11/624.

3.2.3. Abdominal fat pad

The abdominal fat pad was weighed in six of the penguins and ranged from 4.1 to 16.1 g (Table 2), with an

average of 8.6 ± 2.3 g for the males and 9.9 ± 3.2 g for the females. The mass of the abdominal fat pad as a percentage of body mass varied from 0.3 to 1.3%. The average for the males was $0.7 \pm 0.2\%$ and $0.8 \pm 0.2\%$ for the females. This was lower than that for healthy males ($1.4 \pm 0.9\%$) and slightly lower than that for females ($0.9 \pm 0.8\%$) (Hocken, 2000b).

3.3. Histopathological findings

The degree of autolysis ranged from minimal to moderate-marked and rendered histopathological examination of some tissues difficult in some cases (however parasites were obvious in all ten cases).

The livers from all penguins exhibited varying degrees of multifocal, randomly scattered areas of hepatocellular necrosis (Table 4), which in the worst affected cases was multifocal to coalescing. Associated with these areas were varying numbers of parasites, present in all ten cases. The protozoa were present both extracellularly (scattered amongst necrotic tissue) and intracellularly within macrophages/Kupffer cells, hepatocytes and endothelial cells (the latter was difficult to confirm, given the host cell was significantly enlarged/distorted; however they were often in an intracellular location immediately adjacent sinusoids) at the periphery of the necrotic areas. Each parasite varied from 2 to 4 μm diameter and was round to ovoid with a dark basophilic (in haematoxylin and eosin stained sections) paracentral to eccentric nucleus and pale amphophilic cytoplasm (cytome). When present intracellularly they were often clustered in small groups (approximately 20 μm diameter) of up to 18 cytomeres contained within a thin walled vacuole (meronts containing cytomeres) (Fig. 3). Increased numbers of macrophages were scattered throughout the liver (particularly associated with areas of necrosis) in five cases, with two of these also exhibiting heterophilic infiltrates (Table 4). Scattered hepatocytes and Kupffer cells (particularly at the periphery of necrotic areas) contained small amounts of intracytoplasmic pigment in four cases (Table 4). This material appeared to be comprised of two components

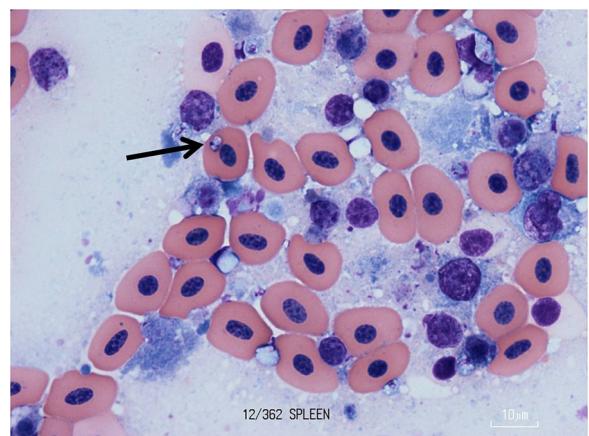

Fig. 4. Splenic impression smear, penguin 12/362. 1000 \times (oil immersion) magnification, Wright–Giemsma stain. The arrow indicates an intraerythrocytic merozoite prior to its development into a young gametocyte.

mixed together in varying amounts, depending on the area within the section. The first was opaque, golden-brown and granular (in haematoxylin and eosin stained sections), staining bright blue with Perl's Prussian Blue histochemistry, confirming its identity as haeme pigment (from erythrocyte degradation, given the extensive areas of necrosis with accompanying haemorrhage seen); rather than volutin pigment (which can be present in gametocytes of *Haemoproteus* spp.). This is because the latter is intraerythrocytic and also (being protein bound) does not react positively with Perl's Prussian Blue histochemistry. The second was refractile, appearing pale golden to tan (in haematoxylin and eosin stained sections; it was negative for Perl's Prussian Blue); it occasionally (but not reliably) polarised with the use of a polarising lens. Its morphology was interesting in that it was not granular, but rather linear and occasionally formed a lining around apparently clear vacuoles within the affected hepatocytes and Kupffer cells, often in close proximity to individual extracellular merozoites/cytomeres. Its exact identity is unknown; however it was felt it may represent the residual hyaline walls of ruptured meronts having released merozoites/cytomeres.

Multifocal areas of splenic parenchymal necrosis of varying size were observed in all penguins, the worst affected cases exhibited multifocal to coalescing necrosis. Cytomeres identical to those described in the liver were observed scattered extracellularly throughout the necrotic debris. Single to small groups (up to 8) of identical organisms, possibly meronts, were observed intracellularly within both macrophages as well as what appeared to be reticuloendothelial cells on the periphery of the necrotic areas. Rare intraerythrocytic organisms (consistent with intraerythrocytic merozoites prior to their development into young gametocytes) were observed in an impression smear of the spleen of 12/362 (Fig. 4). Accompanying the necrosis and intralesional parasites was a moderate to marked, multifocal to coalescing histiocytic and heterophilic (the latter often appearing degenerate) inflammatory infiltrate in five cases, with another two cases exhibiting solely a histiocytic infiltrate (Table 4).

Table 4

Summary of histopathological findings.

12/362	Minimal	✓		✓	✓	✓	✓		✓

Pigment of mixed morphology as previously described in the liver was observed within the cytoplasm of scattered macrophages in the spleen of one case (12/338).

The lungs of 08/1075 and 11/624 exhibited increased numbers of inflammatory cells, predominantly macrophages; however they appeared to be confined within circulation, rather than being representative of a true inflammatory infiltrate. It is unknown whether this was related to a leukocytosis, as pre-mortem haematology was not performed; alternatively, it could have occurred secondary to stress-related leukocyte sequestration within the pulmonary vasculature. Rare parasites resembling merozoites ($\leq 1 \mu\text{m}$) were observed within alveolar macrophages in the case of 06/1172. Rare merozoite-like organisms were also found within the pulmonary interstitium in three cases (06/1172, 08/1075 and 11/624), but were not observed in the other cases.

Cardiac muscle from four cases (06/1172, 08/1075, 11/628 and 12/362) exhibited rare small focal to multi-focal areas of cardiac myocyte degeneration and necrosis. 06/1172 additionally exhibited a focal histiocytic and lymphoplasmacytic periarteritis. Associated with these foci of necrosis and inflammation were sparse individual parasites resembling merozoites (each 1–2 μm), which appeared largely extracellular and scattered throughout the affected tissue.

3.4. PCR results and sequence analysis

Of the ten Little Penguin samples obtained from 2006 to 2012, only four (11/626, 12/020, 12/021 and 12/338) were positive for haemoparasite cyt-*b* (Fig. 5). When multiple PCR products from each positive bird were cloned and sequenced, each bird was found to harbour a single haemoparasite cyt-*b* sequence (not shown). When compared between birds, the sequences from 11/626, 12/021 and 12/338 were identical. The sequence from 12/020 differed by only a single nucleotide (not shown). When compared to public databases of cyt-*b* genes, the sequences were found to have 86–97% nucleotide identity to sequences from parasites previously identified as *Haemoproteus* subgenus *Parahaemoproteus*, and 80–84% identity to *Haemoproteus* subgenus *Haemoproteus*. The isolated sequences only shared 79–83% nucleotide identity to avian *Plasmodium* isolates. Further confirmation of the

Haemoproteus spp. nature of the sequences was established using phylogenetic analysis (Fig. 6). The sequences obtained from the Little Penguin samples were aligned to representative haemosporidian parasite cyt-*b* sequences obtained from GenBank. A phylogeny based on these alignments reveals that the Little Penguin sequences are clearly within a clade containing avian *Haemoproteus* spp., distinct from *Plasmodium* spp. Within the *Haemoproteus* clade they are most related to the *Haemoproteus* of the subgenus *Parahaemoproteus* as would be expected based on the nucleotide sequence identity. Previously isolated *Haemoproteus* sequences from Galapagos penguins were also in the *Parahaemoproteus* subgenus, however these are distinct from those detected in the Little Penguins.

4. Discussion

Haemoproteus spp. were identified by PCR in four dead penguins in 2011 and 2012, and morphologically identical tissue stage parasites were observed in all ten dead penguins associated with significant pathological changes sufficient to result in acute death. It is worth noting that parasites were not seen in histologically normal tissue, only in areas affected by significant pathological changes. Given that the birds were still in adequate to good body condition (as evidenced by adequate subcutaneous and intra-abdominal adipose); it is unlikely that the penguins died from starvation. This, combined with the fact that significant hepatic and splenic necrosis associated with *Haemoproteus* spp. was seen indicates that disseminated haemoproteosis was responsible for their deaths. These constitute only the second recorded cases of *Haemoproteus* spp. identified in any member of the Spheniscidae family (Levin et al., 2009), however this report is the first to demonstrate the presence of the parasite *in situ* associated with overt pathological changes. Moreover, it is the first time that *Haemoproteus* spp. infection has been implicated in the mortality of Little Penguins.

Although all ten birds tested here for haemosporidian infection using DNA analysis exhibited similar histopathological findings, six of the birds were negative by PCR. Previous investigators have reported similar false negatives using PCR based methodology (Richard et al., 2002; Beadell et al., 2004; Valkunas et al., 2006). Inability to amplify haemosporidians from DNA extracted from

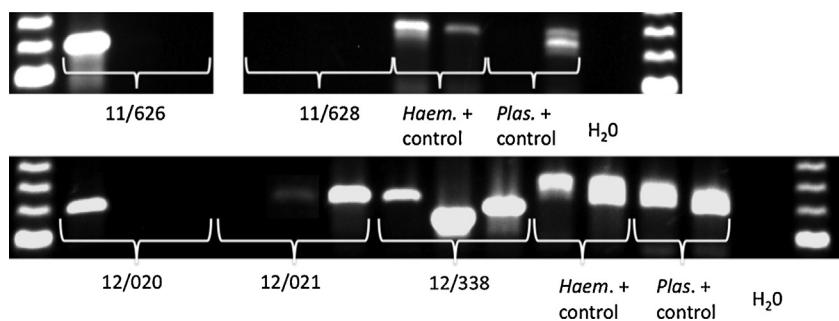

Fig. 5. Visualisation of PCR results of the four positive (11/626, 12/020, 12/021 and 12/338) and one representative negative (11/628) birds. Each sample was run in triplicate except for the positive controls, which were run in duplicate. H₂O was included as a negative control.

microscopically positive samples may be the result of degradation of the DNA sample over time; however this does not seem to be the case here since positive controls performed support the quality of the DNA. Alternatively, due to variation in tissue sampling, parasite DNA may be underrepresented in some samples. Microscopy alone can also result in false negatives due to low infection levels and often does not provide species level information on the parasite. For example, it is difficult or impossible to

use the morphology of the preerythrocytic tissue stages alone for accurate diagnosis of *Haemoproteus* spp. infection (Atkinson, 2008). Hence the value in the use of both molecular as well as microscopic methods in identifying infection (Valkiunas et al., 2008a) is supported by the results presented here.

The molecular methodology used in this study has been used previously to identify both *Haemoproteus* and *Plasmodium* spp. (Hellgren et al., 2004; Waldenström et al.,

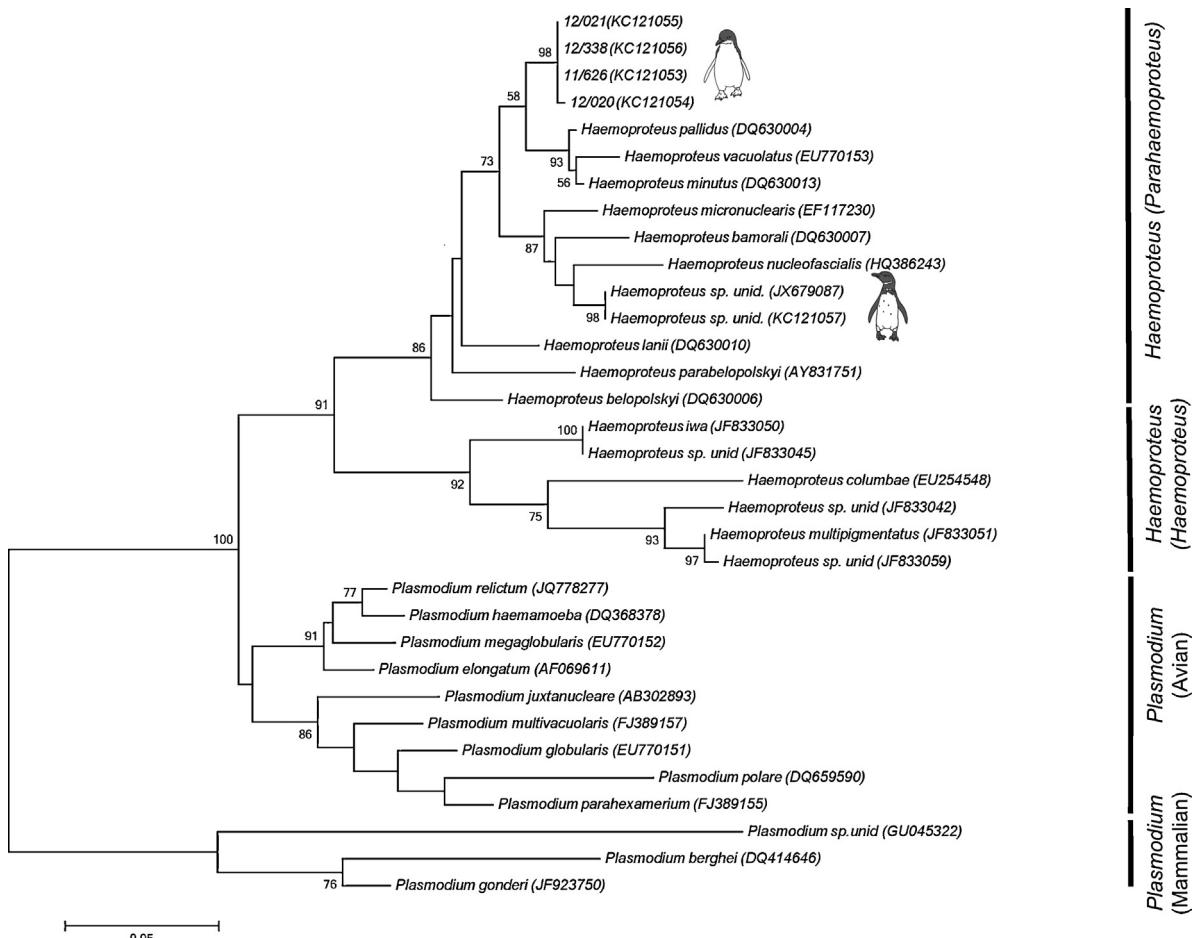

Fig. 6. Phylogenetic tree based on mitochondrial cytochrome *b* sequences of haemosporidian parasites obtained from the liver of Little Penguins along with representatives obtained from GenBank.

2004). Indeed, the close phylogenetic relationship between *Plasmodium* and *Haemoproteus* spp. makes it difficult to design primers specific for one that would not amplify the other (Beadell and Fleischer, 2005). Only *Haemoproteus* was identified in the Little Penguins tested here, however it is impossible to rule out the presence of other infections based on negative results. Mixed infections can result in preferential amplification of DNA from the parasite with the greatest level of parasitemia and/or tissue burden (Valkiunas et al., 2006). Therefore PCR based methods can underestimate the occurrence of mixed *Haemoproteus* and *Plasmodium* spp. infections. One method to reduce such underestimation is by sequencing multiple independent clones from more than one independent PCR reaction, increasing the chances of identifying dual infections, as was performed here.

As the primers used only amplify the *Plasmodium* or *Haemoproteus* spp. *cyt-b* gene, we cannot rule out the possibility that the penguins could have also harboured *Leucocytozoon* spp. infections. In addition, the clinical observations of splenomegaly, hepatomegaly and histiocytic infiltrates in the current study not only correlate with previous reports of *Haemoproteus* spp. infections (Atkinson and Van Riper III, 1991; Ladds, 2009) but also those of *Plasmodium* and *Leucocytozoon* spp. infections (Fix et al., 1988; Graczyk et al., 1994; Valkiunas, 2005; Ko et al., 2008). However, the intraerythrocytic stage observed in 12/362 (noting that this case was PCR negative but histologically positive), did not deform the host cell nucleus, as would be expected of even young *Leucocytozoon* gametocytes (Valkiunas, 2005). Furthermore, the intralesional haemosporidians observed in the six “PCR-negative” cases were morphologically identical by light microscopy to that of the four PCR positive cases. However, many of the necropsy findings could also apply to infection with *Babesia* spp., and concurrent infection with *Babesia peircei* cannot be excluded. This piroplasm has been identified from Little Penguins in Australia (Peirce, 2000), and from Jackass Penguins (*Spheniscus demersus*) in South Africa (Erlé et al., 1993). Schizonts and trophozoites of *B. peircei* are difficult to differentiate from early intraerythrocytic stages of haemoproteids, the main difference being the absence of pigment in species of *Babesia* (Homer et al., 2000). However, refractile hyaline pigment of unknown significance was present in the livers of four out of the ten birds in this study, including one which was negative for *Haemoproteus* spp. by PCR (11/624). In addition, no organisms consistent with *Babesia* were noted in the splenic impression from 12/362 (P. Irwin, pers comm.), even though intraerythrocytic merozoites were present in this case. It should be noted that the molecular techniques that we used for haemosporidia do not detect *Babesia* spp.; therefore, the potential remains for mixed infections. However, ticks are vectors of *Babesia* spp., and although they are usually associated with nesting bird colonies, none were found on Little Penguins or in their nests in this study. Therefore we conclude that a diagnosis of *Haemoproteus* spp. is likely the case for all 10 dead penguins.

Haemoproteus spp. are normally considered benign in birds (Bennett et al., 1993b; Quillfeldt et al., 2010), although it has also been postulated that heavy infections of

Haemoproteus spp. may delay bird migration (Valkiunas and Iezhova, 2001). In addition, tissue stages of the parasite have been reported to cause necrosis of pectoral muscle fibres surrounding megaloschizonts in several avian species (Atkinson and Forrester, 1987; Atkinson, 2008; Olias et al., 2011); pneumonia-like symptoms (Valkiunas, 2005) and haemorrhage and necrosis associated with cyst rupture (Ferrell et al., 2007). However, all but one of these cases were from captive or laboratory animals, and the apparent lack of pathogenicity in the wild could be artefactual, arising from sampling birds that are in apparent good condition (i.e. aclinical/asymptomatic), and not those found ailing or dead (Valkiunas, 1998). Indeed, Ladds (2009) notes that the severity of the disease may be underestimated in wild birds.

The exact life cycle and pathogenesis of the *Haemoproteus* spp. identified is unknown; however it is assumed that they follow the general scheme of the haemoproteid life cycle as elaborated by Valkiunas (2005). Unlike the members of the genus *Plasmodium*, to which they are closely related, haemoproteids undergo merogony (asexual reproduction) in tissues, rather than circulating erythrocytes. It is these developing preerythrocytic tissue stages that have, albeit in a limited number of cases, been reported to be pathogenic, causing significant myonecrosis (Ferrell et al., 2007; Atkinson, 2008; Olias et al., 2011) as they mature and rupture to release merozoites capable of invading erythrocytes. No gross signs of skeletal myonecrosis were noted in our cases, and unfortunately skeletal muscle was not examined histologically. Four of the ten cases did exhibit small foci of cardiac myonecrosis associated with sparse intralesional merozoites.

No haemoparasites were previously found in blood smears taken from penguins on Penguin Island in 1992 (Jones and Shellam, 1999a), nor from any of the other 124 penguins from the Perth region that have been necropsied since 2004. This, and the fact that only a limited number of preerythrocytic tissue stages (and rare intraerythrocytic merozoites in the case of the spleen of 12/362) were seen in all individuals, suggests that these cases represent the outcome of lethal abortive development of *Haemoproteus* spp. in a non-adapted penguin population (Valkiunas, 2011). This is similar to the cases reported by Olias et al. (2011) in which non-adapted exotic parrots of various species in Europe died acutely; with PCR identifying parasites with 99–100% homology to *Haemoproteus* spp. known to be highly prevalent in wild European songbirds (without causing overt disease or mortality).

It is assumed, similar to the situation in human malaria (particularly that associated with *Plasmodium falciparum*) (Clark et al., 2006); that the birds, having had heavy parasite burdens (i.e. disseminated infection), died acutely as a result of the excessive release of pro-inflammatory cytokines (in particular TNF and IL-1; “cytokine storm”) secondary to the damage caused by the tissue stages (and therefore before gametocytes were able to develop), leading to systemic inflammatory response syndrome (SIRS). It is unclear whether these birds had a significant anaemia which might also have contributed to disease and death by way of exacerbating tissue ischaemia. It is also unclear how much of a role the pathogen-associated molecular pattern

(PAMP) glycosylphosphatidylinositol anchor (GPI) plays in the pathogenesis of *Haemoproteus*-associated disease; this highly conserved molecule is present in the membranes of many parasitic protozoa and elicits the synthesis of pro-inflammatory cytokines as well as nitric oxide (Ropert and Gazzinelli, 2000); thus having been implicated in human malaria via its recognition by host cell toll-like receptor 2 (TLR2) (Oakley et al., 2011).

It is probable that the dead penguins found elsewhere originated from Penguin Island, as shown by previous radio and satellite tracking data (Cannell unpubl. data). The penguin located near Garden Island (12/021) could have been either from the colony at Garden Island or from Penguin Island, as penguins from both colonies forage in Cockburn Sound (Cannell unpubl. data). As penguins are unlikely to be bitten by competent vectors of *Haemoproteus* spp. while at sea, and the penguins do not land on the mainland, they were probably infected whilst at their colony. The competent vectors of *Haemoproteus* spp. include biting midges (Ceratopogonidae) and louse flies (Hippoboscidae) (Valkiunas, 2005). The presence of louse flies on Little Penguins has rarely, if ever, been observed (Cannell pers. obs.), with fleas, lice and ticks being the listed ectoparasites on these birds (Obendorf and McColl, 1980). In contrast, biting midges are likely to be on Penguin Island and are therefore the most likely competent vector for *Haemoproteus* spp.

Apart from the 10 cases in this study, no haemosporidian have been previously found in Little Penguins in this region (Cannell unpubl. data, Jones and Shellam, 1999a), nor from colonies elsewhere in Australia and New Zealand (Quillfeldt et al., 2011). However, the distribution, density, biology, physiology and transmission rates of vectors are influenced by changes in climate and habitat (Harvell et al., 2002; Rogers and Randolph, 2006). In addition, the growth rate of the haemoparasite can also change with altered climatic conditions (Harvell et al., 2002). An anomalously strong La Niña from September 2010 and throughout 2011 was responsible for above average sea surface temperatures along the West Australian coast (Pearce et al., 2011; Pearce and Feng, 2013) and high tides causing inundation of coastal wetlands (City of Mandurah, 2011, 2012). It also affected other climatic conditions, with the mean minimum and maximum daily temperature well above average throughout the year resulting in the hottest year on record, with a record number of days $\geq 32^{\circ}\text{C}$. This temperature increase was combined with above average rainfall during the austral spring as well as heavy rainfall in the first two weeks of December (beginning of the austral summer) (Australian Bureau of Meteorology). It is therefore possible that these climatic changes contributed to a sudden increase of vectors present on the island and hence in the cases of avian haemosporidiosis documented.

Even if prevailing climatic conditions are suitable for an increased presentation of the haemoparasite, it must first be available to be transmitted and for it to shift hosts. There is evidence to suggest that some *Haemoproteus* spp. have a low host specificity and thus can be transmitted between birds belonging to different families (Fallon et al., 2005; Križanauskienė et al., 2006). However, Beadell et al. (2004) found that the stability of jumps between different host families in tropical songbirds is low, though this

could be due to the type of birds they sampled as well as their isolation. Fallon et al. (2005) found that one lineage of *Haemoproteus* was found in different bird families, dependent on the geographic region. Furthermore, the families of birds in one region were migrants that overwintered in another region. There are several species of migratory birds on Penguin Island. For example, bridled terns (*Sterna anaethetus*), caspian terns (*Hydroprogne caspia*) and crested terns (*S. bergii*) breed on Penguin Island, but migrate from the island after breeding. The caspian and crested terns are likely to move to wetland areas within the localised region (Cannell, 2004), whereas bridled terns migrate to the Sulawesi Sea for the austral winter (Dunlop and Johnstone, 1994). Further research needs to be undertaken to determine if any of these species are reservoir hosts for the *Haemoproteus* spp. found in the Little Penguins.

The dramatic increase in penguins presenting with disseminated, fatal haemosporidiosis is of concern. It is known that island hosts tend to be more susceptible to pathogens compared to mainland hosts due to lower exposure to pathogens (Levin et al., 2011 and refs within Valkiunas, 2005). In addition, the prevalence of *Haemoproteus* parasites has been shown to increase in other bird species when stressed (Quillfeldt et al., 2010). While the penguins that died from *Haemoproteus* spp. infections were not in poor body condition, the average weight of the fat pad as a percentage of body weight was lower than that identified by Hocken (2000b), particularly for the males. However, it is unknown if the Hocken (2000b) study included penguins in a premoult or moult stage, which would carry a large reserve of fat. Nevertheless, in this study, the infected penguins for which we have body-mass data were lighter than their mean body mass, and a greater than average number of penguins were found to have died as a result of starvation in 2011 (Cannell unpubl. data). It is therefore likely that the infected penguins in the present study were in a state of stress and perhaps thus more vulnerable to succumbing to the infection.

Inclusion of the *Haemoproteus* sequences from Little Penguins continues to support two main haemoparasite clades, one containing mammalian *Plasmodium* and the other avian parasites. The avian clade is further subdivided into *Plasmodium* and *Haemoproteus* clades. Previous classification divided the genus *Haemoproteus* into two subgenera, *Haemoproteus* and *Parahaemoproteus*, that form sister clades in phylogenetic analyses (Valkiunas et al., 2008b; Levin et al., 2011). Martinsen et al. (2008) found *Haemoproteus* and *Parahaemoproteus* each form distinct monophyletic clades based on limited gene sequence analysis and suggested raising *Parahaemoproteus* to be a distinct genus. The addition of the sequences isolated from the Little Penguins continue to support the conclusion that *Parahaemoproteus* and *Haemoproteus* are distinct sister clades with the penguin parasites in the *Parahaemoproteus* subgenus.

5. Conclusion

Fatal infection by haemosporidian parasites, identified by molecular means in conjunction with histopathological findings as *Haemoproteus* spp., is reported in four

of ten Little Penguins in Western Australia. Additionally, the other six cases exhibited identical histopathological findings with the presence of morphologically identical intralesional parasites. One of these also had rare intraerythrocytic merozoites. This population has previously been free of infection. Recent changes in climate, ocean currents and the presence of other species of birds which could introduce *Haemoproteus* spp. to the area could all be contributing factors ultimately leading to these infections. Further studies are needed to ascertain the epidemiology and pathology of this parasite; and indeed, to investigate the possibility of mixed apicomplexan infections in this population.

Acknowledgements

We would like to thank various departments within the Department of Environment and Conservation (DEC), who have funded the necropsies (WA Marine Monitoring Program, Species and Communities Branch, Marine Science Program) and the retrieval of many of the dead penguins (WA Marine Monitoring Program). DEC had no role in the study design, analysis and interpretation of data, writing the report or decision to submit the article. We would also like to thank all those people who have found, and informed the corresponding author about the dead penguins. Additionally, we would like to thank Daithi Murray (School of Veterinary and Life Sciences, Murdoch University) for performing the DNA extractions, Gerard Spoelstra and Michael Slaven, technologists in histology (School of Veterinary and Life Sciences, Murdoch University), for their invaluable assistance in preparing the histological sections, Victoria Hansen (University of New Mexico) for the penguin drawings used in Fig. 6, Dr Cheryl Moller (Resident in Clinical Pathology, School of Veterinary and Life Sciences, Murdoch University) for Fig. 4, and Dr Peter Irwin (Associate Professor, School of Veterinary and Life Sciences, Murdoch University) for his expertise and advice on *Babesia*. We also thank Dr Gediminas Valkunas (Nature Research Centre, Lithuania) for his very constructive comments on the manuscript. DNA samples were transferred from Western Australia to the Museum of Southwestern Biology at the University of New Mexico under U.S. Department of Agriculture permit no. 102547. The Museum of Southwestern Biology at the University of New Mexico provided assistance in importing the samples to the US. All DNA based analysis utilised the Molecular Biology Facility at the University of New Mexico which is supported by grant no. P20 GM103452-09 from the National Institutes of Health Institutional Development Award program.
