## **DEDICATION**

To my parents, Barry and Maureen, who always took interest in what I was doing, even if they thought I was just making stuff up. Thank you for the constant love, support and the steady flow of baked goods, without any of which this would not have been possible.

## **ACKNOWLEDGEMENTS**

If the past six years have taught me nothing else, it has shown me that success is seldom achieved alone. Throughout this journey I have received many helping hands from advisors, mentors, colleagues and friends. Those of you know who you are and deserve more than just a small mention on this page. Nevertheless, here goes.

First and foremost, I must thank my advisor, Dr. Debra Dunaway-Mariano, for her significant contributions to my education and research. Her expertise and guidance in my research and post-grad life has proven to be invaluable. Also, I would like to recognize Dr. Patrick Mariano and my remaining committee members (Dr. Chad Melançon and Dr. Karen Allen), and thank them for all of their advice and helpful suggestions along the way.

During my time in DDM's lab, I was fortunate enough to work with a truly fantastic group of people that I am proud to call my colleagues and friends. I want to thank my mentor, Hong, for showing me the ropes and teaching me all of the molecular biology and enzymology basics. Also, many thanks to Chunliang, who seemingly had an unlimited amount of patience in helping me with organic synthesis. To my two best friends in the lab, Tyrel and John -- thanks for all of the intellectual conversations, research discussions, the stupid pranks and of course, the dirty jokes. You guys made life in and out of the lab a ton of fun. To my two undergraduate minions, Kaila and Rachel -- you guys put in a lot of truly spectacular

work on the ligase project. Without your hard work and dedication, we would not have accomplished nearly as much as we did.

Lastly, to Kaila -- your love and support outside of the lab was the only reason I kept my sanity during these last few months. Thank you for keeping me motivated and focused on the finish line. It "litrally" means the world to me and I will be forever grateful.

**ABSTRACT**

Some of the biggest contributors to cellular respiration (and cellular metabolism in general) are acyl-CoA derivatives, a subclass of biological thioesters. Known to function in a variety of pathways, the regulation of their formation and breakdown are critical, carried about by acyl-CoA synthetases and thioesterases, respectively. The work reported within this dissertation will focus on functional divergence within two enzyme superfamilies -- the hot dog-fold and acyl-adenylate-forming superfamilies – and can be broken down into two main parts.

Part one will look at tracking the functional divergence within the hot dog-fold superfamily thioesterases. A highly evolved thioesterase, fIK, has been found to function in the critical, and highly specific role of fluoroacetate detoxification within the fluorometabolite-producing bacteria, *S. cattleya*. Using an extensive bioinformatics analysis, fIK orthologs were identified and tracked throughout all

three domains of life, primarily in bacteria that make up the gut microbiome. Additionally, sequence and structural analyses revealed distinct fIK scaffolds, a further indication of divergent functionality. Various fIK orthologs were then isolated, cloned and subjected to substrate screening by measuring their individual steady-state kinetic parameters  $k_{cat}$ ,  $K_m$  and  $k_{cat}/K_m$ . Combined with gene context analyses, divergent *in vivo* functionality was assigned to members of the fIK subfamily, as they were proposed to be involved in supplying formate for the one-carbon pool.

Part two will focus on the functional characterization of the acyl-CoA synthetases (ligases) in *Pseudomonas aeruginosa*, the dominant pathogen present in all patients with cystic fibrosis and the leading cause of morbidity and mortality within this afflicted population. Nine freestanding ligases were cloned, isolated and subjected to an extensive substrate screening for acyl-CoA synthetase activity using a novel high-throughput assay. Individual activities were verified by measuring the steady-state kinetic parameters. Combing these results with extensive gene context analyses, *in vivo* functions were proposed for the tested ligases, implicating them in a variety of nutrient scavenging pathways as well as in virulence factor production.

## **The Biological Thioester: An Overview of its Function and Regulation in Cellular Metabolism**

### **1.1 Overview of Cellular Metabolism**

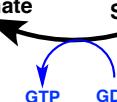

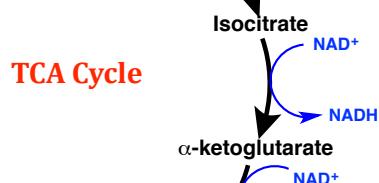

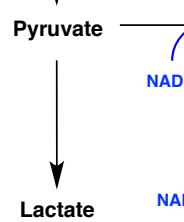

#### **1.1.1 Cellular Respiration**

Cellular respiration is the collection of metabolic processes that convert organic carbon sources (nutrients) into ATP (energy). As the main energy generation pathway for all domains of life, cellular respiration is a collection of redox reactions in which biological fuels (carbon precursors) are oxidized in the presence of an inorganic electron acceptor. Depending on the type of electron acceptor, cellular respiration can be broken down into three different categories: aerobic respiration, fermentation and anaerobic respiration. Aerobic respiration utilizes molecular oxygen ( $O_2$ ) as the terminal electron acceptor and represents the pathway utilized by all eukaryotic species as well as all obligate and facultative aerobes [1]. Aerobic respiration occurs in four steps (Figure 1-1). In short, glucose is converted to two molecules of pyruvate in a process known as glycolysis. In this process, two molecules of  $NAD^+$  are reduced to NADH and two molecules of ATP are formed. Pyruvate is then oxidized to acetyl-CoA and  $CO_2$  by the pyruvate dehydrogenase complex (PDC) in a step known as oxidative decarboxylation. Another molecule of  $NAD^+$  is reduced to NADH in the process. From here, acetyl-CoA enters the tricarboxylic acid (TCA) cycle where it is oxidized to  $CO_2$  and  $H_2O$  in an

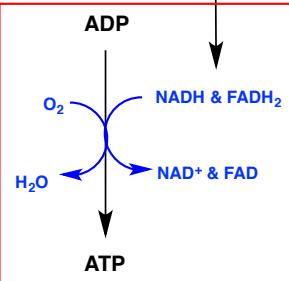

## Glycolysis

## Oxidative Decarboxylation

## Oxidative Phosphorylation

## B-oxidation

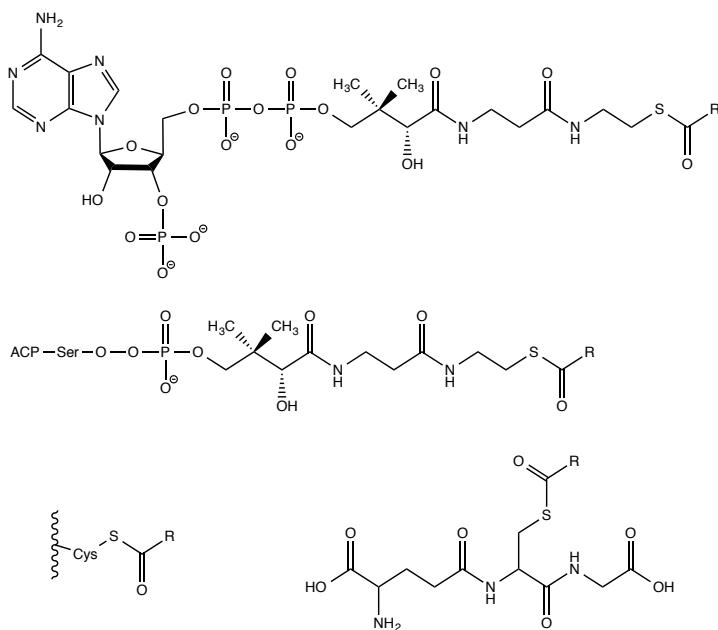

**Figure 1-1.** Overview of aerobic respiration showing how β-oxidation can feed into the TCA cycle to generate NADH and FADH<sub>2</sub>.

8-step process. The resulting molecule of oxaloacetate can combine with another molecule of acetyl-CoA to restart the cycle. During the TCA cycle, one turn produces 3 NADH, 1 FADH<sub>2</sub> and 1 GTP (which can be converted to ATP). In the last part of the aerobic respiration pathway, all of the NADH and FADH<sub>2</sub> molecules produced from the first three stages are oxidized back into their substituent NAD<sup>+</sup> and FAD. This process, known as oxidative phosphorylation, or the electron transport chain (ETS), utilizes O<sub>2</sub> as the electron acceptor and creates a chemiosmotic proton gradient that is used to drive ATP synthesis. Overall, one molecule of glucose is converted to roughly 32 molecules of ATP during aerobic respiration [2].

Both fermentation and anaerobic respiration are utilized when oxygen is limiting or completely absent. In the case of fermentation, pyruvate (formed from glycolysis) is converted into small molecule waste products, such as lactate, ethanol and CO<sub>2</sub>. During this process, NADH is oxidized back to NAD<sup>+</sup> so it is available to be re-used in glycolysis. During anaerobic respiration, neither oxygen nor pyruvate derivatives are available as the final electron acceptor. Instead, nitrate and sulfate are the most common acceptors. While both processes occur in the absence of oxygen, they differ in their mode of ATP synthesis. While anaerobic respiration utilizes an electron transport chain to generate a proton gradient (as in aerobic respiration), fermentation utilizes substrate-level phosphorylation to drive ATP synthesis. Both processes are common in gut-dwelling bacteria that survive under oxygen-limiting conditions [3].

While glucose is the preferred carbon source during aerobic respiration, carbohydrates, lipids and proteins may also be consumed as reactants when it is not

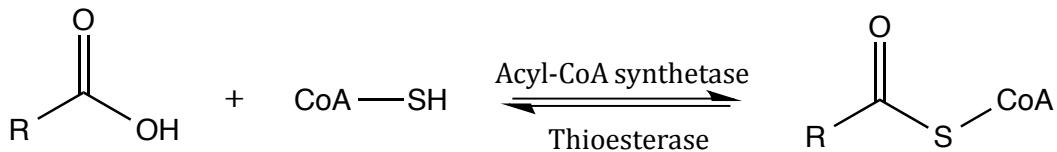

**Figure 1-2.** Common biological thioesters including (top to bottom) acyl-CoA, acyl-holo-ACP, acyl-cysteine and acyl-S-glutathione.

readily available. When protein levels are high, amino acids released from the breakdown of proteins are metabolized by a variety of specialized pathways and are converted into useful components that can enter respiratory pathways at various spots. In the case of lipids, stored fat molecules (triacylglycerides) can be broken down into their constituent glycerol and long-chain fatty acid (LCFA) components in the process of lipolysis where both can enter the respiration pathway. While glycerol can be converted to glucose, the fatty acid components must be broken down into acetyl-CoA precursors in the process of  $\beta$ -oxidation (Figure 1-1). Once converted, the acetyl-CoA byproducts enter respiration via the TCA cycle. During the

bacterial fermentation process, the breakdown of carbohydrates produces short-chain fatty acids (SCFA) like acetate, propionate and butyrate along with CO<sub>2</sub> and molecular hydrogen (H<sub>2</sub>) [3, 4]. While the SCFA ratio is dependent on diet, their absorption has been shown to play various roles in colonic health. For example, acetate can be converted to acetyl-CoA and act as a precursor for fatty acid biosynthesis or enter the TCA cycle [4]. Butyrate acts as the main energy source for colonocytes and has been implicated in the prevention and treatment of various colonic diseases [3, 4]. Overall, fatty acids of all types play a large role in cellular energy production across all domains of life. However, in order to be activated for usage in such pathways, fatty acids must first be converted to thioesters.

### **1.1.2 Biological Significance of Thioesters**

Biological thioesters serve the cell as the activated form of free organic acids and are made up of two main components: a carboxylic acid and a free thiol. While the carboxylic acid (organic acid) can vary greatly in shape, size and polarity, the free thiol component is typically the free pantotheine arm of coenzyme A (though acyl carrier protein (ACP), a free cysteine residue or glutathione may be used as well) (Figure 1-2). As an activated form of fatty acids, thioesters play important roles in cellular metabolism that include lipid synthesis and degradation, amino acid catabolism, and central carbon metabolism [5]. Additionally, thioesters have been implicated in polyketide biosynthesis and in the degradation of aromatic compounds and acylated proteins [6-8]. Beyond roles in regulating cellular metabolism, thioesters have also been found to function in solubility and transport,

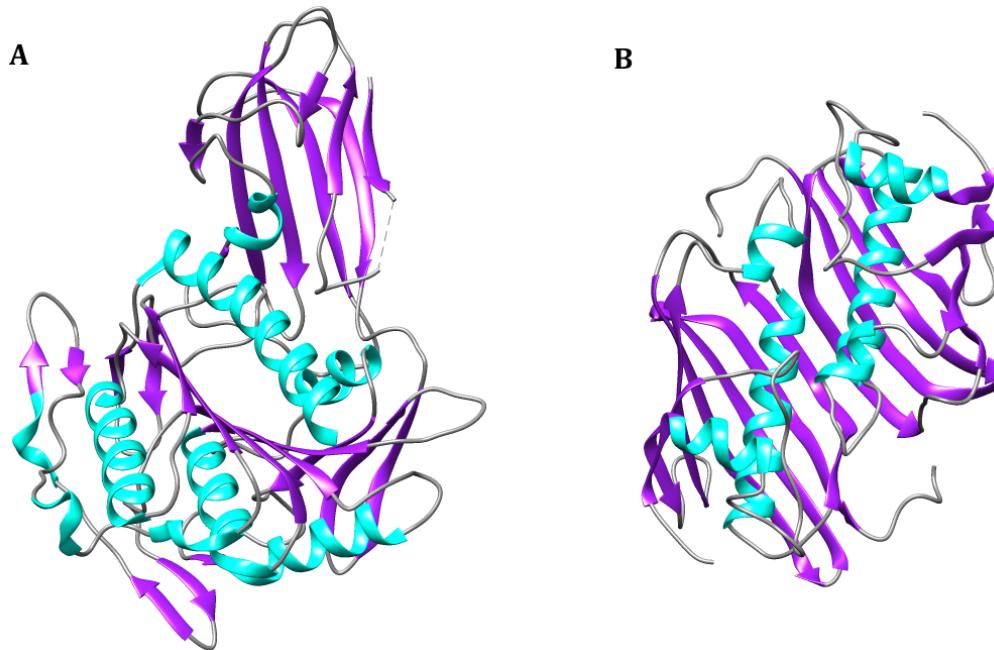

**Figure 1-3.** Activation (formation) and deactivation (breakdown) of biological thioesters.

cell cycling, signal transduction pathways and even in gene regulation [9]. Given the functional importance of these roles, the regulation of thioester formation and breakdown are critical functions carried out in the cell. Acyl-CoA synthetases (ligases) are responsible for the formation (activation) of thioester linkages while thioesterases are responsible for their degradation (Figure 1-3). The reactions carried about by both acyl-CoA ligases and thioesterases will be covered in more detail in the following sections.

## 1.2 Acyl-CoA Thioesterases

Thioesterases catalyze the hydrolysis of acyl-CoA into its free fatty acid and coenzyme A (CoA) constituents. Given this role, thioesterases are considered regulators of free CoA, fatty acid levels within the cell. Two enzyme superfamilies, the  $\alpha/\beta$ -hydrolase-fold and hotdog-fold, have evolved this function over time [10, 11]. Interestingly enough, while the overall tertiary structures of the two superfamilies are completely different, they carry out the same function, utilizing

**Figure 1-4.** Comparison of the tertiary structures of the  $\alpha/\beta$ -hydrolase fold (A) and the hot dog-fold (B). (A) Human acyl-CoA thioesterase 4 (PDB: 3K2I). (B) *E. coli* FabA (PDB: 1MKA). Residues are colored by secondary structure.

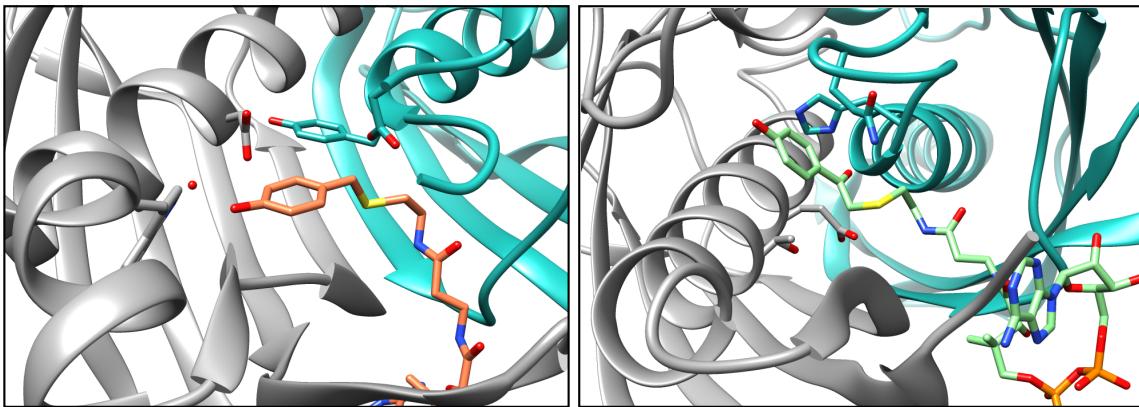

similar modes of catalysis (Figure 1-4). While both  $\alpha/\beta$ -hydrolase thioesterases and hot dog-fold thioesterases have been reported to play critical roles in cellular processes, this report will focus solely on the hot dog-fold superfamily of thioesterases.

### 1.2.1 The Hot Dog-Fold Superfamily and Hot Dog Thioesterases

The first member of the hot dog-fold superfamily was reported in 1996 as FabA, a dehydratase-isomerase involved in the *E. coli* type II fatty acid synthase

(FAS) [12]. The superfamily was given its name based on the FabA tertiary structure, which was described as a long,  $\alpha$ -helix surrounded by a highly curved, anti-parallel  $\beta$ -sheet resembling a hot dog in a bun (Figure 1-4B) [12]. All members of the hot dog superfamily share this conserved core topology, with the highly curved  $\beta$ -sheet wrapping around the right-handed,  $\alpha$ -helix ( $\alpha$ HD) in the order of  $\beta$ 1- $\alpha$ HD- $\beta$ 3- $\beta$ 4- $\beta$ 5- $\beta$ 2. Additionally, some hot dog-fold family members contain extra sequence motifs inserted between  $\beta$ 1 and the  $\alpha$ HD, as seen in the hydratase/dehydratase subfamily [13]. The minimal functional unit of the hot dog-fold family is the dimer, as the active site is formed at the dimer interface and utilizes residues from both monomer units (Figure 1-5). The hot dog-fold is ubiquitous in nature, found in all domains of life. To date, over 1300 members of the hot dog-fold superfamily have been identified, with over 60 crystal structures deposited in the protein database (PDB) [11, 14]. These enzymes are part of over 15 distinct subfamilies, which include enzymes functioning as hydratase/dehydratases, isomerasases and acetyltransferases [15]. However, the majority of hot dog-fold superfamily members are thioesterases.

The first hot dog-fold thioesterase crystal structure was reported in 1998 by the Dunaway-Mariano and Holden groups [16]. Isolated from *Pseudomonas sp.* CBS-3 and characterized as a 4-hydroxybenzyl-CoA thioesterase (4-HBT), it was discovered to function in a pathway for the degradation of 4-chlorobenzoate (4-CBA) (Figure 1-7). In 2003, another TE crystal structure was reported by the same groups from *Arthrobacter sp.* SU [17]. While it was found to be another 4-HBT functioning in an orthologous 4-CBA degradation pathway, the crystal structure

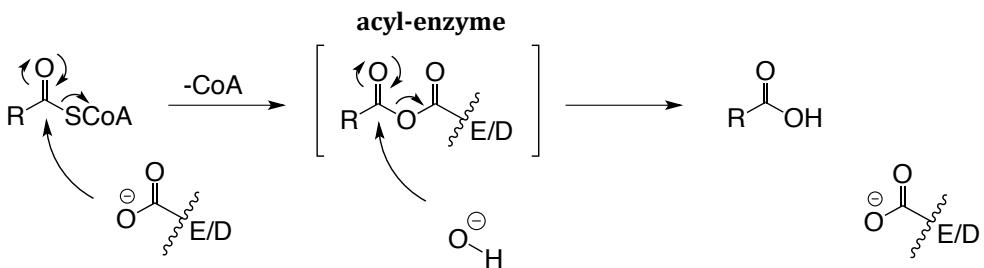

**Figure 1-5.** Active site scaffolds of 4-HBT-I from *Pseudomonas* sp. CBS-3 (PDB: 1L08) (left) and 4-HBT-II from *Arthrobacter* sp. Strain SU (PDB: 3R3F) (right). Active sites are positioned at the dimer interface. Monomer units are colored separately. 4-hydroxybenzoyl-CoA substrate analog inhibitors are colored in orange and green.

revealed a completely different active site architecture from the *Pseudomonas* 4-HBT. Soon after, the 4-HBT from *Pseudomonas* came to be known as 4-HBT-I and from *Arthrobacter* as 4-HBT-II. Since then, other HD TE subfamilies have been identified, though the majority of HD thioesterases have been discovered to resemble either 4-HBT-I or 4-HBT-II, depending on their active site scaffolds (Figure 1-5).

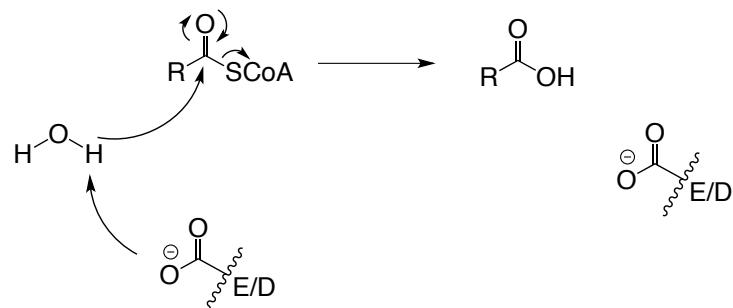

### 1.2.2 Mechanism of Catalysis of HD Thioesterases

In general, the majority of HD thioesterases (regardless of active site scaffold) utilize one of two distinct mechanisms to catalyze the hydrolysis of acyl-

### Nucleophilic Catalysis

### General Base Catalysis

**Figure 1-6.** Mechanisms of catalysis utilized by HD thioesterases.

CoA substrates (Figure 1-6). Both mechanisms, nucleophilic catalysis and general base catalysis, rely on an active site glutamate or aspartate. In nucleophilic catalysis, the active site Glu/Asp attacks the thioester carbonyl, forming a tetrahedral intermediate. Collapse of the intermediate to reform the carbonyl leads the expulsion of the CoA leaving group and the formation of an acyl-enzyme anhydride intermediate. In the final step, an activated water molecule positioned in the active site attacks either carbonyl group of the acyl-enzyme intermediate, leading to formation of the free carboxylate product. In general base catalysis, instead of

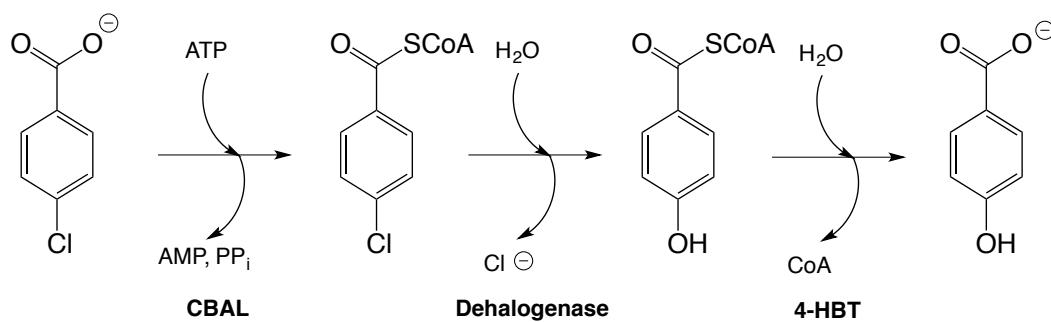

attacking the substrate carbonyl directly, the active site Glu/Asp deprotonates a water molecule, activating it for attack. Formation and subsequent collapse of a tetrahedral intermediate results in the concerted formation of both free carboxylate and CoA products.

### **1.2.3 Divergence of Function Within HD Thioesterases**

A central trait to HD thioesterases and all members of the HD family in general is degeneracy of sequence. Due to the robustness of the HD fold, a large degree of sequence degeneracy is allowed while maintaining the same overall tertiary structure. As sequence plasticity is a necessary trait for the divergence of function, the HD superfamily (and thioesterases specifically) has evolved to perform a myriad of functional roles within critical metabolic pathways.

As widely distributed substrates in nature, many bacterial organisms have evolved metabolic pathways for the utilization of aromatic compounds as carbon sources [18, 19]. Two such aromatic utilization pathways involve the degradation of 4-chlorobenzoate (4-CBA) and phenylacetate (PA).

The dehalogenation of 4-CBA proceeds through two acyl-CoA intermediates before its final conversion to 4-hydroxybenzoate (4-HBA) (Figure 1-7). The first step involves the activation of 4-CBA to 4-chlorobenzoyl-CoA (4-CBA-CoA) by 4-chlorobenzoate ligase (CBAL). The dehalogenation step follows, as a dehalogenase substitutes the chloro group for a hydroxyl group, forming 4-hydroxybenzoyl-CoA (4-HBA-CoA). The final step is carried out by the 4-hydroxybenzoyl-CoA thioesterase (4-HBT) to form 4-HBA. As mentioned earlier, the 4-HBT thioesterase

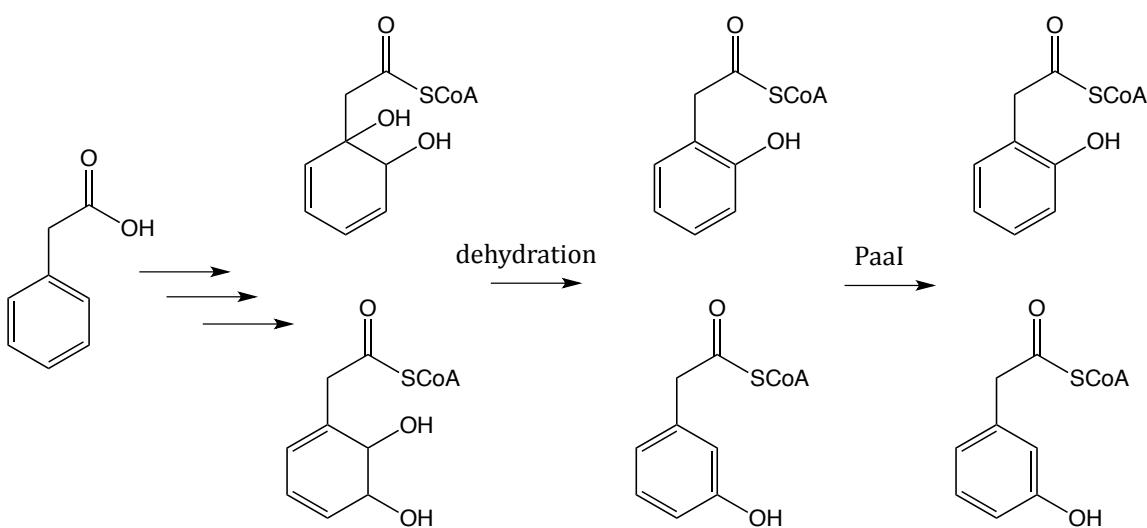

**Figure 1-7.** Pathway for 4-chlorobenzoate (4-CBA) degradation. The enzymes that carry out each step are listed in bold.

from the *Pseudomonas sp.* CBS-3 4-chlorobenzoate degradation pathway was the first HD thioesterase ever characterized.

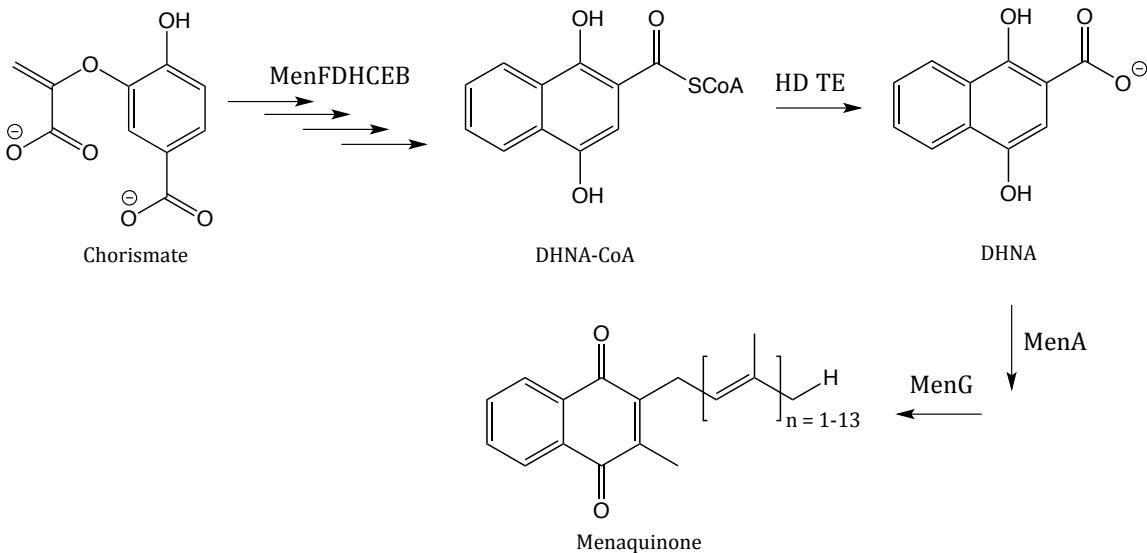

Another widely distributed aromatic compound that can be utilized by bacteria as a viable carbon source is phenylacetic acid (PA). The genes that mediate the utilization of PA are clustered together in what is known as the PAA degradation operon (Figure 1-8). The operon consists of 14 separate genes, made up of various aromatic oxygenases (PaaABCDE), genes analogous to  $\beta$ -oxidation enzymes (PaaFGHIJ) and a phenylacetyl-CoA ligase (PaaK). PaaI has been shown to hydrolyze PA-CoA and its various hydroxylated derivatives. A hot dog-fold thioesterase of the 4-HBT clade, PaaI is thought to function in rescuing CoA after spontaneous dehydration leads to the formation of the dead-end products 2- and 3-hydroxyphenylacetyl-CoA [19].

Menaquinone, also known as vitamin K<sub>2</sub>, is an essential cofactor in both

**Figure 1-8.** Abbreviated pathway for PA degradation highlighting the functional role of the HD thioesterase, Paal.

eukaryotic and prokaryotic organisms, shown to play crucial roles in blood clotting, calcium binding and cell cycle regulation [20]. Mammals, unable to synthesize menaquinone, rely on its acquisition from bacterial species within the gut microbiome and also from the ingestion of leafy vegetables. Menaquinone synthesis in bacterial systems has been extensively studied due its potential as a drug target. The synthetic pathway is a 9-step route that converts isochorismate to menaquinone, catalyzed by a gene cluster known as the Men operon (Figure 1-9). Through the actions of MenF, D, H, C, E and B, choristmate is converted to 1,4-dihydroxy-2-naphthoyl-CoA (DNHA-CoA). The subsequent step is the hydrolysis of the thioester bond, resulting in 1,4-dihydroxy-2-naphthoate (DHNA). In 2009, after much confusion about which thioesterase was responsible for this reaction

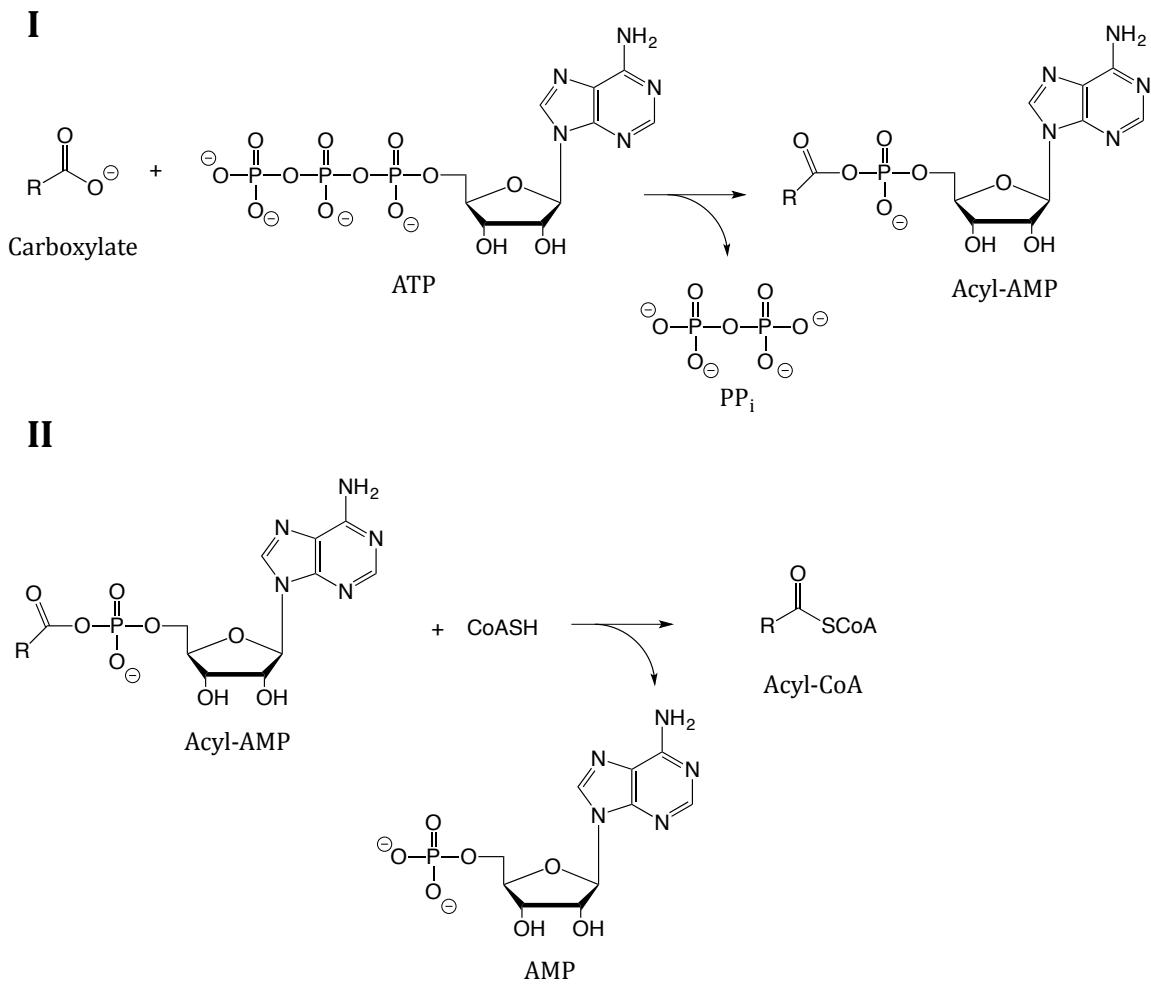

**Figure 1-9.** Abbreviated pathway for menaquinone (Vitamin K<sub>2</sub>) synthesis highlighting the role of a hot dog thioesterase.

step, it was discovered that a HD thioesterase of the 4-HBT-I clade catalyzed the hydrolysis of DHNA-CoA [21]. More recently, the *E. coli* HD thioesterase YdI was also shown to function in the Men pathway, catalyzing this particular reaction step [22].

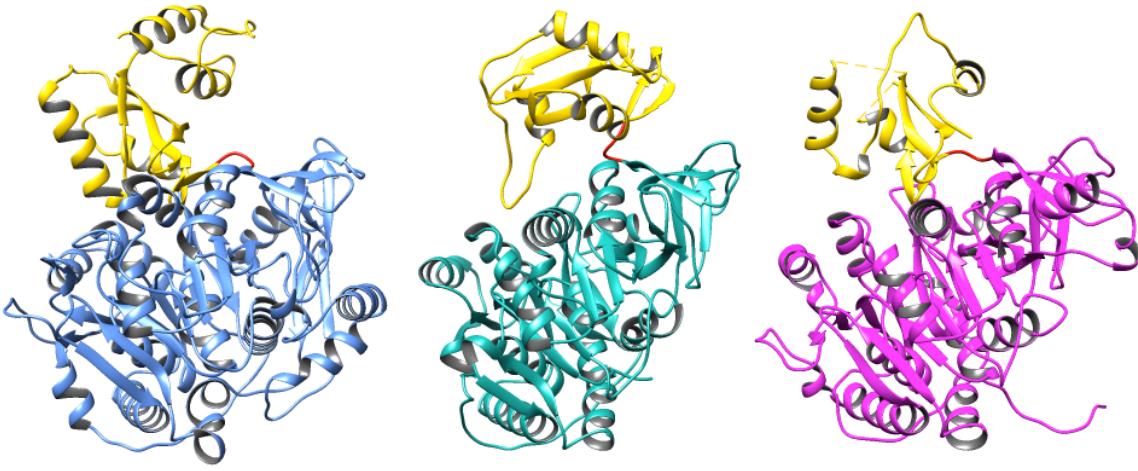

### 1.3 The Acyl-Adenylate-Forming Superfamily

Adenylation is the process by which semi-reactive carboxylate compounds are activated by condensation with amines, thiols or alcohols to give highly reactive amide, thioester or ester constituents. The enzymes that carry out adenylation reactions within biological systems are ubiquitous in nature, functioning across all domains of life, in metabolic pathways (such as fatty acid degradation and aromatic

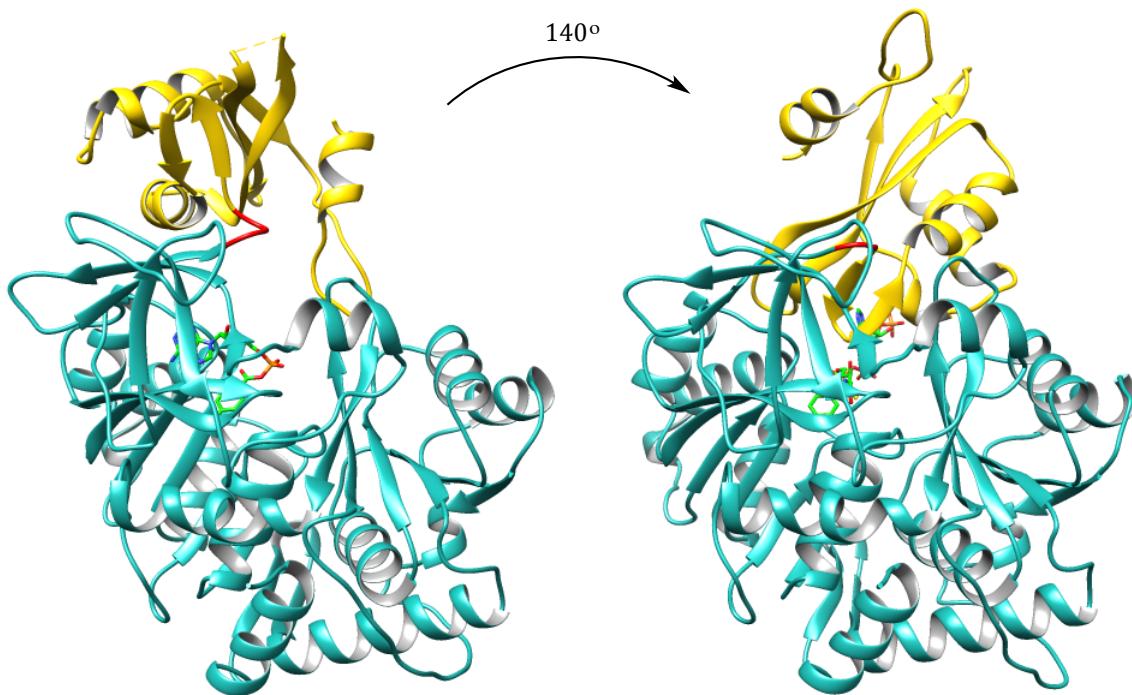

**Figure 1-10.** Reaction scheme of two-step adenylation reaction. (I) Formation of the acyl-AMP intermediate. (II) Formation of the acylated product with CoASH as the nucleophile.

compound degradation), secondary metabolite in pathways (PKS/NRPS systems), survival and virulence mechanisms and DNA translation [23-27]. Some members are even involved in the production of light [30]. Members of the acyl-adenylate-forming superfamily are divided into three classes: (I) adenylation domains within

**Figure 1-11.** Crystal structures (from left to right) of acetyl-CoA synthetase (acsA) from *S. enterica* (PDB: 2P20), 4-chlorobenzoate ligase (CBAL) from *Alcaligenes sp.* AL3007 (PDB: 3CW8) and long chain fatty acyl-CoA synthetase (fadD) from *T. thermophilus* HB8 (PDB: 1V26). N-terminal domains are colored blue, teal and magenta, respectively. C-terminal domains are colored gold and linker/hinge residues are colored red.

PKS/NRPS modules, (II) acyl/aryl-CoA synthetases and (III) luciferase oxidoreductases [28]. While the separate adenylation classes are found to function primarily in separate biochemical pathways, the reaction they carry out is essentially the same (Figure 1-10). An ATP-dependent reaction, adenylation is a two-step process in which the driving force is the production of pyrophosphate ( $\text{PP}_i$ ). Additionally, these reactions have been found to be  $\text{Mg}^{2+}$ -dependent, as the divalent cation neutralizes the charge on ATP and  $\text{PP}_i$  as well as stabilizes the

**Figure 1-12.** Depiction of C-terminal domain movement in acyl-CoA ligases using 4-chlorobenzoate ligase (CBAL) crystal structures from *Alcaligenes sp.* AL3007. CBAL with 4-CBA-adenylate bound (PDB: 3CW8) (left). CBAL with substrate analog inhibitor 4-chlorophenacyl-CoA bound (PDB: 3CW9) (right). The N-terminal domain is colored in teal and the mobile C-terminal domain is colored in yellow. The flexible linker or “hinge” is colored in red.

transition state [29]. In the first reaction, the enzyme catalyzes the nucleophilic attack of the substrate carboxylate on the  $\alpha$ -phosphate group of ATP, leading to formation and release of PP<sub>i</sub>. The second reaction step involves the binding of anucleophile (an amine, thiol, or alcohol), which attacks the carbonyl carbon of the

acyl-AMP intermediate, releasing AMP and forming the acylated product. In addition to being characterized by functional class, members of the acyl-adenylate-forming superfamily are further classified by their adopted tertiary structure. The class I tertiary structure (as seen in the acyl/aryl-CoA synthetase class) is composed of a large N-terminal domain and small C-terminal domain connected by a flexible linker (Figure 1-11). The N-terminal domain has been shown to contain 3 subdomains with an  $\alpha/\beta$  topology. The C-terminal domain, also with an  $\alpha/\beta$  topology, sits on top of the N-terminal domain like a lid [30]. During the course of the reaction, these enzymes undergo a drastic domain movement, as the C-terminal domain rotates nearly  $140^\circ$  (Figure 1-11) [24, 31-33]. This so-called “domain alteration” occurs in the middle of the two-step reaction, after the acyl-adenylate intermediate has been formed. The conformational change creates a new active site scaffold that binds the CoA nucleophile. Upon binding, the second reaction step can then commence. In the acyl/aryl-CoA synthetase class, the nucleophile in the second reaction step is thiol, coenzyme A. These enzymes play critical roles in various metabolic pathways and will be the focus for the remainder of this section.

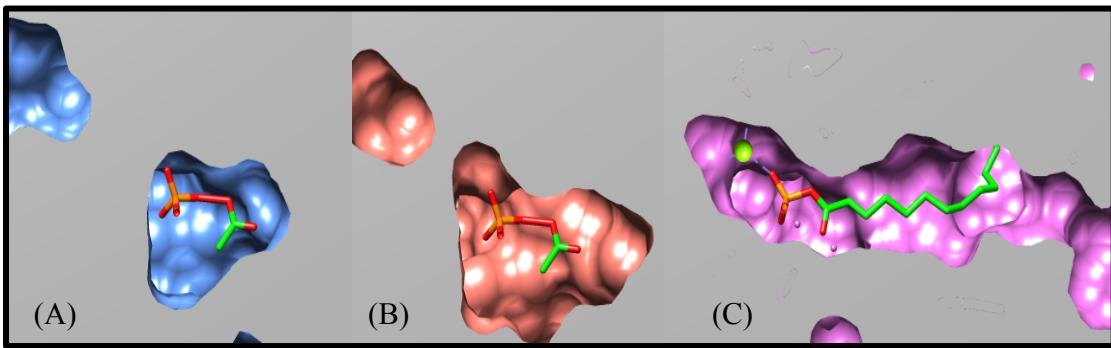

### **1.3.1 Functional Roles of Acyl-CoA Synthetases**

The majority of acyl-CoA ligases through all domains of life can be defined within four main functional roles based on the carboxylate substrates they activate. These roles are acetyl-CoA ligase, medium-chain and long-chain fatty acyl-CoA ligase and aromatic acyl-CoA ligase.

Acetyl-CoA synthetase (acs) is responsible for the conversion of acetate to acetyl-CoA and plays a large role in acetate metabolism and utilization. As acetyl-CoA is the key component of the citric acid cycle, acs genes are found throughout all domains of life. Beyond that scope, however, acs has been found to function in other pathways. For example, in eukaryotic organisms, acs has been shown to play a role in gene regulation, providing acetyl-CoA for histone acetylation by histone acetyltransferase [34].

Medium-chain fatty acyl-CoA ligases (MCFACS) are responsible for the activation of fatty acids between the carbon lengths of C6-C12. While there are few reports in the literature characterizing their function directly, the utilization of medium-chain fatty acids (MCFAs) in  $\beta$ -oxidation has been described before, indicating their functionality in this regard [35]. Some medium-chain ligases have been shown to be promiscuous towards aromatic acyl-CoA substrates, indicating a potential crossover function for these ligases [36].

The main function role of long-chain fatty acyl-CoA ligases (LCFACS) is to activate long-chain fatty acids (LCFAs) for degradation via  $\beta$ -oxidation (Figure 1-1). As a critical source of acetyl-CoA for cellular respiration, long-chain fatty acyl-CoA ligases (generally active with C16 and/or longer chain lengths) are ubiquitous in nature, found throughout all domains of life. Additionally, in prokaryotic organisms, LCFACS has been also been found to function in the transport of exogenous LCFAs across the cell membrane for entry into  $\beta$ -oxidation [37]. In eukaryotes, LCFACS activity has been shown to regulate a number of cellular processes, including

**Figure 1-13.** Relative sizes of various ligase fatty acid binding tunnels. (A) Short-chain ligase from *S. enterica* (2P2F) with acetate bound. (B) Medium-chain ligase from *M. acetivorans* (3ETC) with acetate modeled in the active site. (C) Long-chain ligase from *T. thermophilus* (1V26) with palmitate bound.

protein transport, enzyme activation, cell signaling and transcriptional regulation [37].

As discussed previously, the wide availability of aromatic compounds in the environment has driven the evolution of aromatic utilization pathways. Two such examples discussed in section 1.2.4 were the utilization of 4-chlorobenzoate and phenylacetate. In both pathways, activation of both 4-HBA and PA via aromatic acyl-CoA ligases was required for utilization as a carbon source. Another critical function of aromatic ligases is in virulence and survival, as seen in the anthranilate-CoA ligase (PA0996) in *P. aeruginosa*. An infamous pathogen known for its enhanced virulence factor production, *P. aeruginosa* is found to utilize PA0996 in the

biosynthesis of PQS, one of three main quorum signals produced for virulence factor regulation [38, 39]. This ligase is discussed in further detail in Chapter 3.

### **1.3.2 Structure-Function Relationship of Acyl-CoA Synthetases**

Given the variety of functional roles that acyl-CoA ligases carry out, it is no doubt that ligase active sites have undergone a large amount of structural evolution to accommodate such diverse range of carboxylate substrates. As seen in hot dog-fold thioesterases, a large degree of sequence degeneracy defines the acyl-CoA ligases, with little sequence homology outside of key conserved ATP and carboxylate binding motifs [ref]. Once again, sequence plasticity has allowed for the evolution of distinct active site shapes and volumes, as seen from the comparison of short, medium and long-chain ligase active sites. The crystal structure of acetyl-CoA synthetase (acs) (Figure 1-13A) reveals a short, narrow tunnel, restricting both the length (parent chain) and width (substituent groups) of the fatty acid substrate. While the fatty acid binding tunnels in medium chain-ligases are also restricted in length, they have an increased width compared to short-chain ligases, allowing for medium-chain fatty acids to wind around (Figure 1-13B). This active site shape also resembles that of an aromatic ligase, wide enough to accommodate a (potentially substituted) aromatic ring system. Long-chain ligases, on the other hand, tend to have long, narrow binding tunnels that not only allow for the accommodation of long chain fatty acids but help provide substrate specificity as well (Figure 1-13C).

## **1.4 Summary**

Both the hot dog-fold and acyl-adenylate-forming superfamilies are ancient collections of enzymes evolved to carry out a variety of biochemical functions. As seen in both superfamilies, the strict conservation of a robust tertiary structure combined with the enhanced plasticity of sequence degeneration has allowed for a wide divergence of function while still keeping maintaining a common catalytic theme.

The work discussed within this dissertation will focus on the divergence of function within both the hot dog-fold and acyl-adenylate-forming superfamilies in the context of metabolic pathways. The goal of this work is to study members of both superfamilies to discover how the divergence of function has led to a selective metabolic advantage. Chapter two will explore the f1K thioesterase from *S. cattleya* and an attempt will be made to map its functional divergence as it has evolved to perform such a remarkable role. In chapter three, I investigate the standalone acyl-CoA ligases in *Pseudomonas aeruginosa* in an attempt to discover how such a large number of ligase may contribute to pathogenesis and enhanced virulence in the lungs of cystic fibrosis patients.

The goal of this work is to further understand the critical role that evolutionary divergence of function plays in metabolic pathways and advance our knowledge of novel chemistries being carried out in biological systems.

### **Novel Thioesterase Activity from the fIK Thioesterase Subfamily Reveals a Basis For Divergent Biological Function**

#### **2.1 Introduction**

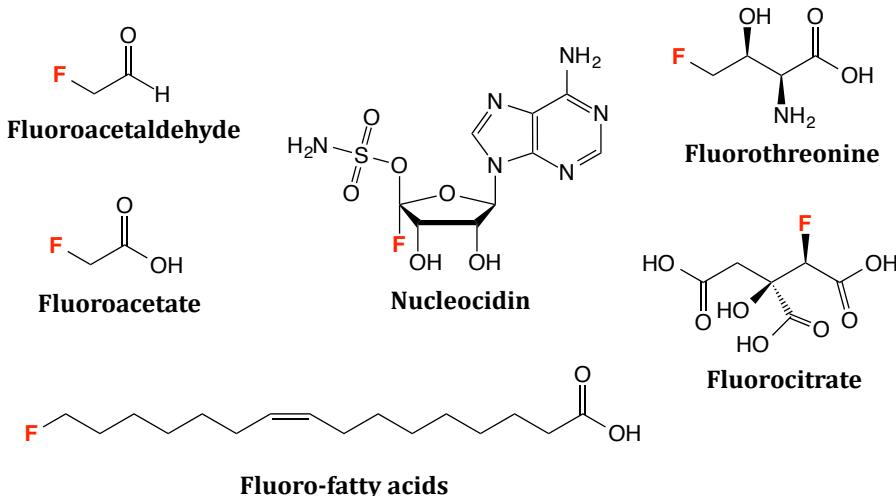

Fluorine is the most electronegative element in nature and when bonded to carbon, forms the strongest bond in organic chemistry [1]. While technically covalent, the large degree of polarization of the C-F bond lends it a significant amount of electrostatic character and provides the bond (and parent molecule) with an opportunity at a number of inter- and intra-molecular interactions otherwise reserved for ionic linkages [1]. Additionally, the atomic radius of fluorine is similar to that of hydrogen, allowing the presence of a C-F bond to provide significant electronic alterations to a given molecular structure without costly steric effects [1]. Given the ability of fluorine to substantially change the way a molecule behaves, its introduction to the pharmaceutical industry has had a profound effect on rational drug design and development. Dramatically increasing the efficacy and potency of many disease therapies, fluorinated pharmaceuticals have been used to treat a variety of diseases ranging from fungal infections and anxiety to arthritis and cancer [2]. In fact, roughly 30% of all drugs currently on the market contain at least one fluorine atom, including some of the top sellers (Figure 2-1) in recent history [3, 4]. Thanks to the development of newer and milder fluorination techniques, more and more synthetic chemists are

**Figure 2-1.** Three of the top ten selling drugs in 2011: Lipitor (Pfizer), Crestor (AstraZeneca) and Fluticasone (GlaxoSmithKline).

trying their hand at fluorine chemistry, continually adding to the already increasing number of synthetic organofluorine compounds in existence.

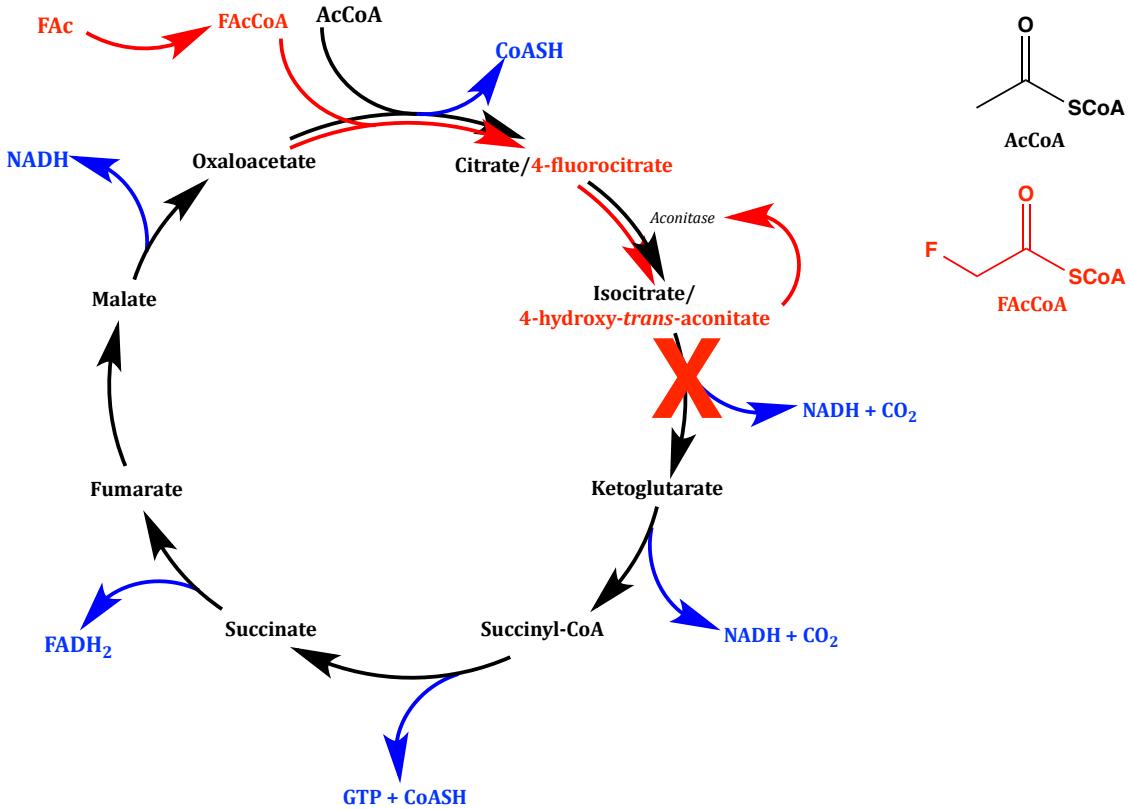

In contrast, nature is a much more modest producer of organofluorines. In general, naturally occurring organohalogen compounds are relatively common -- over 3,700 are known to be in existence [5]. However, despite the fact that fluorine is the 13<sup>th</sup> most abundant element in the earth's crust, only 30 organofluorines (less than 1% of the total number of organohalogens) are known to occur naturally [5]. This shocking revelation is explained by the fact that the majority of naturally occurring fluorine is contained as fluorite ( $\text{CaF}_2$ ) or other minerals that cannot be easily converted to molecular fluorine ( $\text{F}_2$ ) [5]. Organofluorine compounds are produced from both abiotic

**Figure 2-2.** Common biogenically-produced organofluorine compounds.

and biogenic sources, the latter of which (i.e. living organisms) producing mainly carboxylic acid derivatives (Figure 202) [5]. Of particular interest is fluoroacetate (FAc).

The most common naturally produced organofluorine compound, FAc has been found to occur in a variety of tropical and subtropical plant species throughout Africa, Australia and Brazil [5]. Originally discovered in the plant species *Dichapetalum cymosum*, FAc acts as a self-defense mechanism to deter animals like rodents and livestock from feeding on the plant leaves [6, 7]. A small molecule analog of acetate, FAc is a metabolic poison, highly toxic to all obligate aerobic organisms, especially mammals and insects [8]. A potent inhibitor of the TCA cycle, FAc is first activated as fluoroacetyl-CoA (FAcCoA) where it enters the cycle in place of acetyl-CoA (Figure 2-3). The structurally similar FAcCoA is converted to 4-fluorocitrate by citrate synthase and subsequently converted to 4-hydroxy-*trans*-aconitate (HTn) by aconitase [9]. HTn

**Figure 2-3.** Effect of fluoroacetate (FAc) poisoning on the TCA cycle. Black arrows represent normal TCA cycling with acetyl-CoA (AcCoA) while red arrows represent TCA cycling with FAc. TCA cycle inhibition is represented by a red “X”. Blue arrows denote energy-generating byproducts.

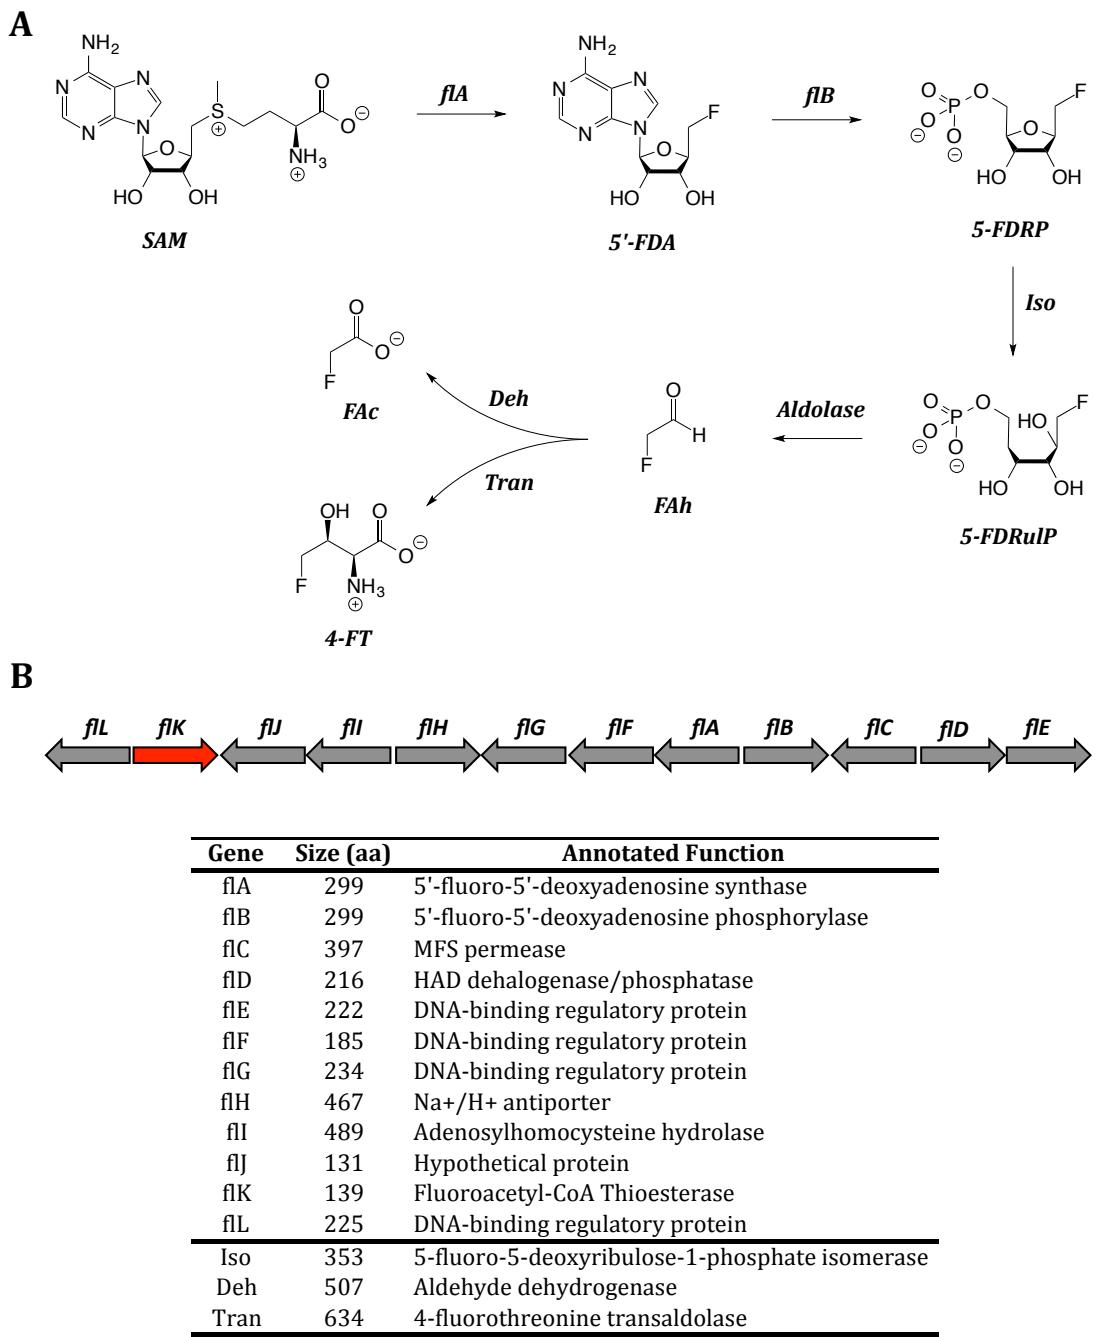

irreversibly binds the aconitase active site, thereby inhibiting any further generation of isocitrate and bringing the cycle to a complete halt [9]. The consequence is a lethal decrease in energy production mainly due to the lack of NADH and FADH<sub>2</sub>, which drive ATP synthesis during cellular respiration. Additionally, accumulation of citrate and 4-fluorocitrate leads to the inhibition of phosphofructokinase-1 (PFK-1) [10]. Regarded as

the most important step in glycolysis, PFK-1 is responsible for the ATP-dependent conversion of fructose-6-phosphate to fructose-1,6-bisphosphate. As a result, PFK-1 inhibition leads to the inability to utilize glucose as an energy source. Without the most effective means of ATP production, the organism cannot sustain and eventually succumbs to death. In fact, the lethal effects of FAc on mammals are so prominent that in the 1940's, it was first marketed and commercially supplied (under the brand name "1080") as a rodenticide and predicide, used to remove unwanted populations of rodents, wild dogs, foxes, wolves and feral pigs [11].

*Streptomyces cattleya*, a soil-dwelling actinomycete, has long been a known producer of natural products and has been found to naturally synthesize important antibiotics such as thienamycin, penicillin and cephamycin [12, 13]. More notably, however, has been the discovery of a biosynthetic pathway within the bacteria's genome inferring the ability to produce FAc as well as 4-fluorothreonine (4-FT) [14]. Extensive research has been conducted to discover the genes directly involved in the pathway and a mechanism for FAc and 4-FT synthesis has been partially elucidated. The first step is regarded as the hallmark of the pathway and is responsible for the formation of the C-F bond (Figure 2-4A). Catalyzed by 5'-fluoro-5'-deoxyadenosine synthase (flA), the SAM-dependent reaction proceeds via nucleophilic attack of a fluoride ion on the SAM ribose ring at the C5 position followed by expulsion of L-methionine to give 5'-fluoro-5'-deoxyadenosine (5'-FDA) [15]. The next step is catalyzed by 5'-fluoro-5'-deoxyadenosine phosphorylase (flB) and involves the nucleophilic attack of phosphate on the 5'-FDA ribose ring at the C1 position and subsequent expulsion of the adenine base to give 5-fluoro-5-deoxy-D-ribose-1-

phosphate (5-FDRP) [16]. Through the action of an isomerase (Iso), 5-FDRP is then converted to 5-fluoro-5-deoxy-ribulose-1-phosphate (5-FDRulP) [17]. An aldolase then catalyzes the conversion of 5-FDRulP to fluoroacetaldehyde (FAh). At this point, the pathway splits, with FAh acting as the last common precursor for both FAc and 4-FT [18]. At one branch point, an NADH<sup>+</sup>-dependent dehydrogenase (Deh) converts FAh to FAc while at the other, FAh is converted to 4-FT by a PLP-dependent transaldolase (Tran) [19, 20]. With the exception of the aldolase, all of the genes in the pathway have been identified and their function's verified. While four putative aldolases have been identified in *S. cattleya*, the one responsible for the conversion of 5-FDRulP to FAh still remains to be determined [21].

In *S. cattleya*, the enzymes responsible for the first two steps of the pathway, flA and flB, are found in the middle of a gene cluster consisting of 12 open reading frames (Figure 2-4B). While the rest of the cluster does not appear to encode any of the remaining enzymes directly involved in FAc and 4-FT biosynthesis, a number of putative auxiliary roles have been identified within. flI has been shown to be an S-adenosylhomocysteine hydrolase and is thought to relieve S-adenosylhomocysteine inhibition of flA [16]. flH is designated as a Na<sup>+</sup>/H<sup>+</sup> antiporter and was thought to be responsible for the uptake of cellular fluoride ions into the cell [21]. However, flH knockout strains showed similar levels of FAc and 4-FT production compared to wild type, indicating either a different function for flH or the presence of a redundant fluoride transporter elsewhere [21]. The proteins encoded by flE, flF, flG and flL are all annotated as DNA-binding regulatory proteins and most likely play some sort of role in regulating the fluorinase pathway. However, their exact function as not been confirmed.

**Figure 2-4.** The fluorinase pathway in *S. cattleya*. (A) Reaction steps for the synthesis of 4-fluorothreonine (4-FT) and fluoroacetate (FAc). (B) Organization of fl gene cluster with homology-based functional annotations. The genes encoding Iso, Deh and Tran are not found in close proximity to the fl gene cluster.

fIC, with an unconfirmed function as well, appears to be a member of the major facilitator superfamily (MFS) and is proposed to be involved in the transport of small metabolites (possibly FAc and 4-FT) [16]. Interestingly enough, attempts to discover the fluorinase biosynthetic cluster in other organisms have revealed its extremely limited biological range. To date, orthologous clusters have only been discovered in four other Actinomycete species: *Streptomyces* sp. MA37, *Actinoplanes* sp. N902-109, *Nocardia brasiliensis* HUJEG-1 and *Streptomyces xinghaiensis* [36-38].

Given the lethal toxicity of FAc, the need for a resistance mechanism in FAc-producing organisms is paramount. In *S. cattleya*, the protein encoded by fID is annotated as a putative HAD dehalogenase/phosphatase. Fluoroacetate dehalogenase has been described before as a mechanism of detoxification in FAc-producing plant species as well as in the non-fluorometabolite-producing bacteria *Burkholderia* sp. FA1 [22, 23]. The de-fluorination reaction not only detoxifies FAc by removing the fluoro group, but creates glycolate in the process, a metabolically useful byproduct [23]. In comparison to known FAc dehalogenase proteins, however, fID does not share a large amount of sequence identity. Additionally, fID does not appear able to rescue *S. cattleya* from the lethal effects of FAc poisoning, indicating its lack of involvement in resistance [24]. Instead, the first (and only) line of defense in *S. cattleya* resistance appears to be a thioesterase.

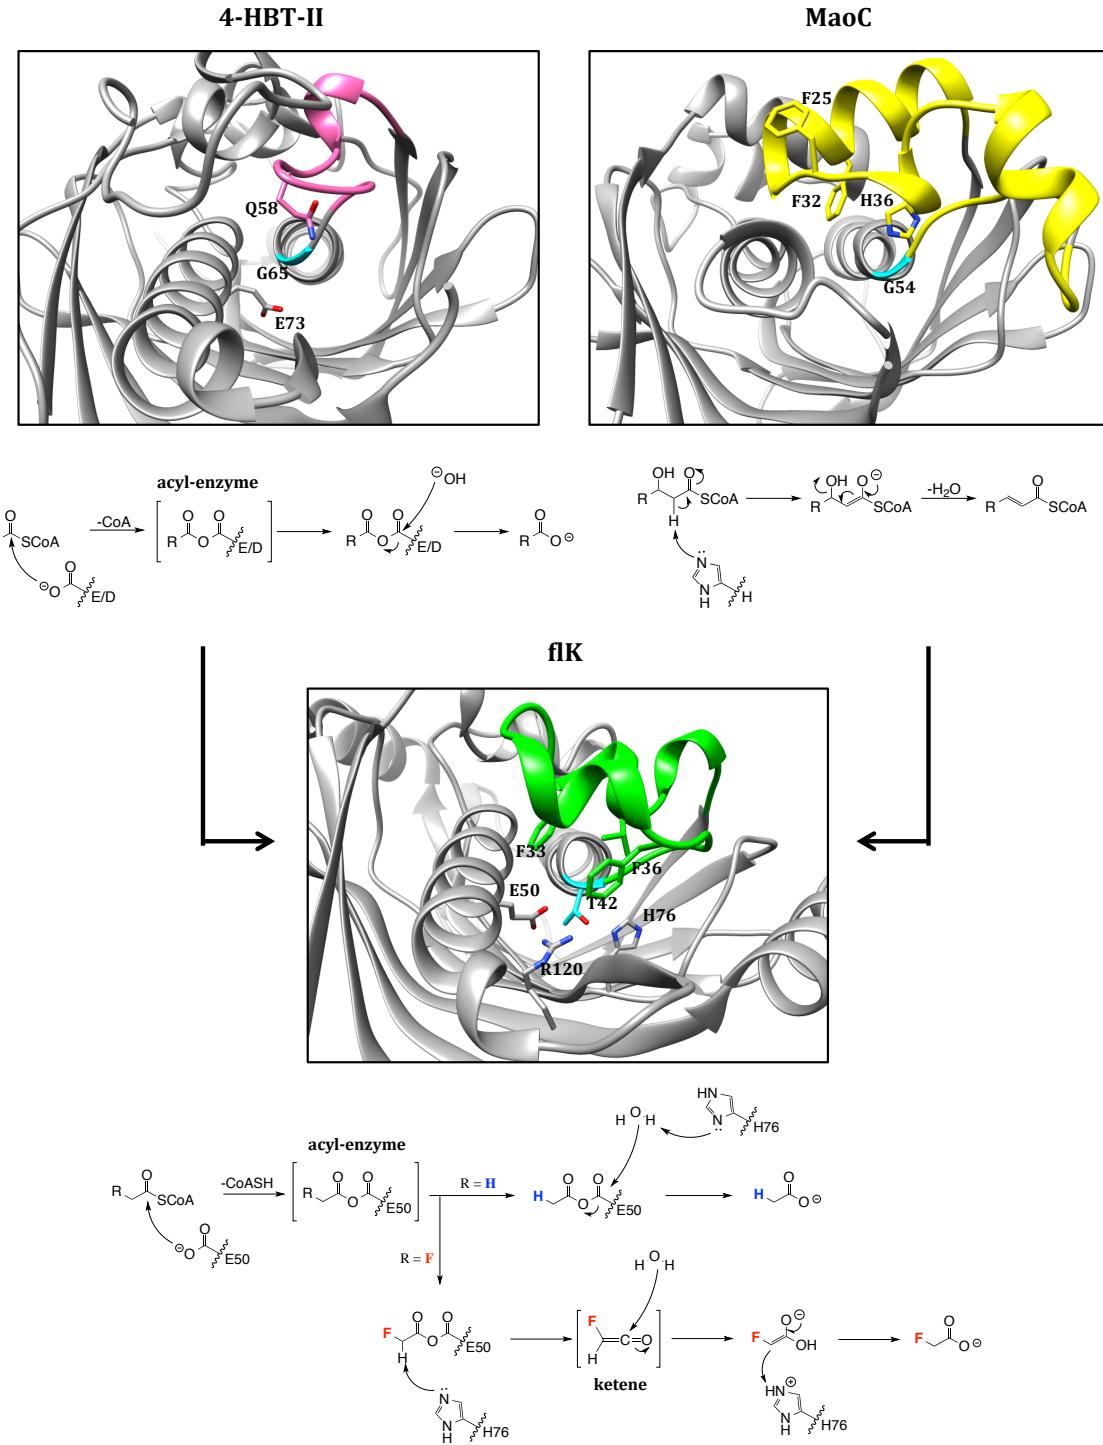

Located within the *S. cattleya* fluorinase biosynthetic cluster is fIK, a gene encoding a hot dog-fold thioesterase. The fIK thioesterase is of particular interest because of the highly specialized role it plays in cellular resistance to FAc. While HD thioesterases are known to function in a variety of metabolic pathways as well as in

other cellular processes (discussed in chapter 1), this is the first known TE to function in a resistance capacity. Multiple reports, including experiments within the body of this work, indicate that flK is highly active towards FAcCoA hydrolysis [24, 25]. The hydrolysis of FAcCoA into its constituent FAc and CoASH prevent its entry into the TCA cycle, thereby blocking the action of FAc poisoning and conferring cellular resistance. What makes the flK-catalyzed hydrolysis of FAcCoA especially impressive is the requirement to distinguish FAcCoA from AcCoA, its structurally similar (and metabolically priceless) relative (Figure 2-3). To this end, flK exhibits remarkable substrate specificity, preferring FAcCoA over AcCoA with a  $>10^5$ -fold difference in overall kinetic efficiency [24].

The high degree of substrate specificity has attracted a lot of interest in uncovering flK's underlying catalytic mechanism and studies have indicated that both catalysis and molecular recognition play a role in FAcCoA discrimination. Interestingly, it has been discovered that flK utilizes two distinct catalytic mechanisms for FAcCoA and AcCoA hydrolysis, the former of which is dependent on the recognition and positioning of the fluoro group (Figure 2-5) [26, 27]. Site-directed mutagenesis studies within the flK active site have identified a catalytic triad (Glu50-His76-Thr42) to be critical for turnover in both mechanisms [24-27]. In either case, hydrolysis is initiated by nucleophilic attack of Glu50 on the substrate carbonyl, forming an acyl-enzyme intermediate. At this point, the mechanisms diverge, depending on the polarity of the substrate C<sub>α</sub> substituent. In the case of acetyl-CoA (nonpolar – weakly polar C<sub>α</sub> substituents), it is thought that His76 is responsible for deprotonation and activation of a water molecule to attack the acyl-enzyme intermediate. The role of Thr42 appears to

be in coordinating both Glu50 and His76, as it is positioned within hydrogen-bonding distance of both. Additionally, Thr42 appears to be within hydrogen-bonding distance of the substrate thiol and may further assist in expulsion of the CoA leaving group. For hydrolysis of FAcCoA (and substrates with highly polar C<sub>α</sub> substituents), His76 is responsible for deprotonation of the fluoro-containing C<sub>α</sub>, resulting in the formation of a ketene intermediate. Attack of a water on the ketene carbon forms an enolate, which subsequently collapses to reform the carbonyl and deprotonate the histidinium group. Once again, this mechanistic pathway is thought to utilize Thr42 to coordinate and align Glu50 and His76. However, given that a T42A mutant abolishes enzyme activity for both FAcCoA and AcCoA hydrolysis, it could be acting in a more expanded, yet unknown role [25].

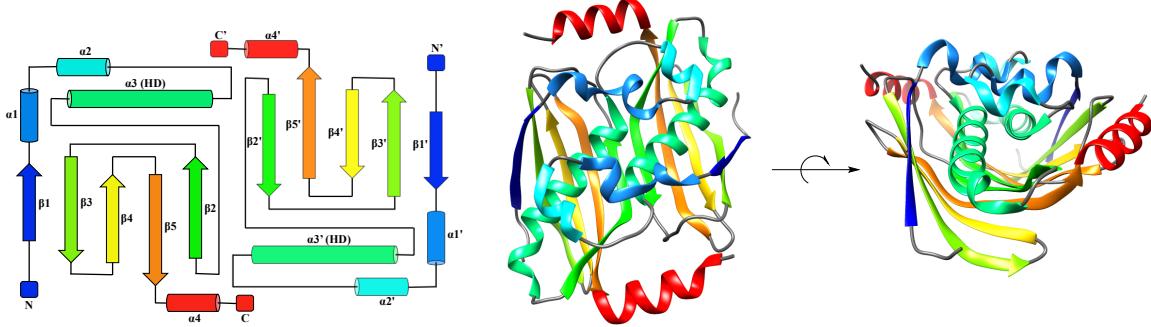

While a ketene-forming C<sub>α</sub> deprotonation mechanism has not been described before in a hot dog-fold TE, analysis of the fIK crystal structure provides further support and a basis as to how it could utilize two distinct catalytic mechanisms. Interestingly enough, fIK appears to be somewhat of a chimera, adopting structural traits characteristic of both the 4-HBT-II thioesterase and MaoC dehydratase subfamilies (Figure 2-5). fIK adopts the prototypical HD fold: a highly curved, 5-stranded β-sheet wrapped around a central α-helix (Figure 2-6). Glu50 is found positioned on the αHD of the opposing monomer subunit (αHD'), roughly corresponding to the same position of the catalytic Glu/Asp in the 4-HBT-II clade of thioesterases [28]. In both the TE and dehydratase subfamilies, hydrogen-bonding interactions with the backbone amide of the terminal αHD residue lead to polarization of the substrate carbonyl, activating it for attack [29, 30]. Additionally the oxyanion hole created in this space is able to stabilize a

**Figure 2-5.** Active site comparison of 4-HBT-II thioesterase (PDB: 1Q4T), MaoC dehydratase (PDB: 1IQ6) and flK thioesterase (PDB: 3KV8) with each corresponding

catalytic mechanism below. The loop between  $\beta$ 1 and  $\alpha$ HD comprising the lid structure are colored pink, yellow or green, respectively.

negatively charged enolate or tetrahedral intermediate. fIK is no different, utilizing the same effect, though the positioned threonine (T42) is different from the conserved glycine in the 4-HBT-II and MaoC subfamilies. This is not abnormal though, given the same effect is seen in the 4-HBT-I clade, whose members generally have a conserved Tyr positioned at the  $\alpha$ HD terminus [29-31]. Perhaps the most interesting feature of the fIK tertiary structure is an extended loop region between  $\beta$ 1 and the  $\alpha$ HD, termed the “helical lid.” While not a conserved structural motif in either 4-HBT clade or HD thioesterases in general, an extended loop region is characteristic of the MaoC dehydratase subfamily [32]. This region generally houses a catalytic histidine that acts in a  $C_\alpha$  deprotonation pathway to initiate loss of water across the  $C_\alpha$ - $C_\beta$  bond of 3-hydroxyacyl-CoA substrates [29, 32]. Furthermore, this extended loop region is known to house conserved aromatic residues that interact with the catalytic histidine through  $\pi$ -stacking interactions [29]. While the fIK catalytic nucleophile H76 is not positioned in the lid structure, two phenylalanine residues (F33 and F36) are present, potential relics of a MaoC fold. Additionally, fIK contains active site residues not conserved throughout either 4-HBT or MaoC subfamily. Arg120 is positioned in the bottom of the active site within hydrogen-bonding distance of Glu50. Given the polar nature of the C-F bond, it has been postulated that Arg120 is responsible for the orientation of the fluoro group,

**Figure 2-6.** flK topology diagram and view of tertiary structure. Each monomer subunit is color coded from N-terminus (blue) to C-terminus (red).

potentially aiding in substrate specificity [25]. However, attempts to probe the catalytic role of Arg120 through site-directed mutagenesis have resulted in unstable protein. While its catalytic role remains inconclusive, this result indicates the importance of Arg120 in a structural capacity [25].

Overall, it would appear that flK is a highly evolved member of the HD superfamily, potentially adopting the catalytic scaffolds of at least two separate subfamilies in order to carry out a highly specialized function. Additionally, given the limited biological range of the fluorinase cluster, it would appear as if this functional role is not ubiquitous in nature, but born of necessity through functional divergence. This chapter will explore the evolutionary path of the flK thioesterase through the lens of the structure-function relationship, and using a combined mechanistic, structural and bioinformatics approach, will attempt to track the divergence of function within the flK subfamily. An in-depth bioinformatics analysis is reported in the determination of the

biological range of the fIK thioesterase and in sequence and gene context analyses of putative orthologous genes. Additionally, we report an expanded substrate screening for fIK as well as the isolation and screening of multiple uncharacterized orthologs. Lastly, we report and utilize the crystal structures of two previously uncharacterized fIK orthologs. Combining all of the results together, we propose potential divergent functions being carried out by the fIK scaffold.

## 2.2 Methods and Materials

### 2.2.1 Materials

All restriction enzymes, T4 DNA ligase and Deep Vent DNA polymerase were purchased from NEB. *Pfu* Turbo DNA polymerase was purchased from Agilent and custom oligonucleotide primers were synthesized by Invitrogen. Genomic DNA was purchased from ATCC. DNA sequencing was performed in part by DNA Sequencing Services at the University of New Mexico as well as by GeneWiz. All protein samples were purified on an ÄKTA FPLC system (GE Healthcare) by monitoring UV absorbance at 280 nm. Protein concentrations were determined using the Bradford method. Various acyl-CoA compounds were synthesized or purchased from Sigma. Synthesized acyl-CoA compounds were purified on a Shimadzu Prominence UFC with a Restek Ultra Aqueous C18 reverse phase column (250 x 10 mm). All other chemicals were purchased from Sigma or Fisher unless otherwise specified. Mass spectrometry analysis was performed by the Mass Spectrometry Facility at the University of New Mexico. NMR analysis was carried out at the NMR Facility at the University of New Mexico.

### **2.2.2 Synthesis of Acyl-CoA Substrates**

Fluoroacetyl-CoA and formyl-CoA were synthesized as previously described [24, 33]. Final products were verified by  $^1\text{H}$  and  $^{13}\text{C}$  NMR.

### **2.2.3 Cloning, Expression and Purification of fIK and orthologs**

The gene encoding fIK was amplified by PCR using *Streptomyces cattleya* genomic DNA (ATCC 35852D) as the template, custom oligonucleotides as primers and Deep Vent DNA polymerase. The gene was digested using NdeI and XhoI restriction endonucleases and ligated into pET-28a(+) expression vector (NdeI/XhoI digested) using T4 DNA ligase. Vector containing the ligated gene was used to transform *E. coli* BL21(DE3) competent cells (Invitrogen). The transformed cells were grown in kanamycin-containing LB medium (50  $\mu\text{g}/\text{mL}$ ) at 37 °C until reaching an OD<sub>600</sub> of ~ 0.8. The cells were then induced with 0.4 mM isopropyl-β-galactopyranoside (IPTG) for 18 h at 25 °C and harvested by centrifugation at 6500 RPM for 10 m. Collected cells were resuspended in 50 mM HEPES, 200 mM NaCl, 50 mM imidazole, pH 8.0 (lysis buffer) until completely homogenized, and disrupted by passage through a French press at 1200 PSI. After centrifugation at 20,000 RPM, the resulting supernatant was loaded onto a 5 mL HisTrap FF column (GE Healthcare) and washed with lysis buffer. Pure protein was eluted off the column with 50 mM HEPES, 200 mM NaCl, 500 mM imidazole, pH 8.0 (elution buffer). Fractions containing pure protein were collected, pooled and dialysed against three changes of buffer (1 L each) containing 50 mM HEPES, 200 mM NaCl at pH 8.0. Purity was verified by SDS-PAGE. Yield: 8.1 mg/g wet

cell paste. Various orthologs of flK were cloned and expressed as described above, each with some modification to the procedure.

The gene encoding MA0038 was amplified from *Methanosarcina acetivorans* (ATCC 35395D-5) genomic DNA and cloned into pET-23a(+) expression vector. Transformed cells containing MA0038 were grown in LB medium containing ampicillin (100 µg/mL). Purification of MA0038 was carried out as described above. Yield: 15 mg/g wet cell paste.

The gene encoding BVU\_1957 was amplified from *Bacteroides vulgatus* genomic DNA (ATCC 8482D-5) and cloned into pET-23a(+). Transformed cells were grown in LB medium containing ampicillin (100 µg/mL). Harvested cells were resuspended and lysed in 50 mM MES, pH 6.5 (lysis buffer). After centrifugation at 20,000 RPM, the supernatant was loaded onto a 10 mL DEAE anion exchange column (GE Healthcare) and washed with lysis buffer. The protein was eluted using a gradient of 0-100% elution buffer (50 mM MES, 1 M KCl, pH 6.5) over 90 m. Semi-pure fractions were collected, pooled and concentrated to a 4 mL aliquot, which was then loaded onto a HiPrep 16/60 Sephadryl S-200 HR gel filtration column (GE Healthcare) and washed with 50 mM MES, 100 mM NaCl, pH 6.5 (dialysis buffer) until protein was eluted. Fractions containing pure protein were collected and pooled. Purity was verified by SDS-PAGE. Yield: 14.1 mg/g wet cell paste.

The gene encoding TTHA0967 was amplified from *Thermus thermophilus* (ATCC BAA-163D) genomic DNA and cloned into pET-28a(+). Transformed cells containing TTHA0967 were grown in LB medium containing ampicillin (100 µg/mL). Purification of TTHA0967 was carried out as described above. Yield: 4.14 mg/g wet cell paste.

The gene encoding Galf\_1995 was synthesized by GenScript. NdeI and XhoI restriction endonucleases were used to cut the gene out of the supplied pUC57 vector and T4 DNA ligase was used to insert it into pET-28a(+) expression vector (NdeI/XhoI digested). Expression and purification of protein was performed as described above using similar buffers at pH 7.8. Yield: 19 mg/g wet cell paste.

#### **2.2.4 Determination of Steady-State Kinetic Parameters**

Thioesterase activity was measured using a Shimadzu UV1800 UV Spectrometer and the 5,5'-dithio-bis-2-nitrobenzoic acid (DTNB) assay. Reactions were monitored at 412 nm ( $\Delta\epsilon = 13.6 \text{ mM}^{-1}\text{cm}^{-1}$ ) and carried out at 25 °C in 500 μL solutions containing DTNB buffer (50 mM HEPES, 100 mM NaCl, and 2 mM DTNB at pH 7.5), enzyme and varying concentrations of substrate ranging from 0.5-5x  $K_m$ . Initial velocity data, measured as a function of substrate concentration, were analyzed using Enzyme Kinetics v1.4 and equation (1):

$$V = V_{\max}[S]/([S]+K_m) \quad (1)$$

where  $V$  is the initial velocity,  $V_{\max}$  is the maximum velocity,  $[S]$  is the substrate concentration and  $K_m$  is the Michaelis constant.  $k_{\text{cat}}$  was calculated from  $V_{\max}/[E]$ , where  $[E]$  is the final enzyme concentration.

#### **2.2.5 Crystallization and X-ray Structure Determination of MA0038 and BVU1957**

MA0038 and BVU\_1957 crystallization and overall X-ray structure

determination was performed by Tianjiang Ji under the advisement of Dr. Karen Allen at Boston University [34].

## 2.2.6 Bioinformatic Analysis

### *Biological Range of the fl Cluster*

The biological range of the fluorinase cluster was determined using an in-house program called ContextBLAST, which was written using the Biopython package for Python 2.7 [35]. In short, individual BLAST searches were run using the NCBI database with each gene in the *S. cattleya* fluorinase cluster (including Iso, Deh and Tran) as the query sequences. Sequence matches containing >30% sequence identity over >70% query coverage were retained. Gene clustering was determined by running a BLAST search on each neighboring gene out to 10 genes on either side of the query gene. Only neighboring sequence matches in the same species as the query sequence and containing >30% sequence identity over >70% query coverage were retained. The BLAST results for all of the query sequences and neighboring sequences were compiled together and manually inspected for conserved gene clusters.

### *Ortholog Biological Range*

A sequence similarity network was generated with the Enzyme Function Initiative Enzyme Similarity Tool (EFI-EST) (<http://efi.igb.illinois.edu/efi-est/>) using the BLAST-based method with the *S. cattleya* flK sequence as the BLAST input, a minimum length of 0, a maximum length of 50,000 and an E-value cutoff of 30. A multiple sequence alignment was generated from the curated list of sequences using

Clustal Omega from the European Molecular Biology Laboratory's European Bioinformatics Institute (EMBL-EBI) (<http://www.ebi.ac.uk/Tools/msa/clustalo/>) where specific marker residues were used to filter out non-orthologous sequences. CD-HIT ([http://weizhong-lab.ucsd.edu/cdhit\\_suite/cgi-bin/index.cgi](http://weizhong-lab.ucsd.edu/cdhit_suite/cgi-bin/index.cgi)) was then used to cluster the remaining sequences into representative groupings at a 90% sequence identity cutoff. The representative sequences were then used as a filter for the original sequence similarity network to create a 90% representative node network. Sequence similarity and representative node networks were visualized using Cytoscape 3.2. Multiple alignment files were visualized using ESPript 3.0 (<http://escript.ibcp.fr/ESPript/ESPript/>).

## 2.3 Results and Discussion

### 2.3.1 Biological Range of the Fluorinase Cluster

Given the seemingly limited biological range of the fluorinase cluster, we attempted to discovered further functional clusters using an in-house program, ContextBLAST. Beyond the four organisms already discovered, our searches revealed only one other potential cluster in *Streptomyces albulus* PD-1. However, upon closer analysis of the remaining hit, alignments of the individual genes with their respective *S. cattleya* counterparts showed very little sequence identity overall. Ultimately this indicates that *S. albulus* does not actually contain a fluorinase biosynthetic cluster, though it is impossible to say for sure given the lack of experimental data.

### **2.3.2 Biological Range and Sequence Analysis of flK Orthologs**

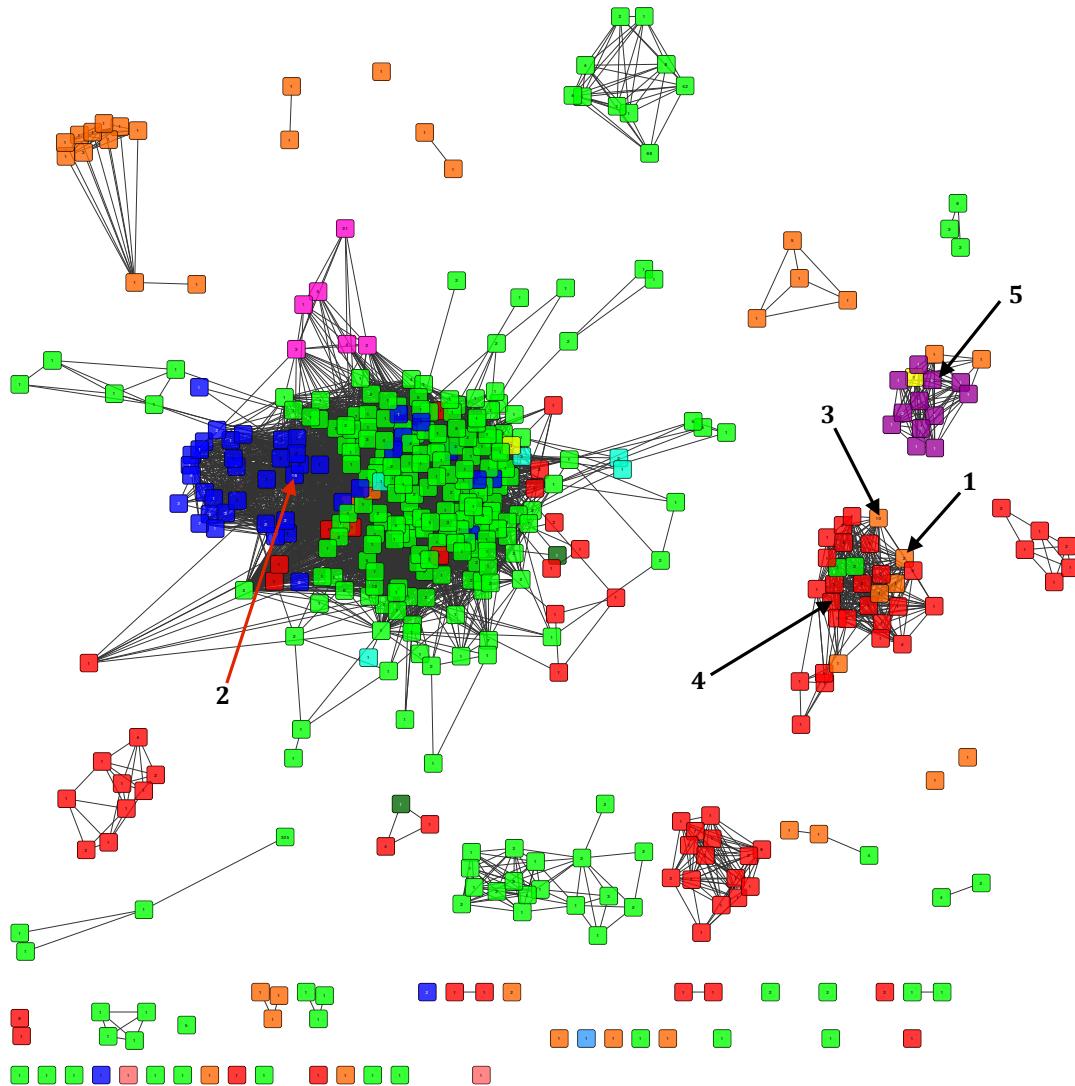

An attempt to discover orthologous flK sequences outside of fluorometabolite producers was made by tracking the biological range of the gene. To identify potential flK orthologs in other bacterial species as well as other domains of life, a BLAST search of the *S. cattleya* flK sequence generated a list of over 1,500 potential flK orthologs. To define a protein as orthologous with as much accuracy as possible, marker residues were selected based on experimental evidence of their involvement in FAcCoA hydrolysis and/or substrate specificity. Based on previous works (mentioned earlier), the active site residues comprising the catalytic triad (Thr42, Glu50 and His76) were selected as the markers. A multiple alignment file of the BLAST results was generated and sequences lacking any of the three marker residues were discarded from further evaluation. Some mutational exceptions were made, including E50D (functional interchangeability) and T42S (based on experimental evidence that a T42S mutation in *S. cattleya* flK still retained FAcCoA hydrolysis activity, albeit lower) [24]. Noteworthy residues included Arg120, which has a proposed function in positioning the substrate fluoro group [25]. However, the lack of experimental evidence indicating its necessity for FAcCoA hydrolysis or selectivity made it unwise to use as a definitive marker residue.

After filtering non-orthologous sequences based on the three defined marker residues, over 1,200 putative orthologs from more than 600 different species were identified. While the majority of orthologous sequences were found in Bacteria, a few are spread throughout Archaea and lower Eukaryotes as well. In Bacteria, putative flK orthologs appear to span a large biological range, with members discovered in 13

different phyla. While flK orthologs have been identified throughout Acidobacteria, Chloroflexi, Cyanobacteria, Deinococcus-thermus, Fusobacteria, Planctomycetes, Spirochaetes and Verrucomicrobia, they only account for roughly 10% of the total number of identified orthologs. The remaining 90% are found in Actinobacteria, Bacteroidetes, Firmicutes and Proteobacteria, indicating the true range to be narrower than previously thought.

Overall, despite sharing the same tertiary structure (the HD fold), the putative orthologs share very modest sequence homology (Appendix A-1-1). Though given the inherent sequence plasticity seen throughout all members of the hot dog-fold superfamily, this was not completely surprising. A large discrepancy can be seen in overall sequence length, with most sequences ranging between 120 and 160 amino acids. Some outlying sequences even range between 200 and 600 amino acids in length, indicating the presence of a fusion domain. However, the largest discrepancy between the flK sequence and the majority of putative orthologs is seen in the length of the lid structure and may possibly hold a clue in identifying a divergent function. Only a handful of lid sequences align with the flk lid motif, though there is still little to no sequence homology throughout this motif. The remaining sequences appear to have a truncated lid sequence (compared to flK), lacking on average six residues in the extended loop. When depicted in a representative node network (RNN), it is evident that sequence homology is quite variable between phyla (Figure 2-7). Within some, the lack of any significant sequence homology can be seen through the existence of many separate, non-connecting clusters. While in others, larger, more inter-connected clustering is evident of conserved sequence homology.

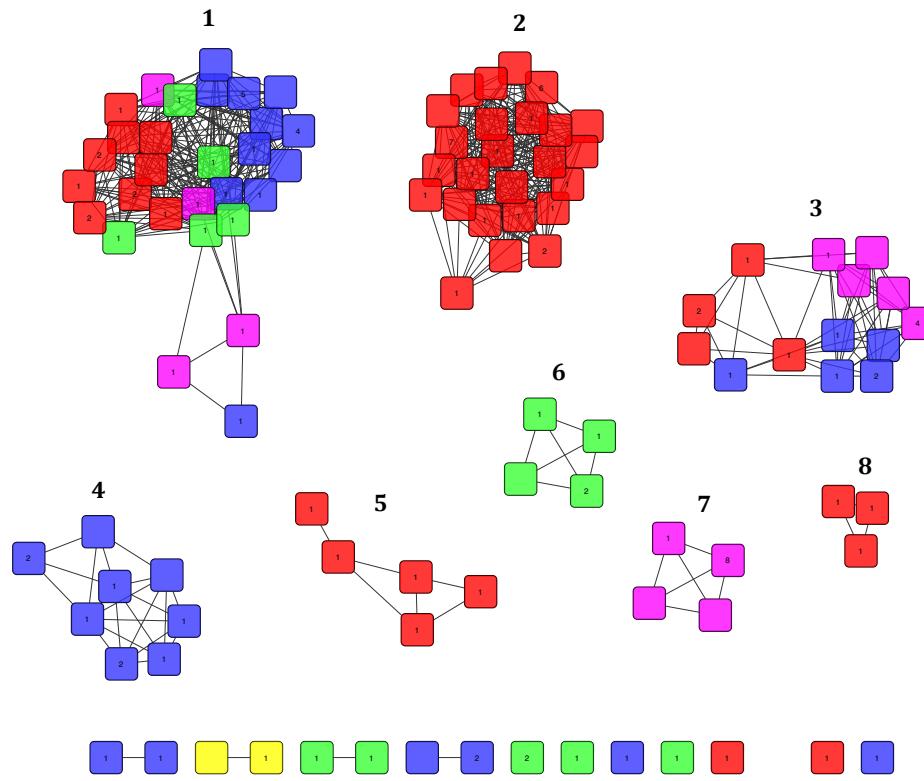

The biological range in Actinobacteria, the only phylum with fluorometabolite-producing organisms, is surprisingly limited with putative orthologs only found in 51 different species (8% of the total number identified). Despite the fact that almost all of the sequences exclusively belong to the order of Actinomycetales, a very modest degree of homology is shared throughout, seen again in the RNN by the many distinct Actinobacteria clusters. Within this small population of orthologs, very little conservation of sequence length is noticed, with monomers ranging anywhere from 119 to 156 amino acids, and even one at 197 amino acids in length. Additionally, the same large discrepancy in the length of the lid sequence can be tracked within Actinobacteria, with the majority of putative orthologs containing a truncated lid structure (Appendix A-1-2). Unexpectedly, the closest fLK orthologs (with the exception of *S. xinghainesis* and *S. sp MA37*) are not members of Actinobacteria, but rather part of Proteobacteria. Altogether, it would appear is if the fLK thioesterase has not been traditionally evolved throughout Actinobacteria. Rather, it would appear as if *S. cattleya* and the other fluorometabolite-producing organisms acquired the TE from Proteobacteria through horizontal gene transfer (HGT). As for the remaining orthologs, the limited range and lack of sequence homology with any other bacterial members give little clues as to the biological roles they may be playing. Putative orthologs within the Bacteroidetes phylum are found primarily within the Bacteroidales order, evenly distributed throughout the Bacteroidaceae, Porphyromonada, Prevotellaceae and Rikenellaceae families. Orthologs in this phylum account for only 12% of the total number, and while conservation of sequence length is modest (about the same as in Actinobacteria), the RNN shows a large grouping of inter-connected clusters, indicating that the overall

**Figure 2-7.** Representative node network of putative bacterial fIK orthologs. Representatives are color-coded by phylum: Acidobacteria (Dark Green), Actinobacteria (Orange), Bacteroidetes (Blue), Chloroflexi (Yellow), Cyanobacteria (Lavender), Deinococcus-Thermus (Purple), Firmicutes (Green), Fusobacteria (Pink), Planctomycetes (Salmon), Proteobacteria (Red), Spirochaetes (Teal), Verrucomicrobia (Grey). Cloned orthologs are indicated by arrows: (1) fIK, (2) BVU\_1957, (3) cgp\_0542, (4) Galf\_1995, (5) TTHA0967.

sequence homology within Bacteroidetes is much higher. Additionally, a multiple sequence alignment indicates the majority of residue positions are moderately-to-highly conserved within the phylum (Appendix A-1-3). Furthermore, the truncation of the lid structure appears to be a defining feature within Bacteroidetes, as every putative ortholog is lacking residues in the extended loop. Given the higher overall sequence homology within Bacteroidetes, it is more likely that these sequences were all derived from a more common ancestor, and therefore, a common function.

In Proteobacteria, the second largest grouping of fIK orthologs (25%), sequences are distributed predominantly throughout the Alpha and Beta classes, modestly throughout the Delta and Gamma classes and weakly in Epsilon. As seen in Actinobacteria, there is a large degree of sequence diversity within the phylum (Figure 2-7). Furthermore, a multiple sequence alignment indicates a very low overall shared homology (Appendix A-1-4). However, further inspection shows the presence of distinct groupings that share moderate sequence identity within, and based on the lid motif alone, three distinct groupings were identified. Roughly 60% of the sequences within Proteobacteria contain a truncated lid sequence while 40% contain a full-length lid as seen in the fIK sequence. Interestingly enough, the sequences containing the full lid motif are further divided into two distinct groupings. While the motifs in either group appear to be similar in length, sequence homology is wholly unconserved. The larger of the two groupings shows fair conservation within its motif and the sequences align more or less with the fIK lid. The smaller grouping indicates no conservation beyond a similar sequence length. While it would appear that the majority of sequence homology within Proteobacteria is class-dependent (Figure 2-8, clusters 2 and 4-8), the

**Figure 2-8.** Representative node network of putative bacterial fIK orthologs within Proteobacteria. Representatives are colored by class: Alpha (red), Beta (blue), Delta (green), Epsilon (yellow), Gamma (pink).

closest orthologs to the original fIK sequence are spread throughout all 4 classes (Figure 2-8, cluster 1).

Firmicutes contains the largest number of ortholog-containing species (over 55%). Given that the number of compared sequences (over 350) is significantly larger than in any other phylum, sequence conservation within the Firmicutes is fairly high. While separate groupings of low sequence homology do exist with the phylum, the

majority of sequences are clustered together, indicating a possible common function (Figure 2-7). Within Firmicutes, the majority of sequences belong to the Clostridia class with moderate groupings in Bacilli and Negativicutes. Furthermore, over 50% of the sequences within Clostridia are found in the genus *Clostridium*. Interestingly enough, the majority of Firmicutes sequences are clustered with the majority of Bacteroidetes, indicating a large degree of inter-phylum homology. Additionally, this could point to a potential common ancestor in the evolution of a divergent function. Analysis of the sequences within Firmicutes indicates that the majority contains a truncated lid structure, not surprising given the close clustering of the Firmicutes with the Bacteroidetes (Appendix A-1-5).

While the orthologs within Deinococcus-Thermus (DT) only account for roughly 3% of the total number identified, they contain some interesting sequence modifications not seen across other phyla. Orthologs within this phylum contain the largest degree of sequence homology, with the majority of residue positions highly or completely conserved. This can be seen in both the RNN by the tight clustering of the phylum (Figure 2-7). Interestingly enough, while members of DT contain a semi-truncated lid motif (as compared to fIK), it appears to be distinct from the lid truncation seen throughout Bacteroidetes and the majority of orthologs (Appendix A-1-6). Additionally, the most distinct sequence variation is in the highly conserved active site Arg residue. Throughout all of the orthologs within DT, this residue is mutated to Gln. Given the proposed (though unverified) function of this residue in fIK, this mutation could have a profound effect on the active scaffold, altering its chemistry and substrate specificity.

Overall, sequence analyses of the fIK orthologs indicate three distinct sequence motifs centered on the helical lid structure. Given its proximity to the active site, discrepancies in its overall shape could potentially alter substrate specificity and overall functionality, and may provide a basis for functional divergence. The full-length lid (fIK-like) motif has been found to be fairly limited within the fIK subfamily, and may indicate that its function is not widespread throughout. As well, the semi-truncated lid motif seen in DT is limited within its phylum, potentially a result of specific functionality within this group of bacteria. Conversely, the truncated lid motif seen in all Bacteroidetes species has a wide biological range, as it is found in the majority of orthologous sequences. If the truncated lid sequence has indeed resulted in a divergent function, the majority of fIK orthologs would be performing a biological role that is different from the FAc resistance function performed by fIK.

The human gut microbiome is a complex community of bacterial species that have been found to play significant roles in human health. Thought to be composed of over 1,000 species of bacteria, the gut microbiome is estimated to contain over 100-fold more genes than the human genome, and is often referred to as a “hidden organ.” [43] Given the staggering number of inhabiting species, the biological range of the gut microbiome could be considered fairly limited, as its inhabitants (primarily) are members of Firmicutes and Bacteroidetes. Within Firmicutes, the dominant species are members of the genus *Clostridium* whereas in Bacteroidetes, the dominant species are members of *Bacteroides* and *Prevotella* genera [43]. To a lesser degree, the gut is also populated by species within Actinobacteria, Fusobacteria and Verrucomicrobia [43]. Overall, this biological range is consistent with the biological range of fIK orthologs.

Additionally, as the majority of sequences within these phyla contain the truncated lid motif, especially in Firmicutes and Bacteroidetes (the two major factions of gut microbiota), it is possible that the fIK scaffold may have evolved throughout the gut microbiome to perform a role specific to this environment.

### **2.3.3 Cloning and Isolation of fIK Orthologs**

To test for alternative functionality within the fIK subfamily, specific orthologous sequences were selected for cloning, isolation and testing. In total, ten (previously uncharacterized) orthologs (*S. cattleya* fIK included) were chosen (Table 2-1). Unfortunately, only six of the ten selected (MA0038, cgp\_0542, fIK, BVU\_1957, TTHA0967 and Galf\_1995) were successfully isolated. The remaining orthologs were successfully cloned but were unable to be isolated due to stability issues.

### **2.3.4 Substrate Specificity of fIK Orthologs**

All of the cloned and isolated orthologs were assayed for thioesterase activity by measuring individual steady-state kinetic parameters for the hydrolysis of various acyl-CoA substrates (Table 2-2). To start, each protein was assayed for FAcCoA and AcCoA hydrolysis activity in order to measure the amount of substrate discrimination exhibited between the two. High-level discrimination is the hallmark of the fIK reaction and the basis for its biological function in allowing normal TCA cycle in the presence of FAc. Discrepancies in this trend may indicate alternative functionality. For accurate comparison, FAcCoA and AcCoA hydrolysis activity was also measured with the original *S. cattleya* fIK under the same conditions. As expected, fIK displays high activity towards

**Table 2-1.** Taxonomic information of fIK orthologs selected for cloning and isolation.

FAcCoA while exhibiting an almost  $10^5$ -fold decrease in AcCoA activity. This large discrepancy in activity between the two substrates is mainly due to the  $>2000$ -fold decrease in  $k_{cat}$  for AcCoA, though  $K_m$  is also increased by  $>100$ -fold. Overall, this activity measured for FAcCoA and AcCoA hydrolysis by fIK is in good agreement with previously reported steady-state parameters [24, 25].

While all isolated orthologs displayed activity towards FAcCoA hydrolysis, not all were able to discriminate between FAcCoA and AcCoA at a high level. In fact, only MA0038 and TTHA0967 displayed fIK-like discrimination ( $10^4$  and  $10^3$ -fold differences, respectively) between FAcCoA and AcCoA hydrolysis. Given the Arg/Gln mutation in TTHA0967 (member of Deinococcus-Thermus), this result indicates that Arg120 in the fIK active site is not critical for FAcCoA hydrolysis. The loss of substrate discrimination in BVU\_1957 and Galf\_1995 was due exclusively to lower FAcCoA activity as both showed AcCoA activity at comparable or lower levels to that of fIK. While BVU\_1957 displayed a  $K_m$  value comparable to fIK, the measured  $K_m$  for Galf\_1995 was almost 10-fold lower. In both cases, the main contribution for the decrease in activity was seen in the measured  $k_{cat}$  value, which was about  $10^3$ -fold lower than that of fIK, indicating that

turnover, not binding, is the major factor. With cgp\_0542, nearly a complete loss of FAcCoA/AcCoA discrimination was seen, as FAcCoA activity was only increased 2.6-fold compared to AcCoA. Both a decrease in FAcCoA activity and an increase in AcCoA activity contributed to this loss. cgp\_0542 displayed faster turnover and tighter binding with AcCoA (as compared to fIK) while FAcCoA activity suffered mainly due to a decrease in turnover, not binding affinity. The large difference in fIK and cgp\_0542 was an odd result, given that the two proteins share a fairly large sequence identity for this subfamily (Figure 2-11). While it seems unlikely, it is possible that slight structural variations have given rise to this dramatic variation in substrate specificity.

Aside from measuring FAcCoA and AcCoA hydrolysis activities, an expanded substrate screening was performed on fIK and all five orthologs. With the exception of BVU\_1957, all orthologs (including fIK) displayed moderate acetoacetyl-CoA (AacCoA) hydrolysis activity, with kinetic efficiencies measuring in the range of  $10^2$ - $10^4$  M $^{-1}$ s $^{-1}$ . Interestingly enough, cgp\_0542 displayed slightly higher activity towards AacCoA than FAcCoA, the only ortholog to do so. Also, all orthologs tested (including fIK) were shown to be active towards formyl-CoA (HCoA). As with fIK, MA0038 and TTHA0967, HCoA hydrolysis activity did not exceed FAcCoA hydrolysis -- their kinetic efficiencies ranged from  $10^1$ - $10^2$ -fold lower. In the case of BVU\_1957, cgp\_0542 and Galf\_1995, HCoA hydrolysis was favored as they each exhibited the highest overall kinetic efficiencies with this substrate. Furthermore, BVU\_1957 exhibited the highest overall kinetic efficiency towards hydrolysis of HCoA of any other ortholog/substrate pair. The measured  $10^7$  kinetic efficiency is due exclusively to a nanomolar K<sub>m</sub>, indicating HCoA has very tight binding interactions in the BVU active site. Given that BVU\_1957

exhibited the smallest substrate range, (only active with HCoA and FAcCoA), this supports the notion that the truncated lid motif has resulted in an altered substrate specificity profile, and potentially a different biological function.

Additionally, both MA0038 and TTHA0967 exhibited slight activity towards aromatic acyl-CoA substrates. While MA0038 displayed only slight to moderate activity towards benzoyl, gentisyl and 3-hydroxybenzoyl-CoA, the measured  $K_m$  values for all three substrates were very competitive with (and in some cases, lower than) the respective  $K_m$  values for formyl-, acetyl-, fluoro- and acetoacetyl-CoA. This indicates that while turnover is low, the active site is able to easily accommodate aromatic substrates. TTHA0967 displayed low level activity for benzoyl-CoA and phenylacetyl-CoA. While the measured  $k_{cat}$  for phenylacetyl-CoA was reasonable compared to other substrates, its high  $K_m$  value indicates that the TTHA0967 active site is not set up to accommodate this substrate. On the other hand, the measured  $K_m$  for benzoyl-CoA was competitive with other measured substrates while  $k_{cat}$  was much lower, highlighting the effect that the phenylacetyl-CoA methylene group plays in substrate binding and specificity.

### 2.3.5 Structural Analysis of fIK and Isolated Orthologs

With the substrate screening results indicating the potential for divergent function, a structural analysis of available ortholog crystal structures was carried out to identify a structural basis for these results. To date, only the crystal structures of fIK and TTHA0967 had been solved [24, 25, 39]. However, attempts to crystallize MA0038 from *M. acetivorans* and BVU\_1957 from *B. vulgaris* were successful. Additionally, a crystal structure of BVU\_1957 with coenzyme A (CoASH) co-crystallized was also

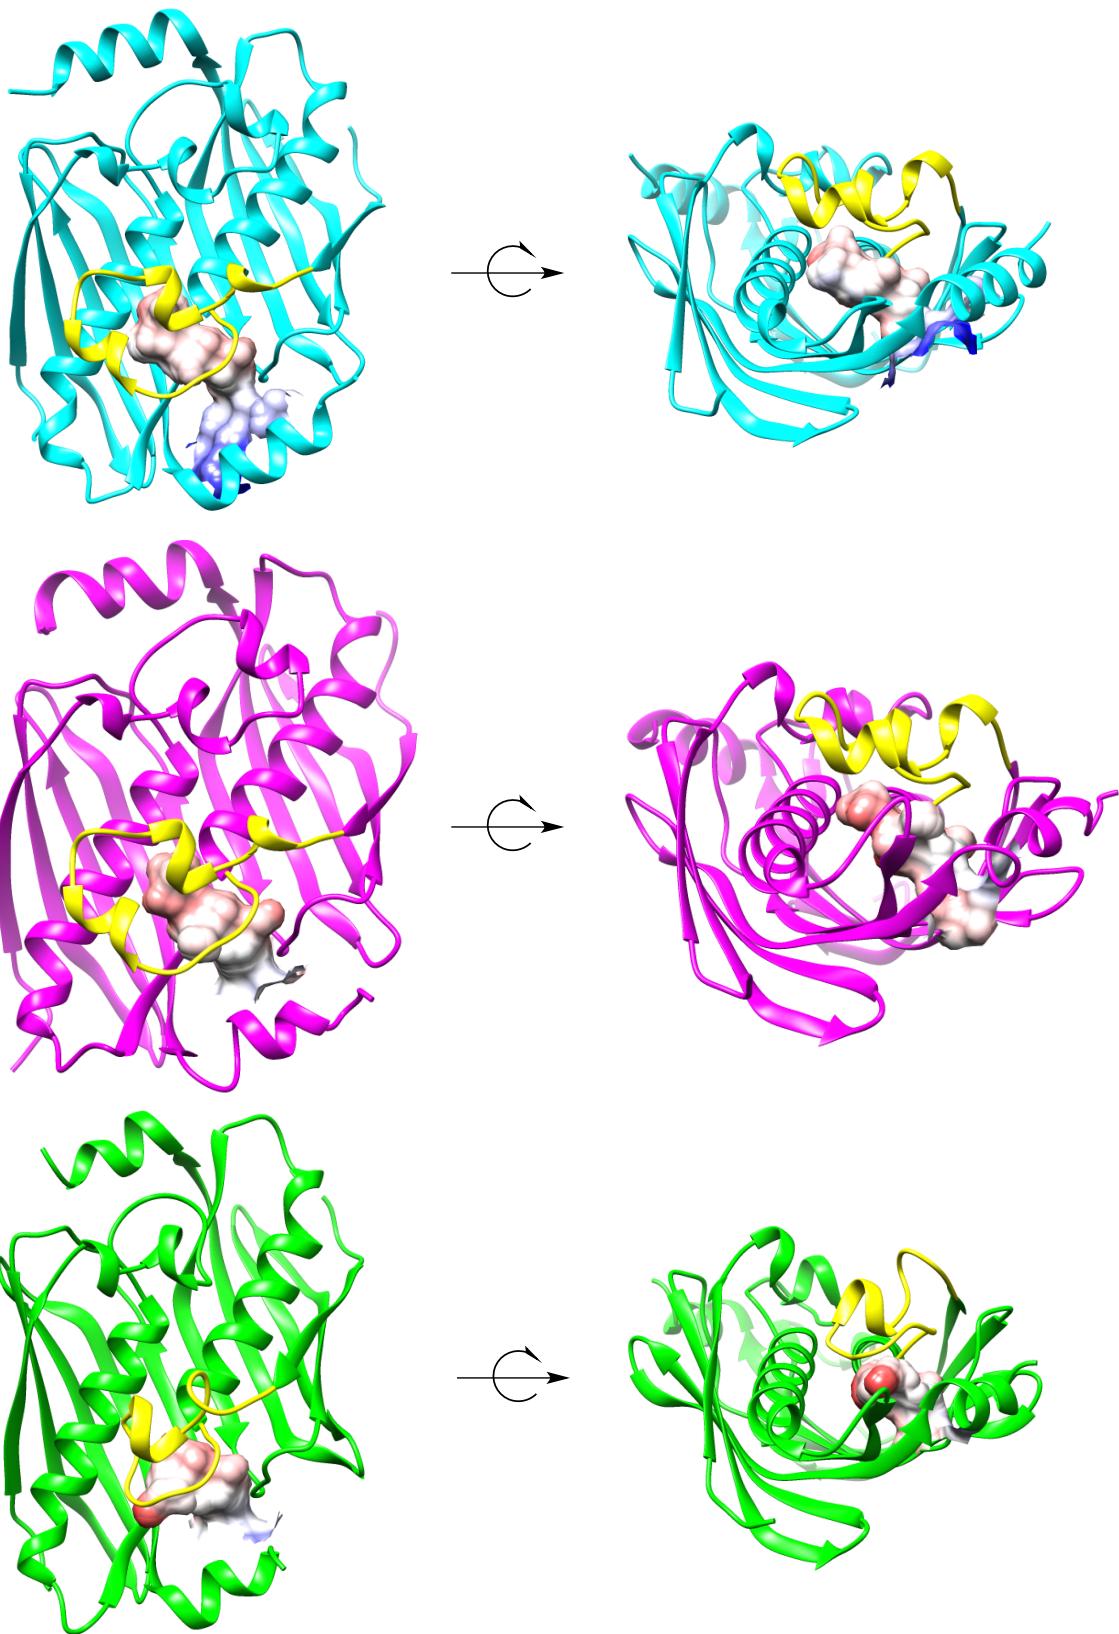

**Figure 2-9.** Crystal structure overlays of flK (PDB: 3KV8) (blue), MA0038 (pink), BVU\_1957 (green) and TTHA0967 (PDB:2CWZ) (orange). Insert shows conservation of key catalytic residues.

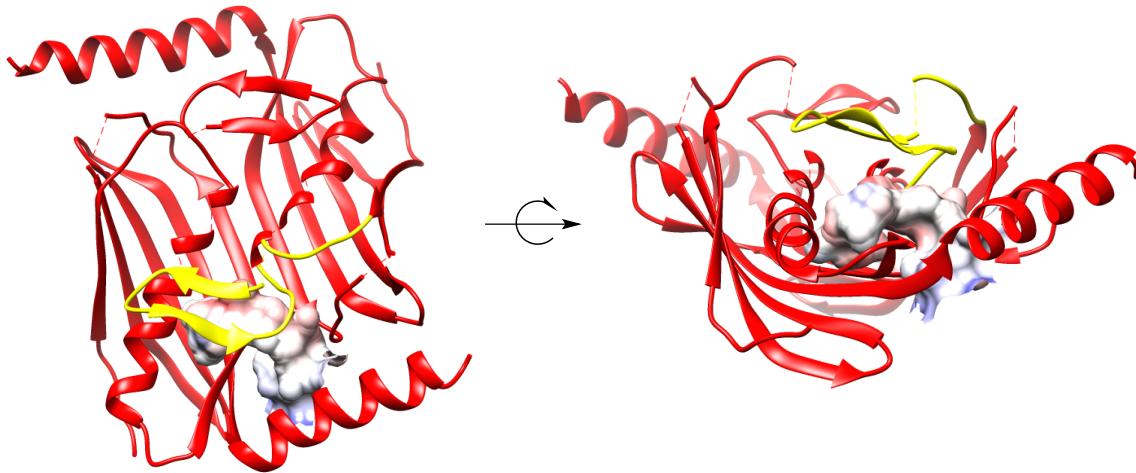

obtained. Unfortunately, attempts to crystallize Galf\_1995 for X-ray structure determination were unsuccessful.

In general, all four of the crystal structures overlay very well, indicating an overall conservation of the core fold (Figure 2-9). Additionally, the active site marker residues (Thr, Glu and His) are all in relatively identical positions, indicating the same mode of catalysis (Figure 2-9). Given the conservation of catalytic residues, the differences in activity must be due to changes in active site topology. To further analyze

the active site architectures of the four orthologs, active site volumes were generated using the CASTp server [40]. Overall, it appears as if two structural features define the active site spaces of fIK and the other orthologs: the size and flexibility of the lid motif and the positioning of the (mostly conserved) arginine residue. According to its substrate specificity profile, fIK shows a fairly limited range, only active towards substrates with relatively small acyl (R) groups. Both the positioning of the lid over the active site and Arg120 along the bottom restricts the available volume within. Furthermore, a number of hydrogen-bonding interactions between the lid and core domains were found to render the lid fairly inflexible, effectively locking the size and shape of the active site [34]. As discussed earlier, the largest discrepancy in sequence between the fIK thioesterase and the majority of putative orthologs is in the lid motif, with fIK containing a larger lid segment than most other orthologs. Of the available crystal structures, MA0038 shares the highest sequence homology to fIK with 50% sequence identity overall. Additionally, MA0038 appears to contain a full lid motif similar to fIK (Figure 2-10). The positioning of Arg121 is in good alignment with fIK as well, resulting in a very similarly sized active site (Figure 2-10). According to CASTp calculations, the size of MA0038's active site is actually slightly larger than that of fIK and may explain why it is able to accommodate benzoyl-CoA and a few of its hydroxylated derivatives. From a structural basis, the slightly larger active site could be due to more lid flexibility as MA0038 was found to have fewer lid-core interactions than fIK [34].

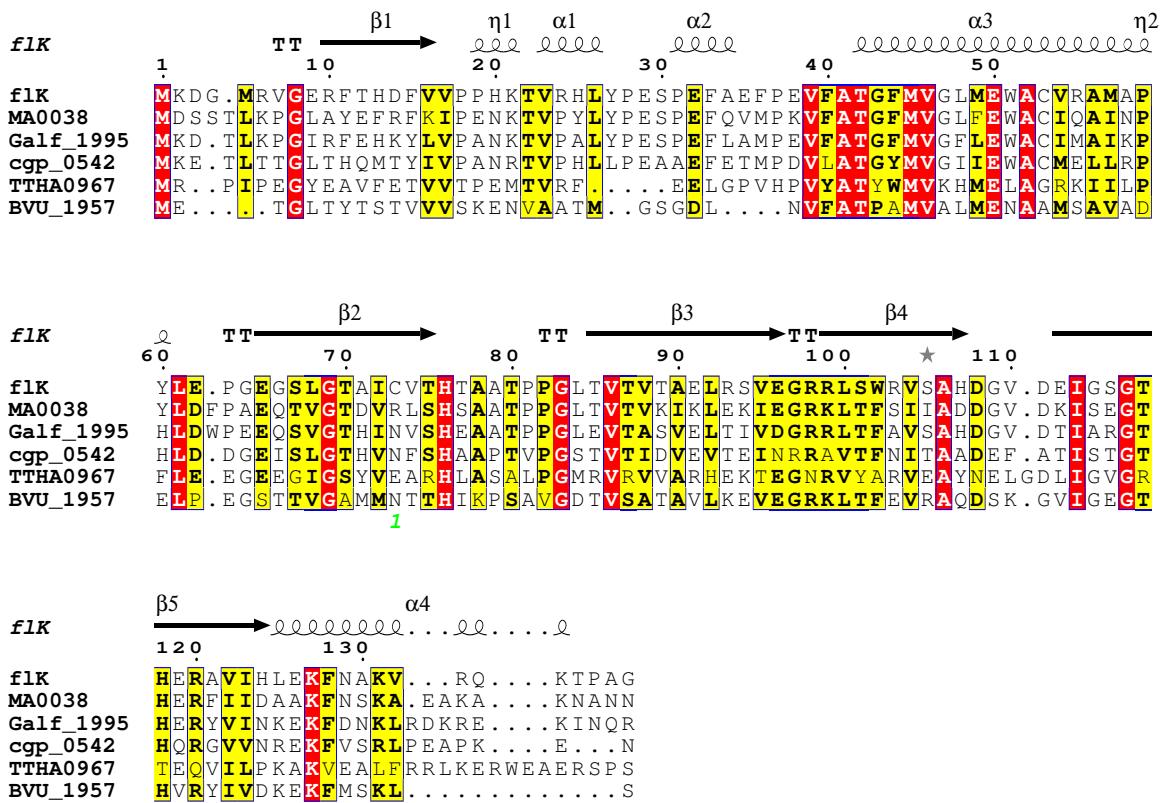

Alternatively, the BVU\_1957 (BVU) crystal structure highlights the profound effect of a truncated lid motif (Figure 2-10). As seen in the substrate screening, BVU was

**Figure 2-10.** Structural comparison of flK (teal) (PDB: 3KV8), MA0038 (magenta), BVU\_1957 (green) and TTHA0967 (PDB: 2CWZ) (red). The helical lid motif is colored in yellow. Active site volumes are colored by electrostatic potential.

not active for any substrates larger than FAcCoA, a direct contrast to the other orthologs tested. Additionally, the high HCoA activity indicated that the active site might be set up to bind this substrate the best. Although the core structure and catalytic residues align very well with flK and MA0038, the BVU active site is almost half the size of either, as calculated by CASTp. Given that Arg110 is in the same position as R120 and R121, the lid motif is solely responsible for this loss in active site volume. In comparison with both flK and MA0038, the truncated lid in BVU appears to shorten the length of the active site, limiting the size of acyl group that could be accommodated. Additionally, the BVU lid motif (despite its size) appears to have more hydrogen bonding interactions with the core, further limiting its flexibility and potentially, substrate specificity [34]. These structural features help to explain why BVU was not active with any substrates

**Figure 2-11.** Multiple alignment of flK and cloned flK-orthologs. Completely conserved residues are highlighted in red and highly conserved residues are highlighted in yellow. Secondary structure was overlaid using the flK crystal structure (PDB: 3KV8\_B).

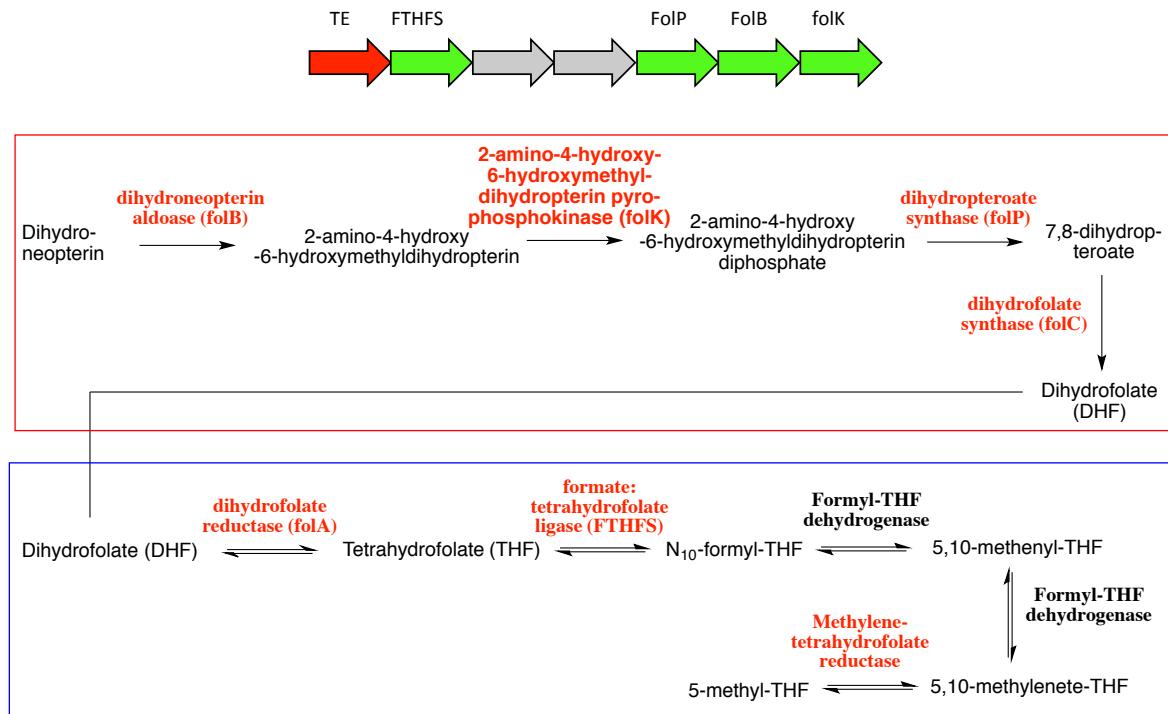

larger than FAcCoA and may also help provide a structural basis for the high level of HCoA activity.

In looking at the TTHA0967 (TTHA) sequence (Figure 2-11), it would appear that its lid motif falls somewhere between truncated and full length. A look at its crystal structure (Figure 2-10) confirms this observation, as it appears larger than BVU but smaller than flK or MA0038. This semi-limitation on the TTHA active site could explain

why it was still able to discriminate between FAcCoA and AcCoA, albeit to a lesser degree than fIK or MA0038. Furthermore, while this semi-truncation should technically limit the volume of the active site (as seen in BVU with the truncated lid), CASTp calculations indicate the active site to be generally around the same size as fIK and MA0038. The reasoning for this can be found in the bottom of the active site. Where fIK, MA0038 and BVU all have identically positioned arginine residues, TTHA has a glutamine residue, positioned away from the active site. This residue swap opens up a large portion of the lower TTHA active site and may explain why it is able to accommodate the aromatic substrates phenylacetyl-CoA and benozyl-CoA.

### 2.3.6 Gene Context Analysis

With sequence, activity and structural analyses indicating a divergence of function in the fIK scaffold, we turned to a gene context analysis in the hopes that neighboring genes may provide further clues in identifying such a function. Unfortunately, compared to the number of organisms with orthologous sequences, the available gene context data is pretty sparse, limiting the power of this analysis. Nonetheless, we were still able to pull a few clues from the data. Starting with the cloned and isolated orthologs, MA0038, TTHA0967, BVU\_1957, Galf\_1995 and cgp\_0542, we found that they really shared no conservation of gene context whatsoever. Though with the majority of genes in the MA0038 cluster unannotated, few clues were provided about the putative function of this particular ortholog. Galf\_1995 appears to be clustered with genes involved in arginine and proline metabolism, given its proximity to an acetylornithine and succinylornithine aminotransferase (Galf\_1990),

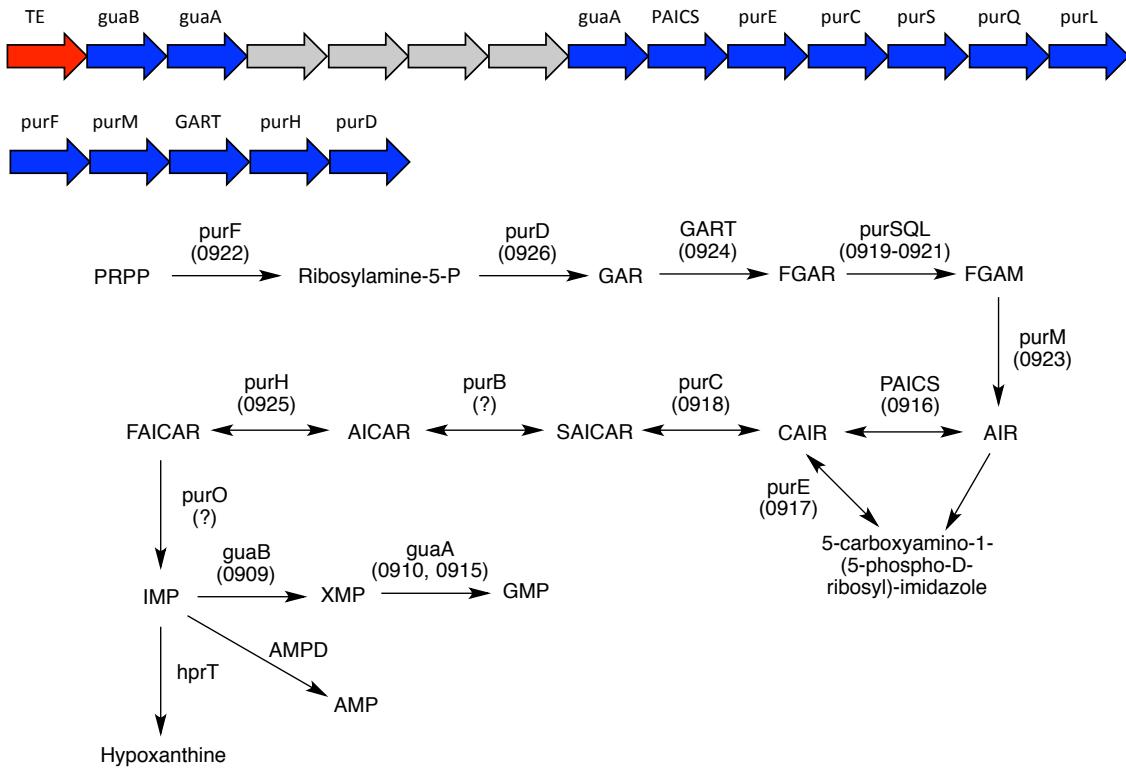

**Figure 2-12.** Gene context within *T. potens* (Firmicutes) showing flK ortholog (TE) co-localization with genes involved in folate biosynthesis (red box) and the one carbon pool by folate (blue box).

an ornithine carbamoyltransferase (Galf\_1995) and an arginosuccinate synthase (Galf\_1996). While arginine is considered one of the most versatile amino acid as its metabolism provides precursors for a number of processes such as the biosynthesis of proteins, nitric oxide, creatine and urea, it is unclear what role a hot dog thioesterase might play in this metabolic pathway [41].

The gene neighborhood surrounding cgp\_0542 reveals to be localized around a gene cluster for the synthesis of menaquinone, or vitamin k. Menaquinone biosynthesis,

known as the men pathway is a 9-step synthetic route, converting chorismate to menaquinone. The cluster is loosely localized as *cgp\_0533* is an O-succinylbenzoyl-CoA ligase (MenE), *cgp\_0548* is a naphthoate synthase (MenB), *cgp\_0551* is an O-succinylbenzoyl-CoA synthase (MenC) and *cgp\_0552* is a 2-succinyl-5-enolpyruvyl-6-hydroxy-3-cyclohexene-1-carboxylate synthase (MenD). Interestingly enough, the men pathway has been shown to utilize a hot dog-fold thioesterase in the hydrolysis of 1,4-dihydroxy-2-naphthoyl-CoA (DHNA-CoA) to its corresponding fatty acid [42]. However, *cgp\_0542* did not exhibit any hydrolysis activity towards DHNA-CoA, making it unlikely to function in this role.

TTHA0967 appears to be clustered in an operon for phenylacetic acid (PAA) degradation. Its gene neighbors include PaaI: phenylacetyl-CoA thioesterase (TTHA0965), PaaK: phenylacetyl-CoA ligase (TTHA0966), PaaDCBA: ring-1,2-phenylacetyl-CoA epoxidase (TTHA0969-TTHA0972) and PaaX: TetR transcriptional regulator (TTHA0973). As a common intermediate in the breakdown of various aromatic compounds, the PAA pathway is critical pathway in the utilization of aromatic carbon sources [39]. Interestingly enough, a broader look at the available gene context of all putative fIK orthologs shows quite a few instances of fIK orthologs clustered in close proximity to a PAA degradation operon. While this appears to be fairly conserved throughout Deinococcus-thermus (the phylum containing TTHA0967), various genes throughout Actinobacteria, Firmicutes and Proteobacteria share a similar gene context as well. Like TTHA0967, PaaI is a hotdog-fold thioesterase that catalyzes the conversion of phenylacetyl-CoA (PA-CoA) to phenylacetate (PA). While TTHA0967 did exhibit PA-

**Figure 2-13.** Gene context within *A. metallireducens* (Firmicutes) showing flK ortholog (red) co-localization with a gene operon for *de novo* purine biosynthesis and salvage.

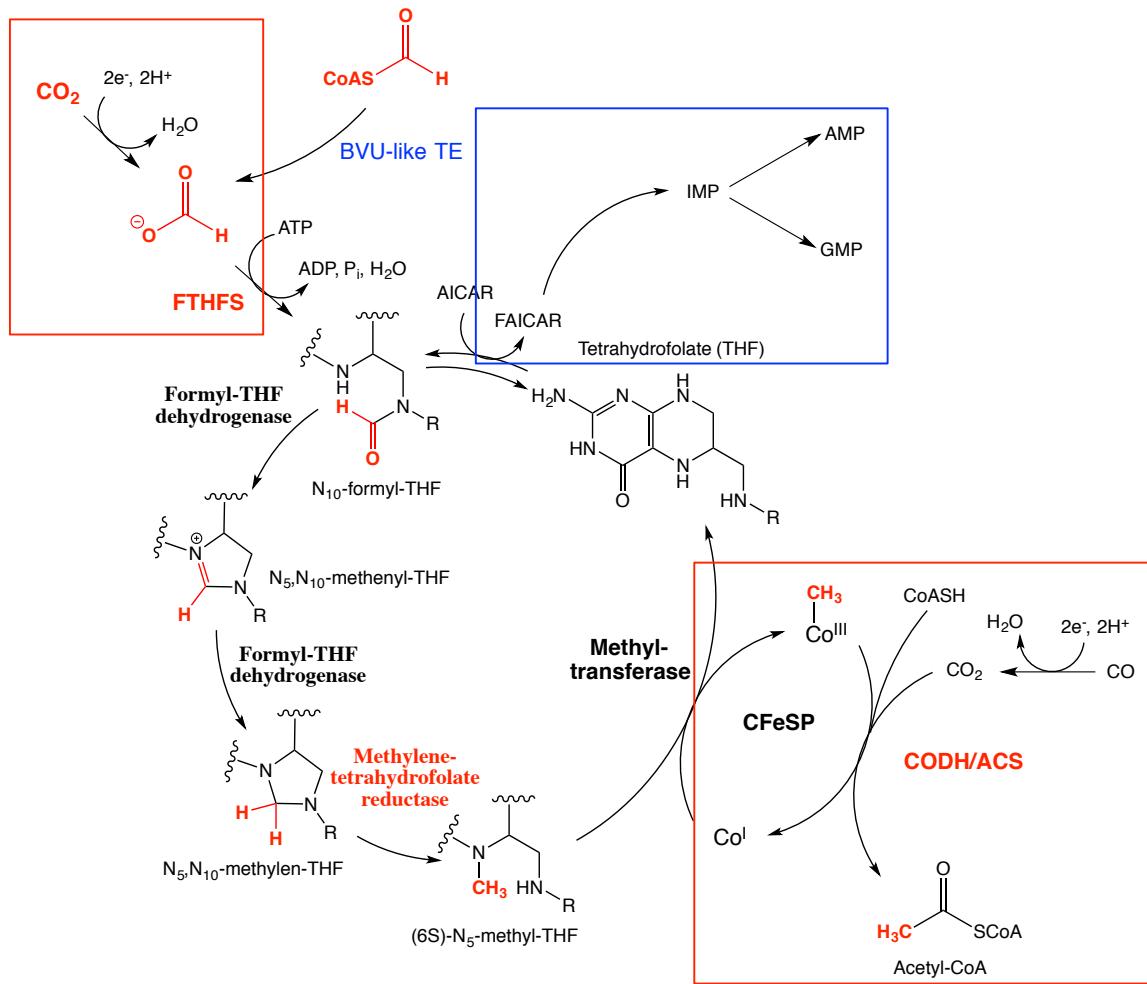

CoA hydrolysis activity, it was not on a biologically relevant scale, indicating its function elsewhere.

A look at the BVU\_1957 gene neighborhood shows it to be near aconitase (BVU\_1959), isocitrate dehydrogenase (BVU\_1960) and citrate synthase (BVU\_1961). All three of these enzymes play critical roles in the citric acid cycle, mediating the multistep conversion of oxaloacetate and acetyl-CoA to  $\alpha$ -ketoglutarate. Given the high formyl-CoA activity and narrow substrate range exhibited by BVU\_1957, it is uncertain if this gene context is relevant. Further downfield from BVU\_1957 is a dihydrofolate

reductase (BVU\_1949) and thymidylate synthase (BVU\_1950). Both genes are involved in one carbon metabolism by folate (Figure 2-12). Folate and folate derivatives act as single carbon donors and play critical roles in various cellular processes such as DNA methylation and repair, purine synthesis and carbon fixation [44]. A wider look at the rest of the available flK ortholog gene context discovered a large amount of orthologs co-located with formate-tetrahydrofolate ligase, the enzyme responsible for the conversion of formate and tetrahydrofolate (THF) to N<sub>10</sub>-formyl-THF in the one carbon pool. Additionally, a number of orthologs were found to co-localize with genes involved in *de novo* purine synthesis and salvage (Figure 2-13). Furthermore, many orthologs were found in close proximity to other genes involved in carbon fixation or one carbon metabolism like carbon monoxide dehydrogenase and malate dehydrogenase.

### 2.3.7 Divergence of Function

The human gut microbiome plays a large role in overall health and wellbeing, as disruption of gut flora has been shown to have significant effects of a variety of intestinal conditions such as obesity, malnutrition, diabetes, ulcerative colitis and Crohn's disease [43, 45]. Living in a symbiotic relationship with the human body, organisms in the gut microbiome can essentially be broken down into two major classes based on their function: fermenters and hydrogenotrophs [46, 47]. The role of fermenters is in the breakdown of undigested dietary components, such as proteins and carbohydrates. In the process, a number of fermentation products such as short-chain fatty acids (acetate, propionate, butyrate) and gases (CO<sub>2</sub> and H<sub>2</sub>) are formed [46, 47]. Responsible for the removal of CO<sub>2</sub> and H<sub>2</sub> from the intestinal tract, hydrogenotrophs

**Figure 2-14.** Reaction scheme depicting the potential involvement of BVU-like orthologs in the one carbon pool and its downfield contributions to *de novo* purine biosynthesis and salvage (blue) and acetogenic carbon fixation (Wood-Ljundahl pathway) (red). FTHFS: formate-tetrahydrofolate synthetase. CODH/ACS: carbon monoxide/acetyl-CoA synthase complex.

(hydrogen consumers) are capable of utilizing these gases as carbon sources through the process of carbon fixation [47]. Given the mostly oxygen-limiting environment of

the gut, carbon fixation is performed under anaerobic conditions. One such group of hydrogenotrophs is acetogenic bacteria, which are capable of producing acetyl-CoA through carbon fixation [48]. Primarily in *Clostridium* species, acetogens are capable of utilizing the Wood-Ljundahl pathway to convert CO<sub>2</sub> and H<sub>2</sub> to acetyl-CoA in a THF and cobalamin-dependent reaction (Figure 2-14). In short, THF is converted to N<sub>10</sub>-formyl-THF by the action of formate-tetrahydrofolate ligase. In a series of redox reactions, N<sub>10</sub>-formyl-THF is converted to (6S)-N<sub>5</sub>-methyl-THF, where it acts as a methyl group donor. Utilizing the carbon monoxide dehydrogenase/acetyl-CoA synthase (CODH/ACS) complex, the methyl group is transferred, along with carbon monoxide to coenzyme A, forming acetyl-CoA. Given the apparent role of BVU\_1957 as a formyl-CoA hydrolase, it is possible that this version of the flK scaffold (truncated lid) within *Clostridium* might function within the gut microbiota in the anaerobic fixation of CO<sub>2</sub> and H<sub>2</sub> by providing an alternate source of formate for conversion to N<sub>10</sub>-formyl-THF. As formylated-derivatives are required for a variety of other cellular processes (like *de novo* purine synthesis and salvage), it is possible that the non-acetogenic orthologs may utilize formyl-CoA hydrolase activity in a similar manner, providing formate for the one carbon pool (Figure 2-14).

## 2.4 Summary

Given the highly specific role of the flK thioesterase in providing resistance to FAc poisoning in the fluorometabolite-producer, *S. cattleya*, it was evident that the flK scaffold was highly evolved, doubtless the result of functional divergence within the HD superfamily. In an attempt to track this functional divergence, we initiated a combined

bioinformatics, mechanistic and structural analysis to uncover novel functionality with the flK subfamily.

While the fluorinase cluster was found to be extremely limited in biological range, the flK scaffold was found in orthologs through many different phyla, indicating an alternative function for the species that without the ability to synthesize fluorometabolites. Additionally, the flK biological range was similar to the biological range of the gut microbiome, indicating a potentially functionality within the human and mammalian digestive tract. Sequence analyses of flK orthologs indicated three distinct versions of the helical lid structure, supported from the analysis of the crystal structures from flK, BVU\_1957 and TTHA0967. The alterations in the helical lid, resulting in distinct reshaping of the TE active site, was found to play a role in substrate specificity and activity, as BVU\_1957 was highly active and specific for formyl-CoA. The truncated lid (BVU-like) structure was found to be the most prevalent amongst the flK orthologs, as all of the Bacteroidetes and the majority of Firmicutes and other species conserved this motif, and indicated that the majority of flK orthologs function more closely to BVU\_1957 and flK.

With additional support from gene context analyses, a novel divergent function was proposed for BVU\_1957 (and the “BVU-like” orthologs) in providing formate for the one carbon pool. Additionally, given the prevalence of flK orthologs co-localized with the PAA degradation pathway (especially in Deinococcus-Thermus), and taking into account, the low-level PA-CoA hydrolase activity seen in the TTHA0967-like scaffold, we have proposed a potential evolutionary path for the flK subfamily.

The original flK thioesterase (TTHA0967-like) may have evolved from the Paal thioesterase as a result of gene duplication events. Through lateral gene transfer, the entire PAA operon (TTHA0967-like ortholog included) was acquired by organisms within Proteobacteria, Firmicutes and Actinobacteria. Over time, further structural divergence led to the evolution of the BVU-like ortholog (truncated lid) and the flK-like ortholog (full lid). The flK ortholog was utilized for the role of FAc detoxification in *S. cattleya*, other fluoroacetate producers and possibly in other bacteria requiring this resistance pathway. Alternatively, the BVU-like thioesterase evolved the role of formyl-CoA thioesterase within the gut microbiome and was traditionally evolved throughout its co-habiting species.

## **Chapter 3**

### **Characterizing the Contribution of Multiple Acyl-CoA Synthetases Towards Enhanced Virulence in *Pseudomonas aeruginosa***

#### **3.1 Introduction**

Cystic fibrosis, also known as mucoviscidosis, is an autosomal recessive genetic disorder primarily affecting the respiratory and digestive systems [1]. The most common lethal genetic disease in Caucasian populations, cystic fibrosis (CF) affects mainly children and young adults, with more than 75% of people diagnosed at age two or younger [1, 2]. With an estimated 30,000 children and adults affected in the United States (70,000 worldwide) and about 1,000 new diagnoses each year, CF is characterized by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR), a membrane-bound protein expressed in epithelial and blood cells [1-3]. An ABC-class ion transporter, CFTR is an ATP-gated anion channel responsible for the soluble transport of chloride, thiocyanate and bicarbonate ions across the cell membrane [2]. This transport helps drive the osmotic efflux of water out of the cell into the surrounding mucus, maintaining its proper fluidity to effectively protect organs from invading bacteria and foreign particles. While two copies of the CFTR gene are carried (one from each parent), only one functioning gene is needed for proper ion transport. In patients with CF, mutation-derived dysfunction occurs in both CFTR genes, resulting in a total loss of ion transport [4]. While over 1,800 CFTR mutations have been documented, only a few occur at a frequency greater than 0.1%

**Figure 3-1.** Comparison of wild-type (I) and mutant (II/III) CFTR. CF-causing mutations in the CFTR gene can result in dysfunctional protein (II) or cause CFTR breakdown before implantation into the plasma membrane (III). Both types of mutation inhibit ion transport across the membrane and lead to accumulation of thick, dry mucus.

[5]. The most common mutation in patients with CF is  $\Delta F508$ , a single amino acid deletion of phenylalanine occurring at position 508. Occurring in over 70% of the CF community,  $\Delta F508$  leads to CFTR misfolding and results in break down shortly after translation and ultimately failure to reach the cell membrane [6]. The consequence of CF-causing mutations in CFTR genes is an accumulation of thick, dehydrated mucus (sputum) that blocks airways and hinders breathing [1]. Additionally, the warm, nutrient-rich environment of CF sputum leads to a veritable breeding ground for bacteria adapted to survive under such conditions. Furthermore, decreased

levels of periciliary fluid preventing the mucociliary clearance of said bacteria results in the recruitment of inflammatory mediators, leading to inflammation on top of chronic bacterial infection and ultimately, irreparable decline in pulmonary function [7]. Although the life expectancy of CF patients has risen dramatically in the past 30 years (from age 7 to ~40), thanks to an enhanced understanding of its underlying genetic causes and treatment, most patients eventually succumb to bacterial airway infection after a shortened lifetime spent in hospitals and on aggressive antibiotic regimens [7].

One of the hallmarks of cystic fibrosis is the complex microbiome that inhabits the lung sputum. This unique environment is comprised of a wide range of microbes and is in constant flux throughout the life of the patient. In some adults with CF, up to 37 different phylotypes have been discovered, including several members from *Bacillales*, *Bacteroidales*, *Burkholderiales*, *Chlostridiales*, *Lactobacillales*, *Methanosaecinales*, *Pseudomonadales* and *Xanthomonadales* [2]. The most prevalent species of bacteria include *Staphylococcus aureus*, the *Burkholderia cepacia* complex, *Haemophilus influenzae*, *Mycobacterium sp.* and *Pseudomonas aeruginosa* [8]. During infancy and early childhood, CF patients suffer predominantly from *S. aureus* infections that damage epithelial surfaces and pave the way for dominating pathogens such as *P. aeruginosa* [8].

*P. aeruginosa* belongs to the genus *Pseudomonas*, whose various groupings include non-pathogenic species (e.g. *P. putida*, *P. denitrificans*, *P. knackmussii*) as well as a variety of other animal (*P. oryzihabitans*), plant (*P. syringae*) and fish (*P. plecoglossicida*) pathogens. Found in soil, water, on plants and in the human gut and

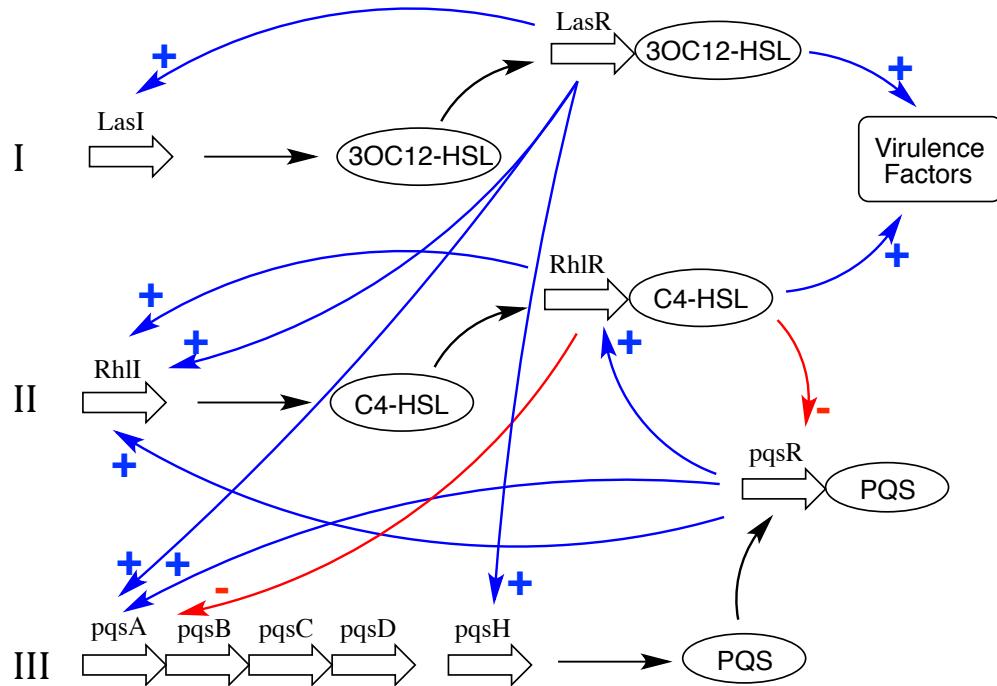

respiratory system, *P. aeruginosa* leads somewhat of a dual life. On the one hand, it acts as a free-living bacterium, capable of surviving and thriving on its own. More notably, however, is its role as an aggressive opportunistic pathogen, infecting immuno-compromised hosts [9]. Found on hospital equipment and implanted devices, such as catheters, *P. aeruginosa* is responsible for a myriad of deadly infections, ranging from urinary tract infections (UTIs) to sepsis in cancer patients, and is one of the most common infections found in patients with nosocomial pneumonia [10, 11]. In CF airways, *P. aeruginosa* infections are intermittent throughout childhood and early adolescence. However, by early adulthood, chronic infection is established and *P. aeruginosa* quickly becomes the dominant infecting species in the CF airway [3]. The underlying mechanism of this success is the ability to rapidly adapt to a constantly fluctuating environment, and despite aggressive antibiotic treatment, *P. aeruginosa* represents the leading cause of morbidity and mortality in adult CF patients [12].

The key for establishing chronic infection and thriving in a pathogenic environment is the ability to effectively utilize host and co-habitant-derived energy sources while successfully fighting off the constant barrage of antimicrobial agents released by both parties. To these ends, *P. aeruginosa* employs an impressive arsenal of virulence factors, signaling molecules, xenobiotic efflux pumps and other various chemical warfare agents to exploit both host and co-habitant alike. Additionally, *P. aeruginosa* is armed with an extensive metabolic suite, allowing it utilize a wide variety of carbon sources from many types of environmental conditions. Perhaps the most important concept in *P. aeruginosa* pathogenesis is

extensive biofilm formation. Biofilms are composed of a complex polymer matrix of polysaccharide, DNA, protein and other macromolecules [13]. Housed within are populations of bacteria that form large, fully networked communities. These communities have significant survival advantages over single colonies in that they are able to communicate by quorum sensing, a process of emitting small molecule signals in response to fluctuating environmental conditions. This system of communication allows the organized population to perform group-wide actions such as extending or limiting biofilm production, inducing the transcription of virulence factors and utilizing communal energy sources. In *P. aeruginosa*, the primary polysaccharide component of biofilm is alginate. Over the course of intermittent infection, the bacterium has been shown to deregulate enzymes directly involved in alginate production (such as *mucA* and *algD*) to undergo conversion to a mucoid phenotype [7]. This overproduction of alginate leads to a thicker, stickier biofilm which renders antibiotic penetration much more difficult and also increases resistance to phagocytosis by host macrophages [7, 14]. Additionally, this enhanced biofilm structure prevents clearance of the bacterium from host airways and generally marks the establishment of chronic infection.

In *P. aeruginosa*, the quorum sensing process is governed by three interconnected regulatory systems. When responding to environmental fluctuations, affected members of the (biofilm-contained) bacterial community release autoinducer molecules, which at high enough concentration, initiate community-wide transcription of genes involved in adaptation and virulence factor production [15]. The *las* and *Rhl* systems are both two-component (LuxI/LuxR-

type) regulatory systems consisting of an autoinducer synthase (LuxI-like) and a cognate transcriptional activator (LuxR-like). Both are mediated by an N-acylhomoserine lactone (HSL) autoinducer, specifically *N*-3-oxo-dodecanoyl homoserine lactone (3OC12-HSL) and *N*-butyryl homoserine lactone (C4-HSL), respectively [16, 17]. The third regulatory system, known as the *pqs* system, is a biosynthetic pathway for the production of 4-heptyl-3-hydroxy-4-quinolone (PQS). An autoinducer for the *pqs* system, PQS is a member of the 4-quinolone class and has been shown to enhance biofilm formation through changes in swarming motility, inhibition of host T-cell proliferation and production of antibacterial agents [18-20]. The carefully coordinated regulatory cascade of the *las-Rhl-pqs* system (Figure 3-2) is thought to control up to 11% of the *P. aeruginosa* genome and not only serves as a form of inter-regulation but also allows for the redundant release of important virulence factors such as elastase, pyocyanin, siderophores, lipopolysaccharides, rhamnolipids and various proteases [21-23]. These virulence factors play a large role in *P. aeruginosa* pathogenesis and are directly linked to its survival. For example, *P. aeruginosa* has been found to modify the O-antigen or lipid A components of lipopolysaccharides (LPS) to either avoid immune detection or trigger inflammation, cytokine release and toxic shock, depending on its environment [15]. The non-ribosomal peptide synthase (NRPS)-produced siderophores pyochelin and pyoverdine allow *P. aeruginosa* to survive under iron-depleted conditions by chelating and transporting host-derived iron into the cell. Furthermore, pyocyanin is thought to be able to scavenge oxygen from biofilm boundaries during anaerobic conditions in addition to inducing apoptosis in host

**Figure 3-2.** Quorum signaling regulatory cascade in *P. aeruginosa* consisting of the *las* (I), *Rhl* (II) and *pqs* (III) systems. Black arrows denote autoinducer synthesis (straight) and binding (curved). Transcriptional activation is denoted by blue arrows (+) and repression is denoted by red arrows (-).

and co-habitant cells [15, 24-26]. Additionally, rhamnolipids facilitate in the uptake and release of hydrophobic compounds, help dictate biofilm morphology, inhibit macrophage function and have been shown to possess antimicrobial activity [27].

Biofilm formation in the CF lung relies on high-density cell (HDC) replication [28]. Like all cellular growth processes, HDC replication is dependent on a readily available source of energy. In CF sputum as well as in extensive biofilm formations,

growth conditions are completely heterogeneous and can range from aerobic to oxygen-limited to completely anaerobic [29, 30]. This steep oxygen gradient provides a constantly changing environment that demands a versatile metabolism for energy acquisition and survival. *P. aeruginosa* is known mainly as a facultative aerobe, preferring to utilize any one of five terminal oxidases (varying in oxygen affinity, energy coupling and stress tolerance) to catalyze the conversion of molecular oxygen to water [31]. In response to constantly changing oxygen levels during pathogenesis, *P. aeruginosa* is able to utilize nitrate and nitrite as terminal electron acceptors (denitrification) when oxygen is limited [31]. Additionally, phenazines like pyocyanin can also act as electron acceptors [32]. Under strictly anaerobic conditions, *P. aeruginosa* has been shown to utilize arginine and pyruvate fermentation pathways to produce ATP, genes of which are linked to virulence, long-term survival and biofilm formation [33-35].

Variable growth conditions inevitably lead to a broad range of energy sources and relative abundances. Under nutrient-poor conditions, the catabolite repression control (CRC) system is responsible for tuning *P. aeruginosa* metabolism and optimizing nutrient utilization *in vivo*. A signaling cascade under the control of the *Crc* gene, the CRC system is intricately linked to *P. aeruginosa* pathogenesis, affecting over 360 separate genes involved in carbohydrate metabolism, biofilm formation, antibiotic resistance and virulence [36, 37]. The CRC system also regulates amino acid import and utilization with research showing amino acid degradation genes, proteases and peptide transporters to be upregulated in CF growth conditions [28]. This indicates host-derived amino acids to be an important

energy source *in vivo*. Another valuable source of host-derived energy is lung surfactant, composed primarily of dipalmitoylphosphatidylcholine (DPPC). *P. aeruginosa* contains lipases and phospholipase C to cleave DPPC into its constituent components: palmitate (x2), glycerol and phosphocholine--all of which can be metabolized for energy [38]. In fact, genes involved in long-chain fatty acid activation and  $\beta$ -oxidation are upregulated in CF models and mutant strains in mouse lungs displayed decreased production of virulence factors and retarded growth [28, 39]. This points to a potentially significant role of host-derived long chain fatty acids toward *P. aeruginosa* virulence and energy acquisition.

In addition to utilizing host-derived energy sources, *P. aeruginosa* may be able to utilize small molecule carbon sources excreted by co-habiting bacterial species. In the mostly anaerobic recesses of the CF lung, co-habiting bacteria utilizing a variety of fermentation pathways release a myriad of small molecule fermentation products including short-chain fatty acids, ethanol and CO<sub>2</sub> [47]. One such product, 2,3-butanedione, has been shown to be present in nearly all CF respiratory tracts [44]. Additionally, studies have shown that utilization of exogenous 2,3-butanedione by *P. aeruginosa* leads to increased biofilm density and virulence factor production, enhanced levels of pyocyanin, HSL and other quorum sensing signals, and increased antimicrobial activity [24]. With the ability to exploit co-habiting bacteria by feeding off of their excreted fermentation products and then instigating an immune response and engaging in chemical warfare to become the dominant pathogenic species, it comes as no shock that over a patient's lifetime, the

diversity of the CF microbiome dramatically decreases, with *P. aeruginosa* consistently found as the main pathogenic species in adults [24].

Perhaps the main reason why *P. aeruginosa* is such a capable and virulent pathogen is the size of its genome. At roughly 6.3 million base pairs (Mbp), this unusually large genome far exceeds the size of many other notable pathogens such as *E. coli* (4.7 Mbp), *S. aureus* (2.8 Mbp), *H. influenzae* (1.8 Mbp) and *M. tuberculosis* (4.4 Mbp) [42, 43]. Analysis of the *P. aeruginosa* genome reveals a much larger number of distinct gene clusters, implying that its size is not due to genomic duplication but rather due to adapted evolution for increased genomic complexity. In fact, with over 5,000 open reading frames (ORFs), the genetic complexity of *P. aeruginosa* is thought to more closely resemble that of the simple eukaryotic yeast *S. cerevisiae* than other actual bacteria [43]. With increased numbers of regulatory genes, nutrient-uptake transporters, xenobiotic efflux pumps and secretory systems, *P. aeruginosa* appears to be evolutionarily adapted to survive and thrive in a number of niche environments. Of particular interest are the large numbers of genes associated β-oxidation and other metabolic pathways and indicates a potential ability to utilize a wide-range of organic substrates as carbon sources.

As discussed in chapter 1, Acyl-CoA synthetases are the enzymes responsible for the activation of carboxylic acids into their respective acyl-CoA substrates. Best known for their role in long-chain fatty acid activation in β-oxidation, acyl-CoA synthetases (ligases) are critical components of cellular metabolism throughout all domains of life. In addition to long-chain fatty acyl-CoA ligases, prokaryotic organisms (which grow under a variety of conditions) are known to employ short

and medium-chain as well as various aromatic ligases [62, 63]. Given the enhanced size of the *P. aeruginosa* genome, it is not totally surprising to discover a large number of standalone acyl-CoA ligases. Given the importance of acyl-CoA ligases in energy utilization, secondary metabolite production and virulence factor production, we hypothesize that the increased number of standalone ligases in *P. aeruginosa* contributes to its enhanced virulence in the CF lung environment. In this chapter we explore the potential activation of host and co-habitant-derived organic fatty acids by the multiple standalone acyl-CoA synthetases expressed by *P. aeruginosa*. The work within defines the parameters and results for a novel high-throughput substrate screening coupled with steady-state kinetic verification of activity. Along with in-depth bioinformatic analyses, the results and the conclusions we draw from them allow us to gain a better understanding of the potential energy acquisition pathways employed by *P. aeruginosa* during pathogenesis in the CF airway.

## 3.2 Methods and Materials

### 3.2.1 Materials

All restriction enzymes, T4 DNA ligase, and Deep Vent DNA polymerase were purchased from NEB. *Pfu* Turbo DNA polymerase was purchased from Agilent and all custom oligonucleotide primers were synthesized by Invitrogen. Genomic DNA was purchased from ATCC. Protein samples were purified on an ÄKTA FPLC system (GE Healthcare) by monitoring UV absorbance at 280 nm. Protein concentrations were determined using the Bradford method. Various carboxylate substrates and all

other chemicals were purchased from Sigma or Fisher unless otherwise specified. Mass spectrometry analysis was performed by the Mass Spectrometry Facility at the University of New Mexico.

### **3.2.2 Bioinformatics Analysis**

Standalone ligases in *P. aeruginosa* were identified using the SupFam database (<http://supfam.cs.bris.ac.uk/SUPERFAMILY/index.html>). BLAST searches of individual standalone ligases were conducted throughout all of the sequenced genomes deposited in the NCBI database using the Standard Protein BLAST server ([http://blast.ncbi.nlm.nih.gov/Blast.cgi?PROGRAM=blastp&PAGE\\_TYPE=BlastSearch&LINK\\_LOC=blasthome](http://blast.ncbi.nlm.nih.gov/Blast.cgi?PROGRAM=blastp&PAGE_TYPE=BlastSearch&LINK_LOC=blasthome)). Protein sequences were aligned using Clustal Omega (<http://www.ebi.ac.uk/Tools/msa/clustalo/>) and visualized in CLC Sequence Viewer 7. Each ligase was selected as the query sequence using the default parameters. Additionally, the search parameters were set to filter regions of low complexity and select for the top 5,000 hits. Each ligase was subjected to three separate BLAST searches: (1) within *Pseudomonas* (excluding *Pseudomonas aeruginosa*), (2) within Proteobacteria (excluding *Pseudomonas*) and (3) within Bacteria (excluding Proteobacteria). To distinguish between orthologs of each ligase, pairwise sequence identities were calculated for each one and a sequence identity cutoff was selected based on the results. Putative orthologs were identified by those sequences containing  $\geq 50\%$  sequence identity for  $\geq 80\%$  coverage with the exception of PA0996, PA1617 and PA2893 where the sequence identity cutoff was lowered to  $\geq 40\%$  sequence identity for  $\geq 80\%$  coverage. Gene neighborhood analysis

was performed by looking at available gene context data in the NCBI Gene database (<http://www.ncbi.nlm.nih.gov/gene/>) and the KEGG Sequence Similarity DataBase (<http://www.kegg.jp/kegg/ssdb/>).

### **3.2.3 Cloning, Expression, and Purification of *P. aeruginosa* Ligases**

The gene encoding PA0887 was amplified by PCR using *Pseudomonas aeruginosa* PAO1-LAC genomic DNA (ATCC 47085D-5), custom oligonucleotide primers and *Pfu* Turbo DNA polymerase. The gene product was digested with NdeI and XhoI restriction endonucleases and ligated into pET-23a(+) expression vector using T4 DNA Ligase. The resulting ligation product was then used to transform *E. coli* BL21(DE3) pLysE chemically competent cells and the transformation was plated on LB media containing ampicillin (100 µg/mL). A single colony containing overexpressed protein was used to inoculate 2 L TB media and incubated at 37 °C/200 RPM until reaching an OD<sub>600</sub> of approximately 0.6. Cells were induced by addition of IPTG (0.4 mM) and allowed to incubate overnight at 18 °C/200 RPM. Cells were harvested by centrifugation at 4 °C/6500 RPM; cell paste was collected and resuspended in ice-cold lysis buffer (50 mM HEPES, 200 mM NaCl, 50 mM imidazole, pH 7.5). Cells were lysed by passage through a French press at 1200 PSI and then centrifuged at 4 °C/20,000 RPM. The collected supernatant was then loaded onto a 5 mL HisTrap FF column (GE Healthcare) and washed with lysis buffer. Pure protein was eluted off the column with elution buffer (50 mM HEPES, 200 mM NaCl, 500 mM imidazole, pH 7.5) and fractions containing pure protein were collected, pooled and dialyzed against three changes of dialysis buffer (50 mM

HEPES, 200 mM NaCl, pH 7.5). Purity was verified by SDS-PAGE. Yield: 4.5 mg/g wet cell paste.

The gene encoding PA0996 was cloned, expressed and purified as described above with some modification to the procedure. The PCR-amplified gene product was digested with NdeI and BamHI restriction endonucleases and ligated into pET-28a(+) expression vector. The ligation product was used to transform *E. coli* T7 Express *I<sup>q</sup>* chemically competent cells and the transformation was plated on LB media containing kanamycin (40 µg/mL). A single colony containing overexpressed protein was used to inoculate 1 L TB media and incubated at 37 °C/200 RPM until reaching an OD<sub>600</sub> of approximately 0.8. Yield: 5.5 mg/g wet cell paste.

The gene encoding PA1997 was cloned, expressed, and purified as described above with some modification to the procedure. The PCR-amplified gene product was digested with NdeI and EcoRI restriction endonucleases and ligated into pET-28a(+) expression vector. The resulting ligation product was then used to transform *E. coli* BL21(DE3) pLysE chemically competent cells and the transformation was plated on LB media containing kanamycin (40 µg/mL). A single colony containing overexpressed protein was used to inoculate 1 L TB media and incubated at 37 °C/200 RPM until reaching an OD<sub>600</sub> of approximately 0.8. Yield: 10.4 mg/g wet cell paste.

The gene encoding PA2555 was cloned, expressed, and purified as described above with some modification to the procedure. The PCR-amplified gene product was digested with NdeI and HindIII restriction endonucleases and ligated into pET-28a(+) expression vector. The ligation product was used to transform *E. coli* T7

Express *I<sup>q</sup>* chemically competent cells and the transformation was plated on LB media containing kanamycin (40 µg/mL). A single colony containing overexpressed protein was used to inoculate 1 L TB media and incubated at 37 °C/200 RPM until reaching an OD<sub>600</sub> of approximately 0.8. Pure protein was eluted off the column with elution buffer (50 mM HEPES, 200 mM NaCl, 500 mM imidazole) and fractions containing pure protein were collected and pooled. Protein was dialyzed by loading onto a HiPrep 16/60 Sephacryl S-200 HR gel filtration column (GE Healthcare) and washing with dialysis buffer (50 mM HEPES, 200 mM NaCl). Yield: 7.3 mg/g wet cell paste.

The gene encoding PA2557 was cloned, expressed, and purified as described above with some modification to the procedure. Cells were harvested by centrifugation at 4 °C/6500 RPM and the resulting cell paste was collected and resuspended in ice cold lysis buffer (50 mM Bis-Tris Propane, 200 mM NaCl, 50 mM imidazole, pH 7.0). Pure protein was eluted off the column with elution buffer (50 mM Bis-Tris Propane, 200 mM NaCl, 500 mM imidazole, pH 7.0) and fractions containing pure protein were collected, pooled, and dialyzed against three changes of dialysis buffer (50 mM Bis-Tris Propane, 200 mM NaCl, pH 7.0). Yield: 11 mg/g wet cell paste

The gene encoding PA3568 was cloned, expressed, and purified as described above with some modifications to the procedure. The PCR-amplified gene product was digested with NdeI and BamHI restriction endonucleases and ligated into pET-28a(+) expression vector. The ligation product was used to transform *E. coli* T7 Express *I<sup>q</sup>* chemically competent cells and the transformation was plated on LB

media containing kanamycin (40 µg/mL). A single colony containing overexpressed protein was then used to inoculate 1 L TB media and incubated at 37 °C/200 RPM until reaching an OD<sub>600</sub> of approximately 0.8. After dialysis, pure protein was loaded onto a HiPrep 16/60 Sephadryl S-200 HR gel filtration column (GE Healthcare) and washed with dialysis buffer (50 mM HEPES, 200 mM NaCl) to remove impurities. Yield: 2.9 mg/g wet cell paste.

The gene encoding PA3860 was cloned, expressed, and purified as described above with some modifications to the procedure. The PCR-amplified gene product was digested with NdeI and XhoI restriction endonucleases and ligated into pET-28a(+) expression vector. The ligation product was used to transform *E. coli* BL21-ArcticExpress chemically competent cells and the transformation was plated on LB media containing kanamycin (40 µg/mL). A single colony containing overexpressed protein was then used to inoculate 1 L TB media and incubated at 37 °C/200 RPM until reaching an OD<sub>600</sub> of approximately 0.8. Cells were then induced by the addition of IPTG (0.4 mM) and allowed to incubate overnight at 12 °C/200 RPM. Cells were harvested by centrifugation at 4 °C/6500 RPM and the resulting cell paste was collected and resuspended in 70 mL ice-cold lysis buffer (50 mM HEPES, 200 mM NaCl, 50 mM imidazole, pH 7.5) containing 500 µL protease inhibitor cocktail P8849 (Sigma 072M4052). The collected supernatant was loaded onto a 1 mL HisTrap FF column (GE Healthcare). Yield: 1.6 mg/g wet cell paste.

The gene encoding PA3924 was cloned, expressed, and purified as described above with some modifications to the procedure. The PCR-amplified product was digested with NdeI and XhoI restriction endonucleases and ligated into pET-28a(+)

expression vector. The ligation product was then used to transform T7 Express I<sup>q</sup> competent cells. A culture containing overexpressed protein was used to inoculate 1 L TB media containing kanamycin (50 mg/mL) at 37 °C/200 RPM until reaching an OD<sub>600</sub> of approximately 1.0. Yield: 4.6 mg/g wet cell paste.

The gene encoding PA4198 was cloned, expressed, and purified as described above with some modifications to the procedure. The PCR-amplified product was digested with NdeI and XhoI restriction endonucleases and ligated into pET-28a(+) expression vector. The ligation product was then used to transform T7 Express I<sup>q</sup> competent cells. A culture containing overexpressed protein was used to inoculate 1 L TB media containing kanamycin (50 mg/mL) at 37 °C/200 RPM until reaching an OD<sub>600</sub> of approximately 1.0. Yield: 1.4 mg/g wet cell paste.

### **3.2.4 High-throughput Substrate Screening**

High-throughput substrate screening was performed using the DTNB method. Reactions were carried out in a 96-well plate and monitored at 412 nm using a Molecular Devices SpectraMax i3 multiplate reader. Each reaction contained buffer consisting of 50 mM HEPES, 5 mM MgCl<sub>2</sub>, 2 mM ATP, 750 μM CoASH, and 10 U commercial pyrophosphatase. Individual substrates were added to achieve a final concentration of 500 μM. Reactions were initiated by the addition of ligase (5 μM final) or H<sub>2</sub>O in the sample and control reactions, respectively. After incubation at 25 °C for 30 m, reactions were quenched by the addition of 2 mM DTNB. The decrease in absorbance attributed to the formation of an acyl-CoA product was measured by subtracting each sample absorbance from its corresponding control

absorbance. Activity was measured as the percent change of the sample from the control absorbance and all reactions were carried out in duplicate. The total relative activity was recorded as an average of the two trials. Note: Any duplicate sample trials with a deviation of activity greater than 10% were discarded and retested.

### 3.2.5 Determination of Steady-State Kinetic Constants

Ligase activity was measured using a Shimadzu UV1800 UV Spectrometer and a coupled assay involving adenylate kinase (AK), pyruvate kinase (PK) and lactate dehydrogenase (LDH). Reactions monitored the decrease in absorbance at 340 nm ( $\Delta\epsilon = 6.2 \text{ mM}^{-1}\text{cm}^{-1}$ ) as a result of the oxidation of NADH and were carried out at 25 °C in 500 µL solutions containing assay buffer (50 mM HEPES, 5 mM MgCl<sub>2</sub>, 3.5 mM ATP, 1 mM CoASH, 200 µM NADH, 3 mM PEP, 5 mM KCl, 11 U AK, 9 U PK and 9 U LDH at pH 7.5), enzyme and varying concentrations of substrate ranging from 0.5-5x K<sub>m</sub>. Initial velocity data, measured as a function of substrate concentration, were analyzed using Enzyme Kinetics v1.4 and equation (1):

$$V = V_{\max}[S]/([S]+K_m) \quad (1)$$

where V is the initial velocity, V<sub>max</sub> is the maximum velocity, [S] is the substrate concentration and K<sub>m</sub> is the Michaelis constant. k<sub>cat</sub> was calculated from V<sub>max</sub>/[E], where [E] is the total enzyme concentration.

### **3.3 Results and Discussion**

#### **3.3.1 Selection of Standalone Ligases**

In order to select standalone ligases for biochemical characterization, we searched for all of the AMP-adenylate-forming domains in *P. aeruginosa* PAO1. We identified 27 ligase domains, 10 of which appeared to be part of multi-domain NRPS or PKS clusters due to their large sequence length (> 800 amino acids) (Table 3-1). PA1215, PA1221 and PA4228 (*pchD*) were also classified as part of NRPS or PKS clusters based on previous literature [40, 41]. After filtering, 14 stand-alone ligase domains remained as potential acyl-CoA synthetases involved in fatty acid and organic acid metabolism. The characterization of some *P. aeruginosa* standalone ligases (PA1617, PA3299 and PA3300) have been described previously [39, 42] and thus allowed us to exclude them from our investigation. Of the ten remaining genes that were targeted, PA2893 proved too unstable to obtain pure protein for high-throughput screening or kinetic testing.

#### **3.3.2 Determination of Ligase Substrate Specificity Profiles**

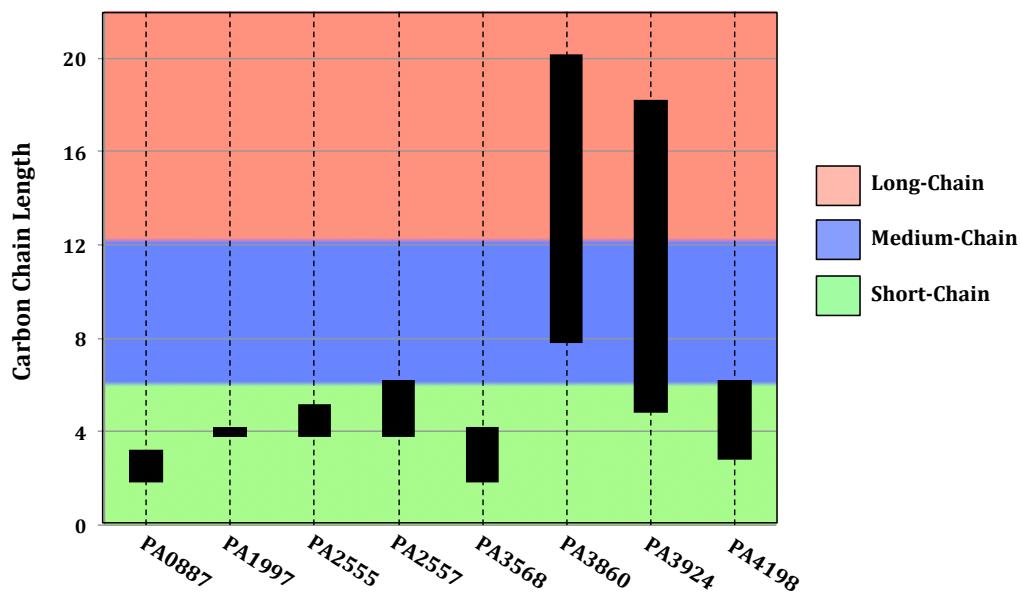

The substrate specificity profiles of the purified *P. aeruginosa* ligases were determined via high-throughput screening (HTS) and verified by measuring the steady-state kinetic parameters of each reaction. Given the solubility limits of long chain fatty acids and the inherent risk of micelle formation, substrates with carbon chains longer than C14 (myristate) were not tested under the HTS assay conditions. However, ligases indicating potential long chain activity from the HTS were individually tested with longer chain fatty acids (> C14) by measuring their steady-

are highlighted in red and previously characterized genes are highlighted in gray.

state kinetic parameters. The various ligases produced by *P. aeruginosa* exhibit a broad spectrum of substrate ranges and specificities (Figure 3-3). While some appear to be specific for just short-chain fatty acid or aromatic acid substrates, others appear to exhibit more promiscuous behavior, activating a range of fatty acid substrates from shorter-chain to long-chain. The results described within imply that chain length is the major contributing factor to specificity and activity while the

addition of substituent groups (hydroxyl, methyl, unsaturated bonds) -- for the most part -- have only modest effects on overall activity.

#### *Acetyl-CoA Synthetase Activity*

Annotated as an acetyl-CoA synthetase (acs), PA0887 (acsA) displays high sequence identity to other previously characterized acs enzymes in other species, including *E. coli* and *S. enterica* [40, 43]. Crystal structures obtained from *S. enterica*

acs show a very small binding pocket, defined by W414, which blocks the rear of the active site and restricts substrate accommodation to short chain fatty acids up to C3 in length [40]. This is consistent with our HTS data (Table 3-2) as it revealed PA0887 to display narrow specificity, preferring parent chain lengths of only C2-C3. The measured steady-state kinetic parameters verified this activity, indicating that PA0887 could only activate acetate and propionate with any biological relevance. While the turnover numbers ( $k_{cat}$ ) measured for PA0887-catalyzed hydrolysis of acetate and propionate were essentially identical (Table 3-3), the  $K_m$  value for acetate is roughly 3.5-fold lower than the  $K_m$  measured for propionate, indicating a more ideal fit in the acsA active site. This discrepancy in substrate binding leads to a 5-fold higher overall kinetic efficiency ( $k_{cat}/K_m$ ) with acetate, indicating it to be the physiological substrate of acsA.

### *Short-Chain Activity*

From the HTS and kinetic data, five ligases (PA1997, PA2555, PA2557, PA3568 and PA4198) were shown to exhibit preferences for short-chain fatty acid substrates. Interestingly, while all indicate a similar overall trend in activity, each ligase displays a different substrate specificity range and physiological substrate, indicating each one's potential involvement in distinct biological roles. PA3568 appears to exhibit a short-chain preference similar to acsA, albeit with a slightly wider range. Able to activate acetate and propionate, the HTS also indicated moderate to high activity with a variety of butyrate derivatives, as well as valerate (Table 3-2). However, steady-state kinetics verified physiologically relevant activity

only with acetate, propionate, butyrate and isobutyrate (Table 3-3). The greatest discrepancies between substrates were seen in their respective  $K_m$  values, with a 10-fold difference between the lowest (isobutyrate) and the highest (acetate). The trend in  $K_m$  value would indicate that the PA3568 active site is set up to best accommodate fatty acids with a C3 parent chain, ideally with branched substituents. This result is not entirely surprising given that PA3568 shares 44% sequence identity with the propionyl-CoA synthetase (prpE) from *S. typhimurium*, a ligase shown to function in the catabolism of propionate [44]. Slight discrepancies in turnover number appear to be proportional to the significantly differing  $K_m$  values, leading to only slight differences in overall kinetic efficiency for each substrate. While PA3568 is able to activate propionate and butyrate with high efficiency as well, the results suggest that isobutyrate is its physiological substrate. HTS analysis of PA1997 indicated it to be moderately promiscuous, as it appeared to be active with acetoacetate, butyrate and other C4 derivatives ((D/L)- $\beta$ - hydroxybutyrate, crotonoate, butenoate) (Table 3-2). Outside of C4 substrates, some moderate activity was also seen with the saturated C5 and C6 fatty acids, valerate and hexanoate. Annotated as an acetoacetyl-CoA synthetase, kinetic analysis showed the highest overall efficiency with acetoacetate, verifying it to be the physiological substrate for PA1997. Furthermore, the data reveals that only the C4 derivatives, acetoacetate and (L)- $\beta$ -hydroxybutyrate, can be activated by PA1997 with any biological relevance, as they displayed a 10<sup>2</sup>-fold higher overall efficiency than all of the other substrates tested. While all of the measured  $k_{cat}$  values (except (D)- $\beta$ -hydroxybutyrate) appear to be competitive with each other, the major contributing

**Table 3-2.** High-throughput screening of *P. aeruginosa* ligases with various fatty acid and amino acid substrates. Activity is colored on a gradient scale from red (high activity) to white (no activity). Untested substrates are denoted by “n/a.”

factor comes from the difference in substrate binding, with acetoacetate and (L)-β-hydroxybutyrate displaying  $K_m$  values 18-70-fold lower than the other substrates tested (Table 3-3). This result indicates the potential importance of a β-positioned oxygen substituent (hydroxy or keto) for tight substrate binding. Additionally, the 32-fold difference in  $K_m$  between (D) and (L)-β-hydroxybutyrate is indicative of a

highly stereospecific active site arrangement. Overall, the results defining PA1997 as an acetoacetyl-CoA synthetase (AACS) are in good agreement with previously characterized AACS enzymes in other organisms, including the stereospecific preference for (L)- $\beta$ -hydroxybutyrate, which has been described previously in the nitrogen-fixing bacterium, *S. meliloti* [45].

Located only two genes apart, PA2555 and PA2557 exhibit similar yet remarkably different substrate specificity profiles. The HTS results indicated a narrow substrate range for PA2555, showing it to prefer saturated and, to a lesser extent, unsaturated C4 and C5 derivatives (Table 3-2). Unfortunately, due to protein stability issues, we were not able to obtain enough pure protein to measure any steady-state kinetic parameters and can not accurately speculate on which activities may or may not be biologically relevant. However, given the overall reliability of the HTS, we feel confident in the conclusions we can draw from it. By far, it appears that isobutyrate is the physiological substrate, as PA2555 exhibited twice as much activity in the HTS as butyrate and valerate. This is interesting considering the negligible activity seen with (the structurally similar) propionate and hints at the significance of the branched methyl group for substrate accommodation and binding. Additionally, the low level activity seen with crotonoate and 3-butenoate, mostly likely attributed to large  $K_m$  values, indicate the binding of unsaturated substrates to be unfavorable and suggests the importance of substrate flexibility as well in the PA2555 active site. An opposing trend was seen with PA2557, as it displayed a large degree of promiscuity for a variety of short chain fatty acids. In general, PA2557 appeared to be highly active with both linear and branched

**Table 3-3.** Steady-state kinetic constants for *P. aeruginosa* ligase-catalyzed activation of various fatty, aromatic and amino acids. Substrates highlighted in grey

indicate  $K_m$  values too high for biologically relevant activity. Substrates highlighted in red represent the highest overall kinetic efficiency. (HB): hydroxybutyrate.

saturated fatty acids ranging from propionate to hexanoate, as well as with a variety of other C4 derivatives including crotonoate, 3-butenoate, (D/L)- $\beta$ -hydroxybutyrate,  $\alpha$ -hydroxybutyrate and acetoacetate. Slight activity was also seen with acetate, hexenoate and the medium and long chain fatty acids, laurate and myristate, respectively. The steady-state kinetic parameters displayed a much narrower range of biologically relevant activity for PA2557, indicating only high-level activity for butyrate, isobutyrate, crotonoate, valerate, isovalerate and hexanoate (Table 3-3). While all of the substrates tested once again exhibit competitive turnover numbers, acetate, propionate and the other C4 derivatives display millimolar-level  $K_m$  values. Isovalerate appears to be the physiological substrate, with its  $10^5$  overall kinetic efficiency at least 10-fold higher than any other substrate tested. The higher degree of efficiency is directly attributed to the measured  $K_m$  value for isovalerate, as it is 8-fold lower than the  $K_m$  for valerate. As with PA2555, this again indicates the significant role of a branched methyl group in substrate binding and orientation. Interestingly enough, PA2557 also displayed activity for benzoate and 4-fluorobenzoate, the only ligase found to be active with both aliphatic and aromatic acid substrates. While the kinetic efficiencies measured for both are  $10^2$ -fold lower than that of isovalerate, the lower  $K_m$  values indicate favorable binding interactions in the PA2557 active site, possibly arising from  $\pi$ -stacking (both) and/or

electrostatic (4-fluorobenzoate) interactions from the aromatic ring and *para*-substituted fluoro group, respectively.

According to the HTS, PA4198 displayed a range of activity (modest to high) with all of the C4 derivatives tested (Table 3-2). High activity was also seen with valerate, along with moderate activity towards acetate and the amino acid, valine. Some low-level activity was indicated for hexanoate as well. The steady-state kinetic parameters revealed the range of physiological activity for PA4198 to be specific for linear substrates from C3-C5 in length (Table 3-3). Substrates active in the HTS such as (D/L)- $\beta$ -hydroxybutyrate,  $\alpha$ -hydroxybutyrate, acetoacetate and isobutyrate all displayed millimolar  $K_m$  values, indicating the presence of a small, narrow binding pocket in which any interactions from branching substituent groups are unfavorable. While PA4198 exhibited the highest turnover rate with acetate, it also exhibited the least favored binding interactions with a  $K_m$  in the  $10^4$  range. Only C3-C5 derivatives had measured  $K_m$  values within a physiological range. Overall, 3-butenoate has the most favorable binding interactions and paired with a fairly high  $k_{cat}$  value, has the highest kinetic efficiency with PA4198.

#### *Medium-Chain Activity*

PA3924 exhibited the largest range of HTS activity, activating linear fatty acids from propionate to laurate (C3-C12). PA3924 also displayed high activity toward a variety of C4 derivatives as well as the medium chain derivatives, citronellate, hexenoate, octenoate and decenoate. From the steady-state kinetic parameters, we found that the low-level propionate activity seen in the HTS was just

an artifact, as PA3924 was unable to activate propionate with any physiological relevance. Of the C4 derivatives, only butyrate and (D)- $\beta$ -hydroxybutyrate were activated at all, and with low-level kinetic efficiency due to millimolar  $K_m$  values. After testing long chain substrates, we found that PA3924 can activate saturated and unsaturated fatty acids from valerate (C5) to oleate (C18) with physiological relevance. We noticed an emerging trend of increasing kinetic efficiency with increasing chain length that maxed out with laurate. As chain length increased further, the kinetic efficiency decreased and remained relatively the same. For the short-medium chain fatty acids leading up to laurate, this trend is described mainly through substrate binding and accommodation. While the calculated  $k_{cat}$  values are relatively competitive with each other, the  $K_m$  decreases over 150-fold from valerate to laurate, where PA3924 exhibits a sub-micromolar value. Beyond laurate, the largest discrepancies in  $K_m$  arise from comparing saturated and unsaturated derivatives. This can be explained from the decreased flexibility of the long chain substrates that most likely need to wind around in the active site in order to be properly accommodated. Overall, the data points to PA3924 as the most promiscuous of the *P. aeruginosa* ligases with optimal efficiency toward medium-chain substrates.

#### *Long-Chain Activity*

The only ligase characterized in this study to be active for long-chain substrates was PA3860. While previous works have characterized PA3299, PA3300 and PA1617 as fellow long-chain ligases, the substrate specificity profile of PA3860,

to date, has yet to be determined [39, 42]. From the HTS, PA3860 exhibited moderate activity with medium to long chain fatty acids from hexanoate to laurate (C6-C12). Interestingly enough, derivatives between C6 and C12 in length such as citronellate, hexenoate, octenoate and decenoate displayed no activity, indicating the specific nature of the PA3860 active site for linear, saturated fatty acid substrates. Upon determination of the steady-state kinetic parameters, PA3860 was found to be even more active for long-chain fatty acids, catalyzing thioester formation of substrates all the way up to C20 in length. As with the trend displayed by PA3924, a similar trend was also noticed for PA3860 activity. The measured  $k_{cat}$  values remain fairly constant and competitive between all substrates tested while  $K_m$  values steadily decreased by over 1500-fold from hexanoate to palmitate. While the  $K_m$  increased with increasing carbon length over C16 (albeit very slow), it was noticed that unsaturated derivatives of long-chain fatty acids were also accommodated by the PA3860 active site. The sub-micromolar  $K_m$  measured for palmitate resulted in the highest overall kinetic efficiency, indicating it to be the physiological substrate for PA3860.

#### *Aromatic Activity*

PA0996, annotated as pqsA, was the only standalone ligase found to be associated with aromatic carboxylate derivatives. The HTS results indicated high activity with benzoate and a variety of derivatives including anthranilate and methyl-, hydroxy- and methoxybenzoate moieties, as well as various halogenated derivatives (Table 3-2). Steady-state kinetic data indicates anthranilate to be the

physiological substrate, due mainly to a 3-20-fold lower  $K_m$  value than other substrates tested (Table 3-3). Besides anthranilate, PA0996 displayed the higher  $K_m$  values (and lower efficiencies) with all benzoate substituents when compared to just benzoate. This indicates that the active site is setup specifically for an *ortho*-positioned amine substituent. Additionally, the halogenated derivatives 2-bromo, 2-chloro and 4-fluorobenzoate displayed the highest respective  $K_m$  values and lowest overall efficiencies. These results are in good agreement with previous characterization of PA0996 as an anthraniloyl-CoA ligase where the highest activity was observed with anthranilate and benzoate in both cases [46].

### **3.3.3 Biological Roles of *P. aeruginosa* Ligases**

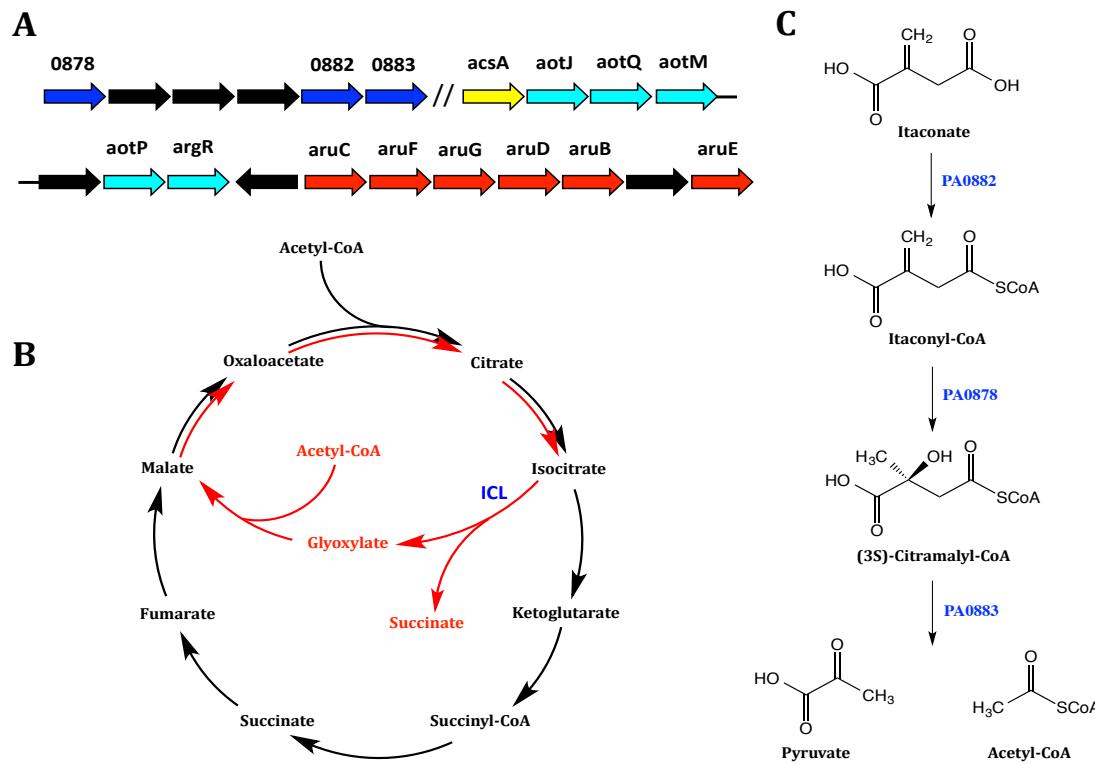

#### *Utilization of Fermentation Products*

Fermentation is the metabolic process utilized by all anaerobic bacteria (and some aerobic bacteria) to generate energy in the absence of oxygen and represents the primary means of ATP production under these conditions. The principal byproducts produced by carbohydrate and amino acid fermentation are acetate, propionate, and butyrate but ethanol, malonate, 2,3-butanediol, valerate, hexanoate, isobutyrate, and isovalerate are also produced in varying amounts [47]. SCFA fermentation has largely been studied in the human colon and butyrate has recently received much attention as a product of microbial metabolism and mucosal immunity modulator. However, as more sophisticated techniques become available to profile bacterial populations, it has become clear that many fermenting species also colonize the CF lung.

In bacterial systems, the *Crc* regulatory system is responsible for controlling the uptake and utilization of various short-chain carbon sources. This is accomplished by binding the mRNA of certain genes necessary for short-chain carbon utilization and repressing their translation. Under anaerobic conditions when the utilization of poor carbon sources is necessary for survival, a two-component regulatory system, CbrAB, is activated and induces the transcription of *CrcZ*, an sRNA. *CrcZ*-mediated repression of *Crc* leads to the de-repression of the target genes, allowing them to function in the uptake and utilization of poor carbon sources. Many target genes have been identified, including *estA* (esterase), *acsA* (acetyl-CoA synthetase) and *aroP2* (aromatic amino acid uptake protein) [37].

PA0887, shown to be an acetyl-CoA synthetase (*acsA*), has been the focus of extensive study. Its role was originally described in the utilization of acetate, whereby acetate is activated by *acsA* and inactivated by sequential phosphorylation and dephosphorylation (*Ack-Pta* pathway) [48]. Further studies revealed that *acsA* is critical for activation of acetate at low cellular concentrations (nutrient-poor conditions), similar to conditions found in the CF sputum environment [49].

Located in the middle of a large open reading frame, PA0887 is sandwiched between two distinct metabolic operons (Figure 3-4A). Downstream from *acsA* is small gene cluster responsible for the degradation of itaconate (Figure 3-4C) [50]. Produced by activated macrophages in response to infection, itaconate is a potent inhibitor of isocitrate lyase, the key enzyme of the glyoxylate bypass (Figure 3-4B). This diverted pathway converts isocitrate to succinate by way of glyoxylate and allows bacteria to synthesize succinate under nutrient-poor conditions when only

**Figure 3-4.** (A) Gene neighborhood of PA0887 (yellow) showing the proximity of an itaconate degradation operon (blue) as well as arginine uptake (teal) and utilization (red) operons. (B) The citric acid cycle (black) showing the glyoxylate bypass (red). The key enzyme Isocitrate lyase (ICL) is shown in blue. (C) *P. aeruginosa* genes involved in itaconate degradation.

simple (poor) carbon sources like acetate are available [51]. Various pathogenic species have been shown to degrade itaconate to pyruvate and acetyl-CoA, not only helping the bacteria survive phagocytosis but also producing useful metabolites [50]. Near *acsA* is the *aot/argR* operon (*aotJQM*) responsible for arginine uptake and

regulation. Along with *acsA*, the *aot-argR* operon is under the control of the CbrAB regulatory system, likely explaining their proximity and indicating the importance of arginine uptake and utilization during nutrient-poor conditions [49]. While it remains unknown if the pathway for itaconate degradation is under the control of the CbrAB regulatory system as well, it would not be surprising considering its function to protect a metabolic cycle that is used during nutrient-poor conditions.

While its paralog, *acsA*, has been extensively studied, research into the individual role of *acsB* (encoded by PA4733) has been largely ignored. Both genes share high sequence similarity to verified acetyl-CoA synthetases in other organisms but searches through the current literature reveal little about the individual role of *acsB* [43]. Due to the high pairwise similarity of *acsB* to *acsA* (63%), it is easy to postulate that the two are acting in a similar manner. Additionally, the *acsB* gene appears to be just upstream from and in the same reading frame as *CbrA* and *CbrB*, and while it has not been determined if *acsB* is a target for *crc* transcriptional regulation, this further supports an *acsB* functional role similar to that of *acsA*.

PA2555 and PA2557 are located only two genes apart, and while their specificity profiles show significant overlap, they share very low sequence identity with each other. Interestingly enough, PA2557 has a moderate biological range, highly conserved throughout *Pseudomonas*, Gammaproteobacteria and within the Actinomycetales class of Actinobacteria. PA2555, on the other hand, seems to have a very limited biological range, as putative orthologs were found only within Proteobacteria. This supports a model of convergent evolution, and may also indicate a specialized role for PA2555 pathogenesis given its limited range

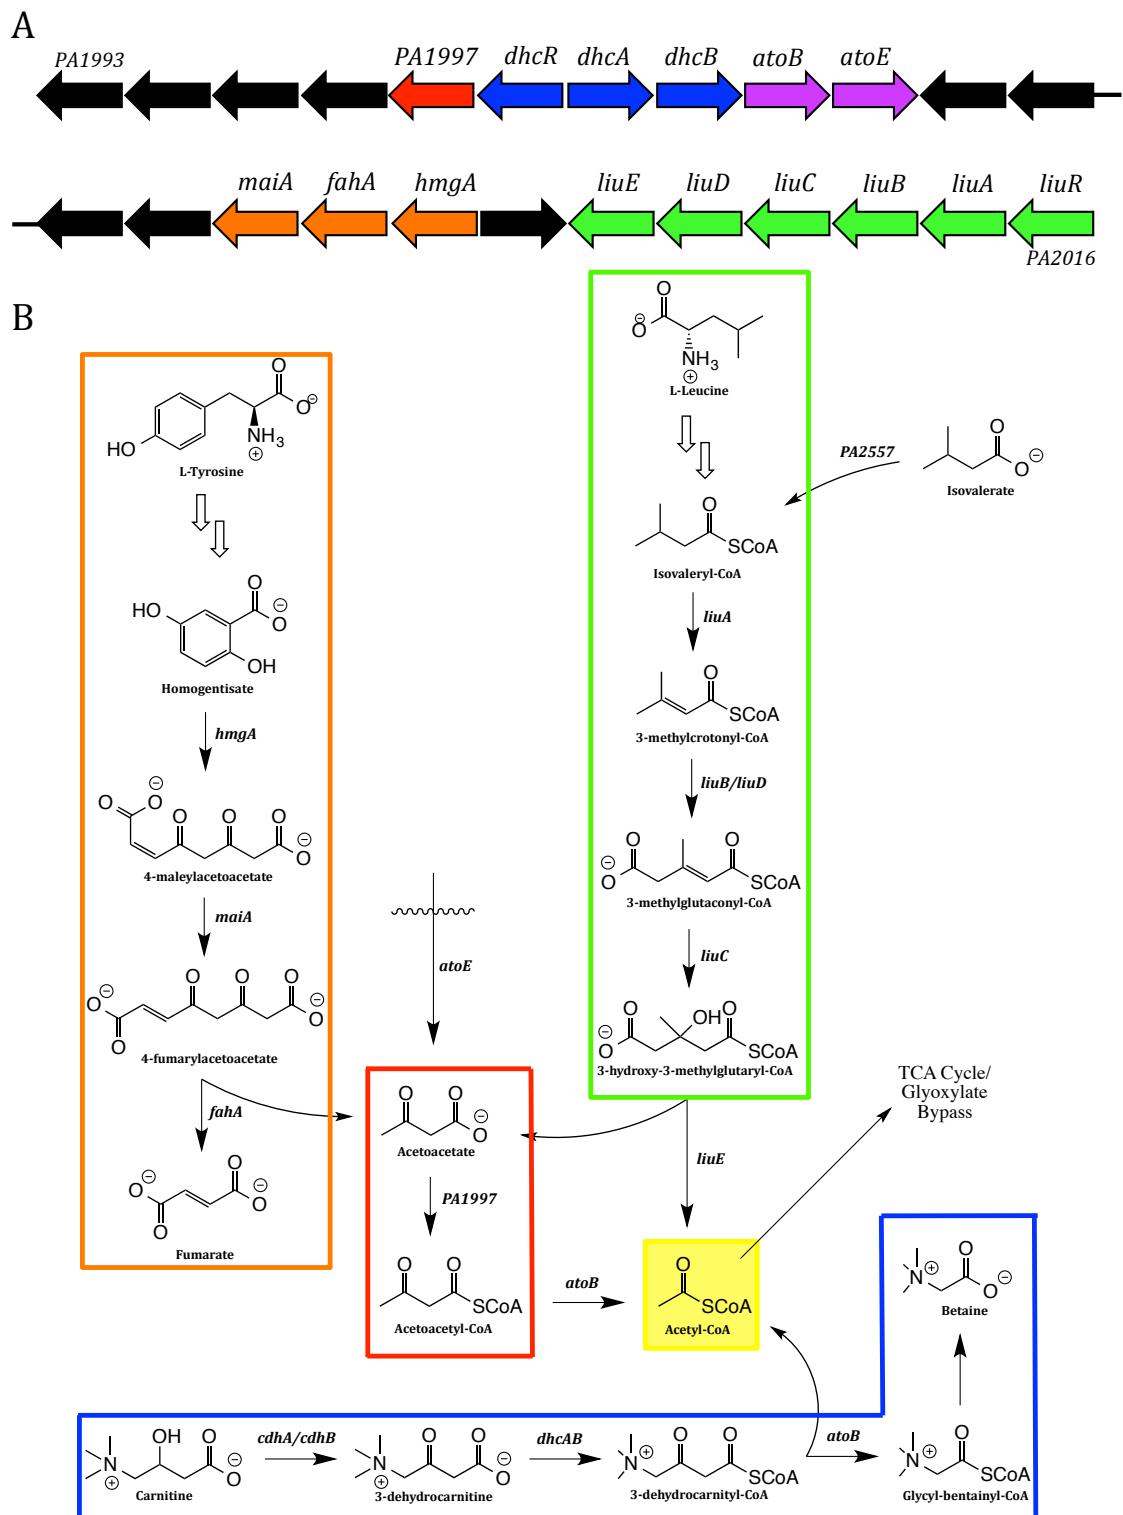

throughout Bacteria. Analysis of the PA2555/PA2557 gene context implies their involvement in a fatty acid  $\beta$ -oxidation operon, given their proximity to the putative  $\beta$ -oxidation operon *fadBA3* (PA2553 and PA2554) [38]. Additionally, PA2550 and PA2552 encode putative acyl-CoA dehydrogenases while PA2554 encodes a putative short-chain dehydrogenase and PA2553 encodes an acyl-CoA thiolase. Given these findings along with the substrate specificity profiles, it is proposed that PA2555 and PA2557 may be able to scavenge medium-chain C4 and C5 fatty acid derivatives for use in a short-chain  $\beta$ -oxidation pathway.

Similar to PA2555/PA2557, PA3568 is also located near a putative  $\beta$ -oxidation operon (*fadBA2*: PA3589-PA3590) involved in short chain fatty acid oxidation [38]. PA3589-PA3591 and PA3593 encode an acetyl-C-acetyltransferase, hydroxybutyryl-CoA dehydrogenase, enoyl-CoA hydratase and an acyl-CoA dehydrogenase, respectively. Adjacent to PA3568 are two genes involved in valine degradation, *mmsB* and *mmsA*. Encoded by PA3569, *mmsB* functions as a 3-hydroxyisobutyrate dehydrogenase while *mmsA* (encoded by PA3570) is a methylmalonate semialdehyde dehydrogenase. During valine degradation, isobutyryl-CoA is converted to (S)-3-hydroxybutyrate by way of methacrylyl-CoA and (S)-3-hydroxybutyryl-CoA. Catalyzing the subsequent step, *mmsB* converts (S)-3-hydroxybutyrate to (S)-methylmalonate semialdehyde, which is then converted to propionyl-CoA by *mmsA*. Given its activity with propionate, it is entirely possible that PA3568 could be functioning in propionate metabolism as well, activating free propionate for degradation.

Additionally, the activated medium- and branched-acyl-CoAs formed from SCFA fermentation products can be incorporated into PHA polymers, degraded via  $\beta$ -oxidation or amino acid degradation pathways, or feed into secondary metabolite synthesis (discussed below). Butyryl-CoA, in particular (produced by PA4198), could provide a precursor for synthesis of the *N*-butanoyl-L-homoserine lactone quorum signal [51]. In addition, activated SCFAs may provide building blocks for rhamnolipid synthesis. Rhamnolipids are composed of a rhamnose sugar linked to a 3-(3-hydroxyalkanoyloxy)-alkanoic acid moiety [27]. *RhlA* is responsible for synthesizing the fatty acid group and utilizes 3-hydroxyacyl-CoA or 3-hydroxyacyl-ACP intermediates drawn from fatty acid synthesis and  $\beta$ -oxidation pathways [27, 52].

#### *Utilization of Branched-Chain Amino Acids*

Amino acids can provide an important source of carbon and nitrogen for *P. aeruginosa* during pathogenesis. In fact, some reports have shown higher levels of amino acids -- particularly leucine and isoleucine -- in CF sputum as compared to non-CF sputum, attributed to the evolution of auxotrophic strains in the CF lung [53]. In *P. aeruginosa*, leucine is degraded via the *liu* pathway (Figure 3-5B). Additionally, the degradation products of acyclic terpenes (like citronellol and geraniol) and the branched-chain fatty acid isovalerate can feed into the *liu* pathway as well. *liuA* has been characterized as an isovaleryl-CoA dehydrogenase and has been shown to be required for growth on isovalerate, and leucine [54]. Given the

**Figure 3-5.** (A) Gene neighborhood surrounding *PA1997* (red) showing proximity to genes involved leucine (green), tyrosine (orange) and carnitine (blue)

degradation. Genes involved in short-chain fatty acid utilization are shown in purple. (B) Reaction diagram showing late-stage steps of leucine and tyrosine degradation as well as carnitine metabolism. All pathways utilize *atoB* to produce the critical TCA cycle metabolite acetyl-CoA (yellow).

specificity of both PA2557 and PA3568 for isovalerate, it could also be involved in the catabolism of isovalerate, leucine, and other methyl-branched compounds (Figure 3-5B).

#### *Acetoacetate Utilization*

Analysis of the PA1997 gene neighborhood further supports its role as an acetoacetyl-CoA synthetase. PA1997 is found near four separate gene clusters that all function in the utilization of short-chain fatty acid derivatives (Figure 3-5A). Just upfield from PA1997 are two genes involved in acetoacetate utilization: *atoE* and *atoB* (PA2001 and PA2002, respectively). The protein encoded by *atoE* is an uncharacterized short-fatty acid transporter potentially involved in the uptake of exogenous acetoacetate. Once in the cell, PA1997-activated acetoacetate (acetoacetyl-CoA) can then be converted to two molecules of acetyl-CoA by *atoB*, an acetyl-CoA C-acetyltransferase. Acetyl-CoA can then feed into the TCA cycle or glyoxylate bypass, depending on cellular growth conditions. Additionally, PA1997 may also be involved in the utilization of intracellular acetoacetate, a product of both tyrosine and leucine degradation pathways. Found further upfield from *atoB*

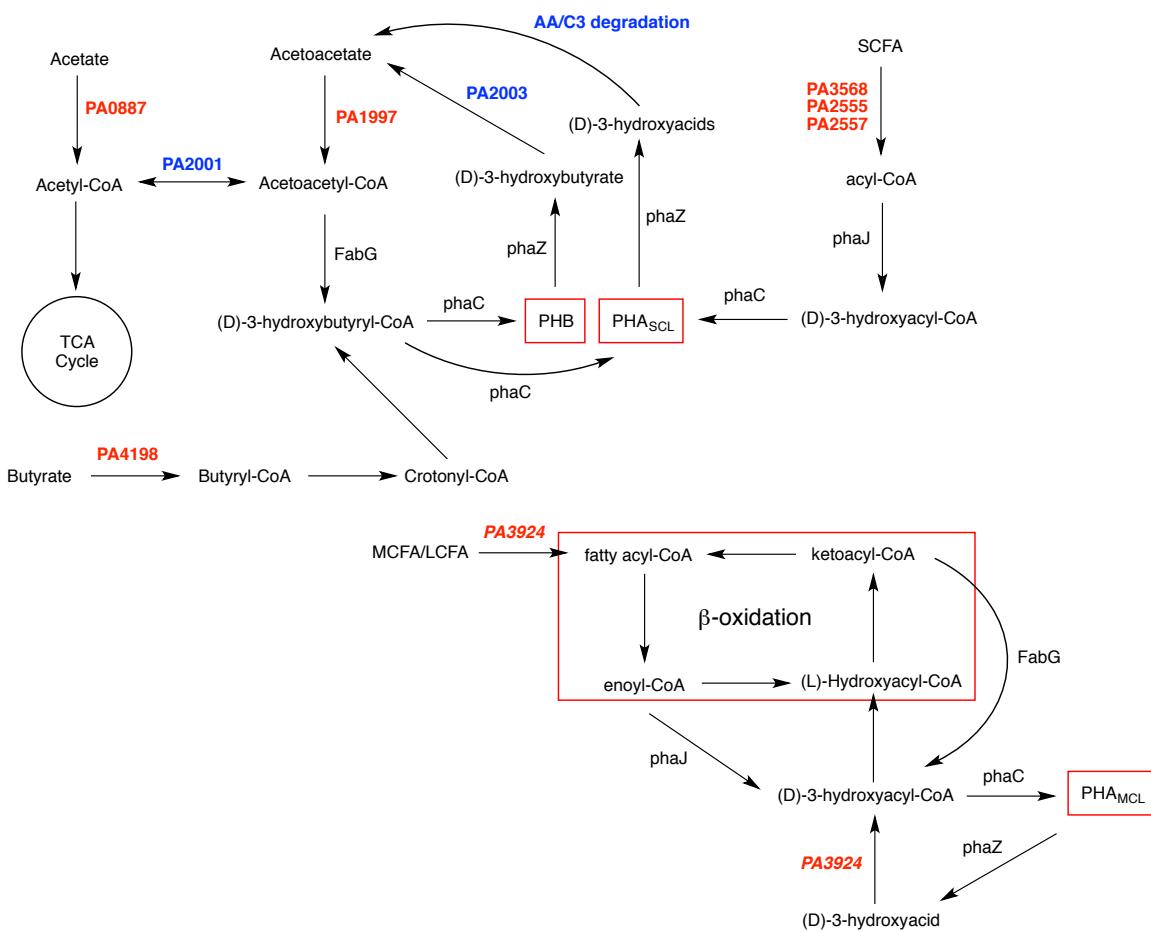

and *atoE* are gene clusters for both of these pathways. The genes encoding *maiA*, *fahA* and *hmgA* (PA2007-PA2009, respectively) represent the final steps of tyrosine metabolism. In the last step, *fahA*-mediated conversion of 4-fumarylacetate to fumarate produces acetoacetate, which can then be activated by PA1997. The *liu* gene cluster (PA2011-PA2016) -- just upfield from *hmgA* -- catalyzes the final steps of leucine metabolism. The terminal step produces acetyl-CoA and acetoacetate, the latter of which can be activated by PA1997. Additionally, sitting adjacent to PA1997 are three genes directly involved in carnitine metabolism. A quaternary amine essential for  $\beta$ -oxidation in animals, carnitine is required for the soluble transport of long-chain fatty acids into the mitochondrial matrix (the carnitine shuttle). Due to the physiological importance of the carnitine shuttle, high cellular concentrations of carnitine are found in fat-metabolizing tissues as well as in circulating and extracellular fluids [55]. While many bacteria can utilize carnitine as an osmoprotectant during times of osmotic stress, some pathogenic species like *P. aeruginosa* are able to metabolize the small molecule, utilizing it as both a carbon and nitrogen source during pathogenesis [56]. The genes encoding *dhcA* and *dhcB* (PA1999 and PA2000, respectively) are the  $\alpha$  and  $\beta$  subunits of a 3-ketoacid-CoA transferase and have been shown to catalyze the activation of dehydrocarnitine [55]. The gene directly adjacent to PA1997, *dhcR* (PA1998), is the divergently transcribed transcriptional regulator of *dhcAB*. The reaction step following *dhcAB* is the formation of glycyl-betainyl-CoA by *atoB*, forming acetyl-CoA in the process. Further catabolism results in glycine-betaine and ultimately glycine. While this

pathway is not directly related to PA1997 functionality, the common reliance of all three pathways on *atoB* further supports the role of PA1997.

In nature, orthologous sequences of PA1997 are mainly concentrated within the alpha and gamma classes of Proteobacteria with the majority of putative orthologs contained within the genus *Pseudomonas*. Outside of Proteobacteria, a few sequences were identified with only modest sequence identity (50-58%) within Clostridia (Firmicutes) as well as Spirochaetes.

#### *Polyhydroxyalkanoate (PHA) Cycling*

Given their relative substrate activity profiles and relative gene neighbors, many of the *P. aeruginosa* ligases may play a role in polyhydroxyalkanoate (PHA) cycling. PHA polymers are linear polyester chains made up of hydroxyalkyl monomers. Found to play a critical role in carbon and energy storage, PHAs are produced as a result of bacterial fermentation under conditions of cellular deficiency (N, O, P-limiting) or during times of excess carbon (energy) sources. Interestingly enough, PHA synthesis has been found to be under the control of the *Crc* regulator in *P. putida*. Repressed when carbon/nitrogen levels are balanced, this indicates a potential role of PHA polymers in providing carbon sources under nutrient-poor conditions [57]. PHA polymers can be composed of short-chain (C4-C5, PHA<sub>SCL</sub>) or medium-chain (C6-C14, PHA<sub>MCL</sub>) fatty acid derivatives depending on the bacterial environment. PHA polymers are quite diverse, with over 150 types of hydroxyacids identified as potential PHA building blocks, including hydroxyvalerate, hydroxybutyrate and hydroxyisovalerate [58]. Granules are synthesized using

**Figure 3-6.** Potential involvement of *P. aeruginosa* acyl-CoA ligases in polyhydroxyalkanoate (PHA) cycling.

hydroxyacyl-CoA monomers, and depolymerized to hydroxycarboxylic acids for use (Figure 3-6). When cells are lysed, PHA polymers are released and members of the community can utilize the stored fatty acids by secreted PHA depolymerases. There is evidence that PHA granules *in vivo* are partially or completely surrounded by a layer of PHA-associated proteins (PGAPs) [59]. Not surprising, proteins detected on

granules include *phaC* and *phaZ* as well as numerous other proteins involved in PHA synthesis and breakdown.

The most common PHA polymer produced is polyhydroxybutyrate (PHB). Under starvation conditions, PHB depolymerases cleave off individual (D)-3-hydroxybutyrate subunits, which are then converted to acetoacetate by (D)-3-hydroxybutyrate dehydrogenase (encoded by PA2003). From here, PA1997 may function in the activation of acetoacetate for utilization as a carbon source. This function is consistent with an acetoacetyl-CoA synthetase from *S. meliloti*, which was shown to activate acetoacetate released from PHB [45]. Additionally, the specific (L)-3-hydroxybutyrate activity measured for PA1997 indicates that it may also be able to activate (L)-3-hydroxybutyrate as a carbon source.

The synthesis and catabolism of PHAs<sub>CL</sub> require acyl-CoA synthetase activity with C4 and C5 branched compounds. Through  $\beta$ -oxidation cycling, an acyl-CoA precursor can be sequentially converted to (L)-3-hydroxyacyl-CoA, enoyl-CoA and then 3-ketoacyl-CoA. When PHAs<sub>MCL</sub> synthesis is required, the stereospecific hydratase (*PhaJ*) and reductase (*FabG*) can convert enoyl-CoA and 3-ketoacyl-CoA to (D)-hydroxyacyl-CoA, respectively (Figure 3-6) [57]. Given the proximity of PA2555, PA2557, PA3568, and PA4198 to putative  $\beta$ -oxidation genes and the presence of their physiological substrates in PHA polymers, it is possible that these enzymes are involved in activation of branched-chain carboxylic acids during PHA polymerization and breakdown. Conversely, PHA breakdown products like isovalerate and isobutyrate may feed into amino acid degradation pathways.

PHA<sub>MCL</sub> polymers consist of monomer units C6-C14 in length. Rare in nature, PHA<sub>MCL</sub> polymers are produced mainly by fluorescent *Pseudomonads* [60]. As one of the few capable bacteria, *P. aeruginosa* uses PHA synthases *phaC1* and *phaC2*. 3-hydroxyalkanoates for PHA<sub>MCL</sub> synthesis are derived from β-oxidation or fatty acid synthesis, depending on growth conditions. PHA<sub>MCL</sub> plays an important role in pathogenesis as it helps bacteria survive during starvation conditions and regulate carbon flow. Although never characterized in *P. aeruginosa*, PA3924 has previously been described as an (R)-3-hydroxyalkanoate ligase capable of synthesizing PHA<sub>MCL</sub> polymers when co-expressed in *E. coli* with PHA synthase genes [61]. PA3924 was shown to enable the production of PHA<sub>MCL</sub> polymers with C8, C10, and C12 hydroxyalkanoate constituents.

#### *Fatty Acid Degradation*

Long-chain fatty acyl-CoA synthetases are the primary activators of fatty acids for degradation via the β-oxidation pathway (Figure 1-1) and have been characterized in many species, including *E. coli*, *P. putida* and *P. aeruginosa* [39, 62, 63]. PA3299 (*fadD1*) and PA3300 (*fadD2*) are associated with the *fadBA5* β-oxidation operon and are the major contributors to long chain fatty acid degradation [39, 64]. *FadD1* and *fadD2* are also induced by the presence of palmitate, their preferred fatty acid substrate [48]. In addition, *fadD2* knockout strains have decreased virulence factor production and decreased survival in mouse lungs, implying long-chain ligase involvement in pathogenesis[38]. However, *P. aeruginosa* contains multiple *fadD* homologs within the genome, the functions of which have yet

to be determined. PA1617 (*fadD4*) has been proposed to be not only the third major contributor (after *fadD1* and *fadD2*) to fatty acid degradation but also solely responsible for acyclic terpene degradation [64]. Previous characterization of PA1617 shows specificity for long-chain substrates, in good agreement with these proposed functions [42]. Adjacent to PA1617 is a thioesterase (PA1618), and while it preferentially hydrolyzes aroyl-CoA substrates, its predicted to function as a CoA scavenger so PA1617 can synthesize necessary acyl-CoA intermediates [42].

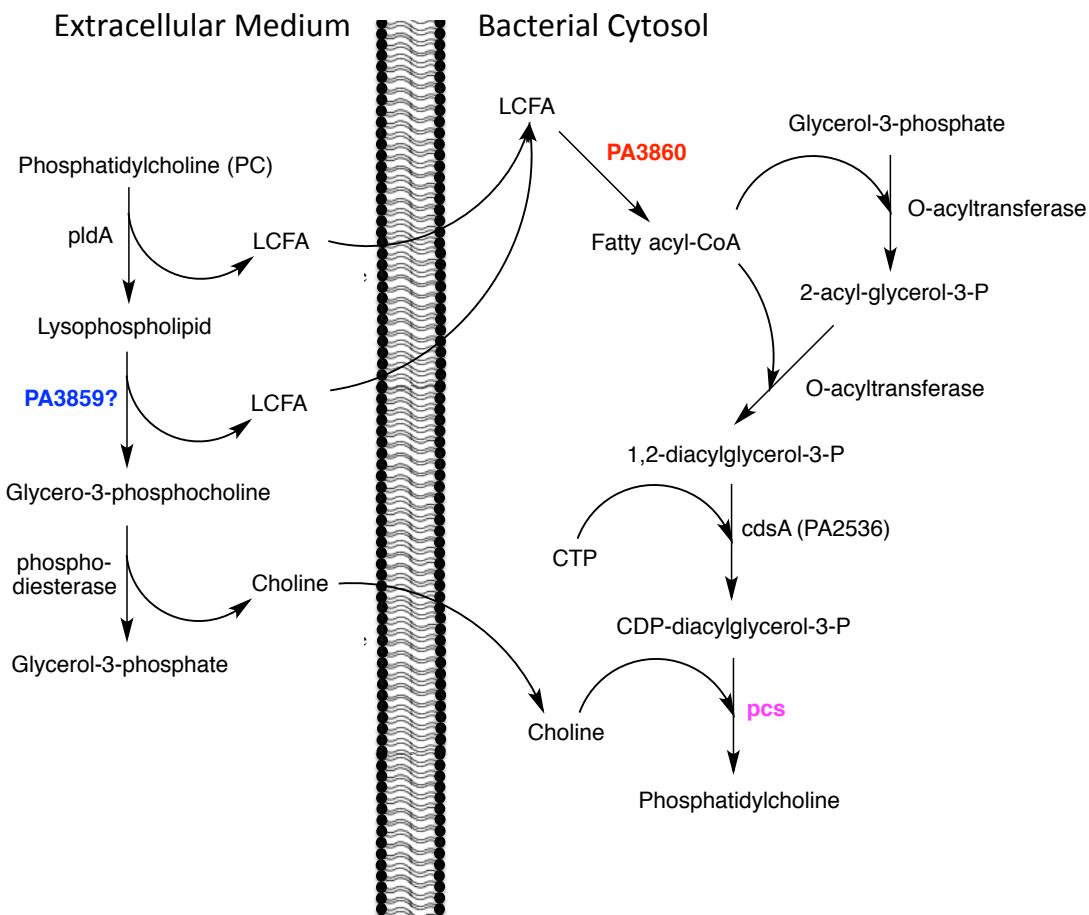

PA3860 (*fadD3*) and PA3924 (*fadD6*) were previously identified as *fadD* homologs but were shown to play minimal, redundant roles in fatty acid degradation as neither was able to support growth on long-chain fatty acids [64].

The final *fadD* homolog, PA2893, was identified as *atuH* (*fadD5*). Similar to PA3860 and PA3924, it was found to play a minimal, redundant role in long-chain fatty acid degradation [64]. Furthermore, given its proximity to the *atu* gene cluster (PA2886-PA2892), PA2893 has been hypothesized to be involved in acyclic terpene utilization as a citronellyl-CoA synthetase [65]. Terpenes are common in plant oils and pigments. The *atu* pathway degrades citronellol, geraniol, and their derivatives to 7-methyl-3-oxo-octenoyl-CoA, which is capable of cycling through β-oxidation [49, 50]. However, in contradiction to this classification, mutant strains lacking PA2893 were still able to survive on acyclic terpene carbon sources [64, 66]. As we were unable to obtain stable protein samples of PA2893 for screening and kinetic analyses, its biological function remains to be elucidated.

### *Membrane Lipid Synthesis*

While most bacterial membranes contain phosphatidylethanolamine, phosphatidylglycerol, and cardiolipid, only roughly 10% of bacterial species also produce phosphatidylcholine (PC) [67]. PC-producing bacteria are confined primarily to Alpha- and Gammaproteobacteria, and include *P. aeruginosa*. PC can be made by methylating phosphatidyethanolamine (SAM-dependent methylation pathway) or by condensing free choline directly with CDP-diacylglycerol (phosphatidylcholine synthase). *P. aeruginosa* exclusively uses phosphatidylcholine synthase (*pcs*) to produce PC and is thought to rely on the host for a supply of choline (Figure 3-7) [68, 69]. Interestingly enough, mutants lacking genes to synthesize PC show a wide range of phenotypes including decreased virulence, decreased swarming motility, inability to escape macrophages, growth-impairment under micro-aerobic conditions and reduced survival upon freezing [69].

While the importance of PC for *P. aeruginosa* remains to be determined, *P. aeruginosa* is the only PC-containing bacteria reported to have a PC-specific phospholipase (*pldA*) that localizes to the periplasmic space [68, 70]. Considering its localization, *pldA* may be involved in lipid maintenance and selectively cleave PC into lipid signaling molecules (analogous to eukaryotic signaling processes) to respond to environmental cues [68]. Conversely, another phospholipase D from *P. aeruginosa* (*pldB*), has recently been characterized as a type IV secretion system effector. Secreted from *P. aeruginosa* along with three cognate proteins, it has been shown to invade both prokaryotic and eukaryotic cells and exhibit antibacterial activity [71]. *PldA* may be involved in similar pathways.

**Figure 3-7.** Potential PA3860 involvement in phosphatidylcholine (PC) synthesis.

Gene context shows proximity of PA3860 to *pcs*, PA3859 (carboxylesterase), PA3853 (putative acyltransferase), and downstream genes involved in PC synthesis.

The gene encoding *pcs* (PA3857) falls three genes downstream of PA3860 and catalyzes the condensation of CDP-diacylglycerol and choline to form

phosphatidylcholine (Figure 3-7). CDP-diacylglycerol is formed by the addition of two acyl-CoA molecules to glycerol-3P followed by conjugation of the diacylglycerol to CDP. The fatty acids present in phosphatidylcholine in *P. aeruginosa* are (primarily) palmitate, palmitoleate, stearate, and oleate, all substrates that PA3860 can utilize. O-acyltransferases specific for glycerol-3-phosphate and 2-acyl-glycerol-3-phosphate add the acyl-CoA units to the glycerol backbone followed by addition of CDP by phosphatidate cytidyltransferase. While PA3860 does not appear to cluster with any O-acyltransferases or cytidyltransferases, the gene context and previous studies suggest a possible role for PA3860 in providing acyl-CoA substrates for 1,2-diacylglycerol synthesis in phosphatidylcholine synthesis.

PA3859 encodes a characterized carboxylic ester hydrolase that has been reported to have highest activity with C8 and C10 carboxylic esters *in vitro* but there is some evidence that it prefers C16 and C18 chain-lengths *in vivo* and can free fatty acids from lysophospholipids [72]. Additional research is needed to clarify the physiological role of PA3859. If PA3859 indeed cleaves lysophospholipids, PA3860 may scavenge the long-chain fatty acids released and may point to the involvement of both enzymes in membrane maintenance. Furthermore, if *P. aeruginosa* uses choline derived from host PC for biosynthesis of membrane molecules, PA3859 may participate in host PC breakdown.

PA3860 appears to have a narrow biological range as putative orthologs with moderate to high sequence identity (50-100%) are only found in *Pseudomonas*. Within proteobacteria, the majority of putative orthologs are in the genus *Burkholderia* genus. Outside of proteobacteria, PA3860 is only identified in three

other species. Overall, this gene context is consistent with PA3860 functioning in a specialized role, such as PC synthesis.

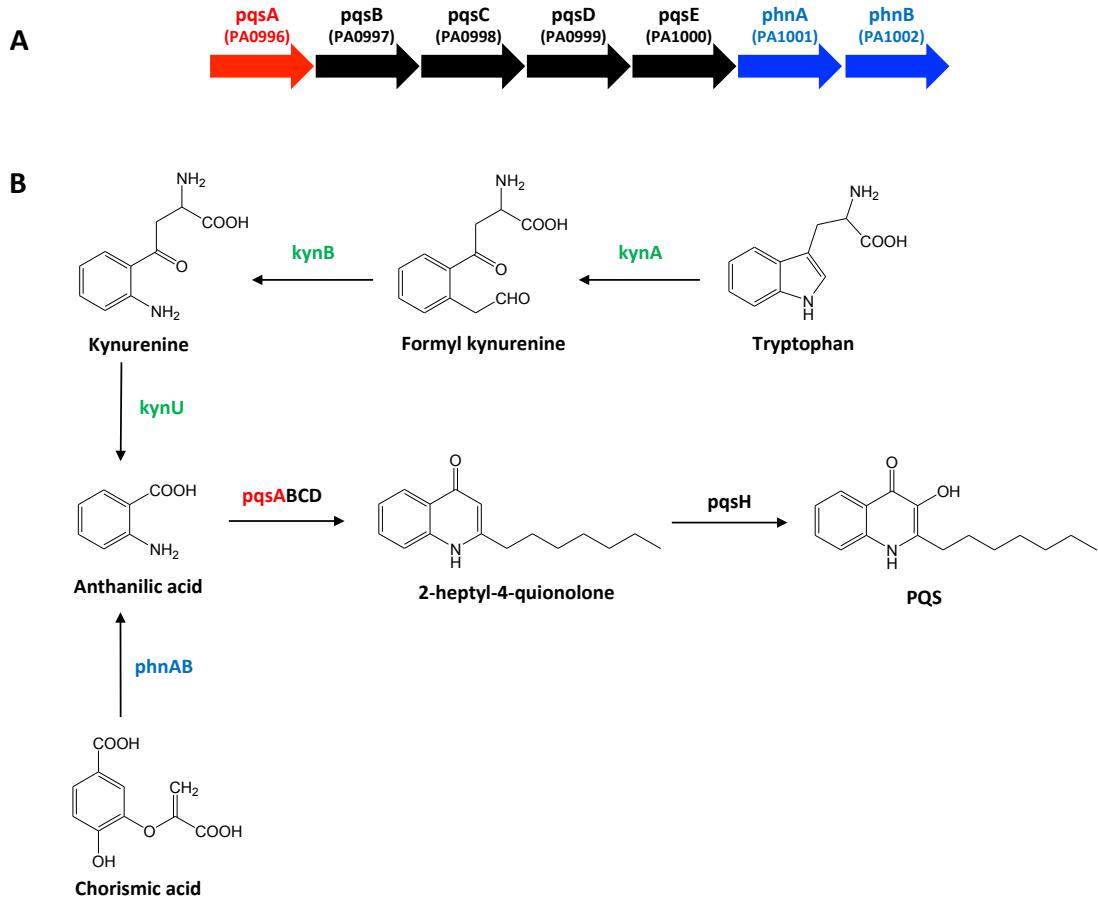

Additionally, PA3860 may play a role in the synthesis of unsaturated fatty acids, given its substrate specificity profile. Producing unsaturated fatty acids to incorporate into phosphatidylcholine, phosphatidylethanolamine, and phosphatidylglycerol is essential for regulating membrane fluidity in response to changes in environment and temperature. All bacteria produce unsaturated fatty acids anaerobically using the *fabAB* dehydrogenase/isomerase and fatty acid synthesis intermediate  $\beta$ -hydroxydecanoyl-ACP as part of type II fatty acid biosynthesis [73]. In addition, some bacteria contain oxygen-dependent desaturases that use saturated phospholipid substrates. *P. aeruginosa* has two desaturases, *desA* and *desB*, and while *desA* functions similar to other bacterial desaturases (using phospholipid substrates), *desB* is unique. Unlike any other bacterial desaturase, *desB* selectively converts palmitoyl-CoA and stearoyl-CoA to their monounsaturated counterparts and provides a way for *P. aeruginosa* to quickly alter its membrane fluidity when long-chain fatty acids are available [73]. While *fadD1* may be the sole provider of fatty acyl-CoA to *desB*, as it is the major contributor to fatty acid and PC degradation, it is possible that PA3860 could moonlight in this role.

#### *Regulation of Virulence Factor Production*

Along with the *N*-acylhomoserine lactone class (HSL), the 4-quinolone class of signaling molecules is one of the largest groups of chemically distinct regulators of biofilm formation and virulence factor production. With over 50 known

quinolones produced by *Pseudomonas aeruginosa* alone [74], many of these secondary metabolites have been shown to exhibit broad-spectrum antibiotic properties as well as quorum sensing abilities [75-77]. Perhaps the most prolific example of the latter is PQS. As discussed earlier, PQS plays a major role in enhancing *P. aeruginosa* virulence by functioning in the *las-Rhl-pqs* regulatory signaling cascade (Figure 3-2). Besides playing a major role in quorum sensing, PQS has been shown to exhibit both pro and anti-oxidative properties during times of oxidative stress and is thought to play a further role in enhancing *P. aeruginosa* virulence by breaking down weaker members of the bacterial community to form smaller, separate populations that are able to better cope with and ultimately overcome antibiotic and oxidative stresses in a “survival of the fittest” manner [78]. Interestingly enough, PQS synthesis has been shown to be upregulated in *P. aeruginosa* isolates taken from CF-infected infants, indicating the additional importance of PQS during the early stages of bacterial pathogenesis in the CF lung environment [79].

Analysis of the PA0996 gene context reveals it to be the first gene of a pqs operon, sitting adjacent to pqsB/C, both  $\beta$ -keto-acyl-ACP, pqsD, a transacetylase homologous to FabH1 and pqsE, a response effector that is not thought to be involved with actual PQS biosynthesis [80]. Found directly upfield and in the same reading frame are the genes encoding phnA and B, the two components of the anthranilate synthase complex (Figure 3-8A). Along with pqsH (found much farther upfield), this gene cluster is known to be responsible for the biosynthesis of PQS (Figure 3-8B) [80]. As previously stated, the starting material for the pqs pathway is

**Figure 3-8.** PQS biosynthetic pathway in *P. aeruginosa*. (A) Organization of the PA0996 gene cluster in *P. aeruginosa* PA01 to show co-localization of pqs (red/black) and phn pathway genes (blue). (B) Reaction steps of the two routes for PQS biosynthesis. The “tryptophan” route is catalyzed by the kynurenine pathway (green) while the “chorismate” route is catalyzed by the phn pathway (blue). Both pathways converge to utilize the pqs pathway (red/black).

anthranilate, which can be produced from two separate sources. The first source comes as a byproduct of tryptophan metabolism by way of the kynurenine pathway.

Previous works have shown that the majority of anthranilate needed for PQS synthesis is produced through this pathway [81]. However, when tryptophan is unavailable, anthranilate can also be produced from chorismate through the action of phnA/B. In direct support of these findings, a variety of knockout growth studies have verified the role of PA0996 in PQS biosynthesis [80].

In nature, PA0996 appears to be quite rare. In fact, outside of various strains of *P. aeruginosa*, we detected no orthologous sequences within the genus *Pseudomonas* or outside the Proteobacteria phylum. Within Proteobacteria, only nine putative orthologs have been revealed, found in the Alpha (1), Beta (5) and Gamma (3) classes. Within Betaproteobacteria are species from the genus *Burkholderia*. This is not completely surprising given that it was once considered to be part of the genus *Pseudomonas*, and in fact, is known to contain plant, human and animal pathogenic species, including *B. cepacia*, a member of the CF-infecting *Burkholderia cepacia* complex [82]. The pqs/phn cluster appears to be highly conserved throughout various strains of *P. aeruginosa* and moderately conserved throughout just a few species of *Burkholderia*. This coincides with recent findings that some pathogenic species of *Burkholderia* have been found to utilize the PQS signaling pathway in a similar manner as *P. aeruginosa* [83]. Given the very limited biological range and overall necessity of PA0996 for PQS biosynthesis, this data would support a model in which *P. aeruginosa* and/or another related pathogenic species have adapted and evolved the pqsA gene specifically to enhance virulence for a greater survival advantage within a host environment.

### 3.4 Summary

In this chapter, we attempted to characterize the contributions of nine standalone acyl-CoA ligases towards enhanced virulence in *P. aeruginosa*. Through high-throughput substrate screening and specificity profiling via steady-state kinetics, we discovered a myriad of acyl-CoA synthetase activities, ranging from aromatic to short-, medium- and long chain fatty acid activation. As a result, it appears as if the individual ligases function in a variety of metabolic pathways, some specific to certain functions while others share an overlapping functionality.

PA0996 (already characterized as pqsA) was verified in its activity as an anthraniloyl-CoA ligase, functioning in the synthesis of PQS, a critical quorum sensing molecule. PA0996 appears to be the only ligase functioning in the activation of aromatic carboxylate substrates, as the remaining eight ligases target alkyl fatty acids of varying length and saturation. Overall, four ligases (PA0887, PA1997, PA2555, PA2557 and PA3568) were characterized as short-chain ligases, capable of activating a carboxylate derivatives in the range of C2-C4, including branched and unsaturated substituents as well as acetoacetate. This is indicative of a high degree of scavenging ability, as *P. aeruginosa* may be capable of utilizing the byproducts of various fermentation and amino acid degradation pathways, and really highlights a potential basis for enhanced virulence.

Alternatively, a number of long-chain fatty acids (PA1617, PA2893, PA3299, PA3300, PA3860 and PA3924) are found in the *P. aeruginosa* genome as well. While PA3299 and PA3300 appear to operate in typical β-oxidation pathways, PA1617 and PA2893 have been implicated in the utilization of acyclic terpenes. Additionally, the

results of our activity assays indicate that PA3860 and PA3924 may be involved, respectively, in phosphatidylcholine (PC) and PHA<sub>MCL</sub> synthesis. Both pathways, rare in bacterial species, are likely to enhance *P. aeruginosa* virulence as well.

Altogether, the results taken from this work give us a broader understanding of the potential energy acquisition pathways employed by *P. aeruginosa* during pathogenesis in CF airways. While antibiotic treatments are somewhat effective during intermittent infection early on, they are rendered all but useless once chronic infection is established. It is our hope that by better understanding the diverse metabolic pathways available to *P. aeruginosa*, differential treatments targeting these survival mechanisms may one day be developed and will provide a more effective treatment for the thousands affected by this terrible disease.

## **Appendix**

### **A-1. Multiple Sequence Alignments**

**A-1-1.** Alignment of flK (F8JPF9) ortholog representatives based on CD-HIT Clustering.

**A-1-2.** Alignment of flK (F8JPF9) with Actinobacteria representative orthologs.

**A-1-3.** Alignment of flK (F8JPF9) with Bacteroidetes representative orthologs.

**A-1-4.** Alignment of flK (F8JPF9) with Proteobacteria representative orthologs.

**A-1-5.** Alignment of flK (F8JPF9) with Firmicutes representative orthologs.

**A-1-6.** Alignment of flK (F8JPF9) and BVU\_1957 (A6L1R5) with Deinococcus-Thermus representative orthologs.

Note: All sequences are listed by UniProt ID. Amino acid positions highlighted in red denote 100% conservation. Positions highlighted in yellow denote highly conserved regions. Structural overlay is based on flK crystal structure (PDB: 3KV8).
