Abstract

Alzheimer's disease (AD) is the most common cause of dementia. The symptoms of AD mainly include short-term memory loss, cognitive defects, and poor judgment, consequently leading to death. Currently 28 million people worldwide are suffering from AD; however, a cure for the disease to retard its initiation and progression has not been developed. Indeed, the discovery of the drug has been very challenging due to involvement of multiple pathogenic factors in the pathogenesis of AD. For example, the aggregates of amyloidogenic amyloid- β ($A\beta$) peptides are accumulated in the AD-affected brain. Among the aggregates, soluble and structured $A\beta$ oligomers have been suggested to be toxic to nerve cells. Additionally, highly concentrated metal ions [*e.g.*, Cu(I/II), Zn(II), Fe(II/III)] are found in senile plaques, composed of $A\beta$ aggregates. Disrupted homeostasis of these metal ions would affect neuron signaling, apoptosis, and inflammation. Lastly, reactive oxygen species (ROS) can be overproduced through Fenton-like reactions causing oxidative damage to nucleic acids and cellular organelles. The studies presented in this thesis describe the development of chemical tools able to regulate single or multiple pathogenic component(s). In Chapter 1, an introduction of the hypotheses of AD is described, along with previously reported chemical tools designed to target pathological elements. In Chapter 2, our interdisciplinary studies of new small molecules towards distinct pathological factors, rationally designed *via* a novel structure-property-directed design strategy, are summarized. Lastly, in Chapter 3, a series of fluorescent sensors for metal ions in living cells, is illustrated, which could provide a better understanding of a link of their concentration and compartmentalization to the pathogenesis of AD. Overall, our approaches and findings presented herein would be useful for constructing effective chemical tools and therapeutics for AD, ultimately serving the illumination of complex pathogenesis of the disease in the future.

Figure 2.5. Metal binding of **1–3** observed by UV–Vis. Spectral changes of our molecules are monitored upon titration of various concentrations of (a) Cu(II) and (b) Zn(II). Conditions: [compound] = 50 μ M, [CuCl₂ or Zn(NO₃)₂] = 0 (blue), 25, 50, 100, and 250 μ M (orange), EtOH [for Cu(II) binding studies] or buffered solution [20 μ M HEPES, pH 7.4, 150 μ M NaCl, for Zn(II) binding studies], room temperature, incubation for 10 min.

Figure 2.6. Redox potentials of **1–3** measured in DMSO. The oxidation of (a) **1–3** and (b) their structural portions was monitored by cyclic voltammetry. The E_{pa} values at 250 mV/s are summarized in (c). Conditions: [compound] = 1 mM; 0.1 M *tetra-N*-butylammonium perchlorate (in DMSO); various scan rates [25 (red), 50, 100, 150, 200, and 250 mV/s (blue)]; room temperature; three electrodes composed of the glassy carbon working electrode, platinum counter electrode, and Ag/Ag(I) reference electrode.

Figure 2.7. Redox potentials of **1–3** measured in H₂O. The oxidation of **1**, **3**, and **DMPD** was monitored by cyclic voltammetry. Conditions: [compound] = 1 mM; 1 M NaCl (in ddH₂O); various scan rates [25 (red), 50, 100, 150, 200, and 250 mV/s (blue)]; room temperature; three electrodes composed of the glassy carbon working electrode, platinum counter electrode, and Ag/Ag(I) reference electrode.

Figure 2.8. Oxidation of thiol groups in *L*-cysteine (*L*-Cys) and compounds, monitored by the DTNB assay. *L*-Cys was used as a positive control in the DTNB assay. Conditions: [DTNB] = 50 μM; [compound] = 50 μM; buffered solution (pH 8.0); room temperature; incubation for 10 min.

Figure 2.9. Oxidation of **1–3** monitored by UV–Vis. Conditions: [compound] = 50 μM; 20 μM HEPES, pH 7.4, 150 μM NaCl; room temperature; incubation for 24 h.

Figure 2.10. Interactions of **1–3** with metal-free Aβ₄₀, analyzed by ESI–MS and ESI–MS². (a) The +3-charged Aβ₄₀ monomers in the samples incubated with **1–3** in the absence of Cu(II) were detected in the ESI–MS spectra. Metal-free Aβ₄₀ is denoted as red peaks. The oxidized ions are indicated by the red asterisks. (b) The oxidized amino acid residue of Aβ₄₀ incubated with **1** was identified through ESI–MS². Conditions: [Aβ₄₀] = 100 μM; [compound] = 500 μM; incubation for 3 h; 20 mM ammonium acetate, pH 7.2; 37 °C; no agitation. All samples were diluted with ddH₂O by 10 fold before injection to the mass spectrometer.

Figure 2.11. Interactions of **1–3** with Cu(II)-treated Aβ₄₀, analyzed by ESI–MS and ESI–MS². (a) The +3-charged Aβ₄₀ monomers in the samples incubated with **1–3** in the presence of Cu(II) were detected in the ESI–MS spectra. Cu(II)–Aβ₄₀ is denoted as light blue peaks, respectively. The oxidized ions are indicated by the red asterisks. The number of the asterisks represents the number of the oxygen atoms incorporated into Aβ₄₀. The degraded Aβ₄₀ with 89 Da loss (orange peaks) was presented from the **1**-

treated samples in the presence of Cu(II). (b) The oxidized amino acid residues of A β ₄₀ incubated with **1** and Cu(II) were identified through ESI–MS². Conditions: [A β ₄₀] = 100 μ M; [CuCl₂] = 100 μ M; [compound] = 500 μ M; incubation for 1 h; 20 mM ammonium acetate, pH 7.2; 37 °C; no agitation. All samples were diluted with ddH₂O by 10 fold before injection to the mass spectrometer.

Figure 2.12. Interactions of **2** with Cu(II)-treated monitored A β ₄₂ monitored by ESI–MS and IM–MS. (a) The +5-charged Cu(II)-treated A β ₄₂ dimer in the samples incubated without (left) or with **2** (right). The non-covalent complex formation of **BT** (153 *m/z*) or **BT_{ox}** (304 *m/z*) with A β ₄₂ was detected in the ESI–MS spectra (green peak, 1868 *m/z*). (b) The altered arrival time distributions (ATDs) of Cu(II)–A β ₄₂ upon incubation with **2** indicate the conformational change of the peptide. Ions selected for the IM–MS analysis are marked with gray and orange circles in the ESI–MS spectra. Conditions: [A β ₄₂] = 100 μ M; [CuCl₂] = 100 μ M; [**2**] = 500 μ M; incubation for 1 h; 20 mM ammonium acetate, pH 7.2; 37 °C; no agitation. All samples were diluted with ddH₂O by 10 fold before injection to the mass spectrometer

Figure 2.13. Reactivities of **1–3** to inhibit metal-free A β and metal–A β aggregation. (a) Scheme of the inhibition experiments. (b) Analysis of the size distributions of the resultant A β ₄₀ and A β ₄₂ species from (a) by gel/Western blot using 6E10. (C) [A β \pm Cu(II) or Zn(II)]; (**1**) [(C) + **1**]; (**2**) [(C) + **2**]; (**3**) [(C) + **3**]. Conditions: [A β] = 25 μ M; [CuCl₂ or ZnCl₂] = 25 μ M; [compound] = 50 μ M; pH 6.6 [for Cu(II) samples] or pH 7.4 [for metal-free and Zn(II) samples]; 37 °C; constant agitation. (c) TEM images of the samples from (b). The inset image represents the minor species. Scale bar = 200 nm.

Figure 2.14. Reactivities of **1–3** against the preformed metal-free A β and metal–A β aggregates. (a) Scheme of the disaggregation experiments. (b) Analysis of the size distributions of the resultant A β ₄₀ and A β ₄₂ species from (a) by gel/Western blot using 6E10. (C) [A β \pm Cu(II) or Zn(II)]; (**1**) [(C) + **1**]; (**2**) [(C) + **2**]; (**3**) [(C) + **3**]. Conditions: [A β] = 25 μ M; [CuCl₂ or ZnCl₂] = 25 μ M; [compound] = 50 μ M; pH 6.6 [for Cu(II) samples] or pH 7.4 [for metal-free and Zn(II) samples]; 37 °C; constant agitation. (c) TEM images of the resultant A β ₄₀/A β ₄₂ aggregates from the 24 h incubated samples from (b). Scale bar = 200 nm.

Chapter 1.

**Development of Chemical Tools Targeting Pathogenic Factors of Alzheimer's Disease
to Elucidate its Complex Pathogenesis of the Disease**

1.1. Introduction

Alzheimer's disease (AD) is the most common neurodegenerative disease, estimated approximately 60-80% of dementia.¹ The disease was first reported in 1906;¹ however, the etiology of the disease has not still been clear.²⁻⁴ The main symptoms of the disease include loss of episodic memory, cognitive decline, disorientation, and poor judgment, which could ultimately lead to death.^{1,5} The hallmarks of AD consist of senile plaques and neurofibrillary tangles, mostly composed of amyloid- β ($A\beta$) aggregates and hyperphosphorylated tau (ptau) protein, respectively.⁵⁻⁸ The Alzheimer's Association reported that the resultant social cost per patient for health care and long-term care services hovers at approximately 50 million won annually.¹ Although 28 million people worldwide are currently suffered by the disease, a few medications (*e.g.*, donepezil, memantine, galantamine, and rivastigmine), approved by the U.S. Food and Drug Administration (FDA), are available but they provide only temporary symptom relief by blocking a single risk factor, cholinesterase or *N*-methyl-D-aspartate (NMDA) receptor.^{1,3} Until now, due to the complexity of AD pathology, a cure for the disease has not been successfully developed. In this Chapter, we illustrate the representative pathological factors of AD and their inter-relationships. In addition, some previously reported chemical tools able to target and modulate such elements are presented.

1.2. Hypotheses of AD

1.2.1. Amyloid Cascade Hypothesis

Figure 1.1. Production and aggregation of $A\beta$ peptides. $A\beta$ is generated by the proteolytic cleavage of APP *via* β - and γ -secretases. The $A\beta$ monomers ($A\beta_{40}$ or $A\beta_{42}$) are prone to aggregate into oligomers, protofibrils, and fibrils.

In order to invent an effective treatment for AD, the etiology of the disease needs to be first identified. Multiple risk factors of AD have been suggested through several hypotheses: the amyloid cascade hypothesis, metal ion hypothesis, and the oxidative stress hypothesis.^{2-5,9,10} Amyloid hypothesis claims that the aggregation of misfolded $A\beta$ proteins is relevant to the neurotoxicity in AD.^{2,4,5,10} $A\beta$ peptides are generated *via* the proteolytic cleavage of amyloid precursor protein (APP) by β - and γ -secretases.^{5,11} The isoforms of $A\beta$ peptides are determined depending on the cleavage site of γ -secretase.^{5,11} $A\beta_{40}$ and $A\beta_{42}$ are the dominant products from the cleavage reactions with the difference in two hydrophobic amino acid residues (*i.e.*, isoleucine and alanine) in the C-terminus.^{4,5,11} $A\beta$

monomers are natively disordered; however, external factors, such as pH and temperature, cause peptides to be partially folded,¹¹ which tend to spontaneously aggregate into oligomers, protofibrils, and fibrils (Figure 1.1).^{2,3,5-7} Among various species, structured soluble A β oligomers are recently reported to be the most toxic species which could disrupt cellular signaling pathways by interfering membrane receptors [*e.g.*, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptor and NMDA receptor] or forming annular structures inserted in the membrane.^{8,11}

1.2.2. Metal Ion Hypothesis

Homeostasis of transition metal ions, including Cu(I/II) and Zn(II), are impaired in the AD-affected brain.^{4,5,12-14} Since metal ions are responsible for numerous signal transduction pathways including apoptosis, inflammation, and cell proliferation, dysregulated metal ions are also pathogenic.⁴ In general, the concentrations of intracellular Cu(I/II) and Zn(II) are tightly regulated by various metal transporters (*e.g.*, ATP7A and ATP7B for copper;^{4,15} ZnT3 for zinc^{4,16}). Under pathological conditions, however, such metal ions are not properly compartmentalized in the regions of the brain (*e.g.*, hippocampus, cortex, amygdala, and putamen).⁴ For example, the deficiency and overload of Cu(I/II) are simultaneously observed in the hippocampus and putamen of AD patients.^{17,18} The loss of protein-bound metal ions in metalloenzymes [*e.g.*, cytochrome c oxidase and Cu/Zn-superoxide dismutase (SOD)] can influence neuron degeneration and apoptosis.⁵ In addition to the effects of metal ions on the activities of metalloenzymes, they can form 1:1 complexes with the peptide [$K_d = 10^{-11}$ to 10^{-8} M for Cu(II); $K_d = 10^{-9}$ to 10^{-6} M for Zn(II)], which facilitates A β aggregation and stabilizes toxic oligomeric species.^{4,13,14,19} The exact mechanisms of how metal ions could affect the aggregation pathways of A β have not been identified.¹³

1.2.3. Oxidative Stress Hypothesis

The overproduction of reactive oxygen species (ROS) can trigger damage to the nucleic acid, membranes, and cellular organelles, consequently leading to neuronal death.^{5,12,20} The oxidative stress hypothesis proposes that the sources of ROS could be hypoxia and amyloid-related events.^{5,21} First, the condition of hypoxia stimulates the respiratory system in mitochondria, reducing dioxygen (O_2) to superoxide ($O_2^{\cdot-}$), that prompts oxidative stress through overexpression of hypoxia-inducible factors (HIFs).²² Under hypoxia conditions, however, HIFs cannot be degraded;²³ thus, the oxidative damages are further amplified through positive feedback.

In addition, as described above, dysregulated metal ions can bind to A β , generating metal–A β complexes (*vide supra*). Particularly, redox-active Cu(II)–A β could generate hydrogen peroxide (H_2O_2) through the H_2O_2 cycle (Figure 1.2)^{5,7,9,24} upon reduction from Cu(II) to Cu(I), with a half potential as 0.34 V [*versus* normal hydrogen electrode (NHE)].²⁵ Moreover, in the presence of

reducing agents, such as ascorbic acids or glutathione,^{7,25} Cu(I)-A β additionally cleaves the O-O bond of H₂O₂ to generate hydroxyl radicals (\bullet OH) through Fenton-like reactions (Figure 1.2).^{5,7,9,24} ROS-mediated oxidative stress can be controlled *via* mitochondrial detoxifying mechanisms (*i.e.*, SOD and catalase) under normal conditions;² however, abnormal mitochondria in the AD-affected brain are able to overproduce O₂⁻ and release H₂O₂ into the cytoplasm.^{2,5}

Figure 1.2. Proposed mechanisms of Cu(I/II)-A β -mediated ROS production. Redox properties of Cu(I/II)-A β can direct the generation of H₂O₂ and \bullet OH through the H₂O₂ cycle and Fenton cycle, respectively.

1.3. Development of Chemical Tools to Elucidate the Pathogenesis of AD

1.3.1. A β -targeting Agents

In order to identify the role of A β aggregation in the neurotoxicity,^{2,4,5,10} chemical tools capable of targeting and regulating them would be necessary. For example, thioflavin-T (ThT) and Pittsburgh compound B (PIB) derivatives have been utilized to interact with β -sheet-enriched amyloid aggregates *in vivo* (Figure 1.3.a).^{2,4} In addition, some A β antibodies (*e.g.*, bapineuzumab, solanezumab, ponezumab) are undergoing Phase III clinical trials, which can specifically bind to certain A β sequences and lower the levels of A β in the brain of AD patients.²⁷ Moreover, the inhibitors against γ -secretase, composed of at least four proteins [*i.e.*, presenilin, nicastrin, anterior pharynx (APH1), and presenilin enhancer 2 (PEN2)], were developed to completely prevent the generation of A β peptides.^{3,28,29} Unfortunately, γ -secretase has other substrates (*e.g.*, notch receptor 1) rather than APP; thus, suppression of this secretase could cause notch-related lethal side effects.^{29,30} As an alternative approach, small molecules able to modulate A β aggregation into off-pathway have been developed.^{29,31} For instance, β -sheet breakers have been recently proposed to inhibit or disrupt the formation of β -sheet by binding to the self-recognition site of A β species (Figure 1.3.b).^{29,31} In an inverse direction, Wanker and coworkers have reported the molecule, **O4**, that could interact with hydrophobic residues of A β and accelerates A β fibrillization leading to reduction of the amount of toxic oligomers (Figure 1.3.b).³²

Figure 1.3. A β -targeting agents and metal chelators. (a and b) Structures of A β -targeting and their reaction mechanisms towards A β aggregations. (c) Structures of metal chelators.

1.3.2. Metal Chelators

In order to redistribute abnormally compartmentalized metal ions in the AD-affected brain, effective metal chelators possessing reasonable binding affinities towards Cu(II), Zn(II), and Fe(II/III) are necessary. At the same time, metal binding affinities of chemical tools should be adjusted to avoid stripping out the essential biometals in metalloproteins.⁸ Moreover, since metal ions have been known to directly bind A β species as well as overproduce ROS, chemical reagents able to attenuate the interactions between metal ions and the peptide would be valuable.^{4,8} Clioquinol (**CQ**) is the common example of metal chelators utilized as an AD therapeutics (specifically, chelation of Cu(II) and Zn(II) [$K_d = 10^{-10}$ M for Cu(II); 10^{-8} M for Zn(II)] as well as decrease in the level of A β in the brain of AD patients (Figure 1.3.c).^{3,33,34} Due to the toxicity of impurity (*i.e.*, 5,7-diiodoquinolin-8-ol) generated during mass production, however, further clinical trials were halted. As a derivative of **CQ**, **PBT2** was shown to function same as **CQ**, along with greater blood-brain barrier (BBB) permeability (Figure 1.3.c).^{3,34,35} Moreover, both **CQ** and **PBT2** are shown to reorganize the disturbed homeostasis of metal ions and activate metalloenzymes responsible for A β clearance (*i.e.*, MMP-2 and MMP-3).^{3,35}

1.3.3. Multifunctional Chemical Tools

Given that various risk factors found in AD are intertwined with one another (*vide supra*), the development of multifunctional chemical tools towards several elements (*i.e.*, A β , metal ions, metal–A β , and ROS) has recently received significant attention. **Cyc-KLVFF**, one of the cyclen derivatives incorporated to the amino acid residues in the self-recognition site of A β , has shown its novel ability to chelate Cu(II) and break the β -sheets as designed as a dual-functional chemical tool (Figure 1.4).³⁶ Interestingly, this molecule could further decrease H₂O₂ production mediated by Cu(II)–A β .³⁶ As described in the previous section, the dyshomeostasis of redox-active metal ions is closely correlated with overproduction of ROS;^{5,7,9,24} thus, **Cyc-KLVFF** can function as an antioxidant by preventing the

oxidative damages induced by ROS.³⁶ Additionally, our group has reported the molecule, **ML**, composed of rationally chosen structural moieties responsible for interacting with metal-free A β , metal-bound A β , and metal ions as well as scavenging free radicals (Figure 1.4).¹⁰ The framework of **ML** is based on *p*-I-stilbene³⁷ and **L2-b**,³⁸ each of which is a well-known A β imaging agent and a previously reported small molecule targeting metal-A β , respectively. In order to afford a tetradentate ligand with a relatively high metal binding affinity,³⁹ an additional hydroxyl group was incorporated into the framework. The distorted square planar geometry of the Cu(II)-**ML** complex is indicated, which is not favorable for the geometry of Cu(I)-**ML** and thus subsequently prevents ROS generation *via* Fenton-like reactions.^{5,7,9,24} Moreover, it contains the moieties of quinoline and phenol that are previously reported to scavenge free radicals.¹⁰ **ML** could redirect the aggregation pathways of both metal-free A β and metal-A β as well as regulate the levels of ROS (*i.e.*, inhibition of forming ROS and scavenging of the free radicals). In addition to the rationally designed molecules, natural products have been investigated to function as multifunctional tools. For example, melatonin, a hormone responsible for maintaining the circadian rhythm, is a well-known antioxidant.⁴⁰ The amide functional group of melatonin could contribute to the interaction with Cu(II) and Zn(II),⁴⁰ inhibiting the formation of metal-A β oligomers (Figure 1.4).⁴¹ Vitamine E (α -tocopherol) was observed to inhibit A β aggregation as well as disaggregate preformed A β fibrils along with its antioxidant capacity (Figure 1.4).⁴²

Figure 1.4. Examples of multifunctional chemical tools towards A β , metal ions, and ROS. The structural moieties for A β interaction (highlighted in green), metal binding (highlighted in yellow), and radical scavenging (highlighted in blue) are responsible for their activity towards pathogenic elements.

1.4. Conclusions

A growing number of AD patients is emerging as a severe social problem; however, the clear

medication has not been provided. Multiple pathological factors, including A β , metal ions, and ROS, are found in the AD-affected brain. These pathogenic factors are observed to be closely inter-related with one another, aggravating the neurotoxicity. In order to advance our understanding of the complicated pathology of AD and provide a new insight into the discovery of therapeutics, the development of chemical tools towards modulation of such pathological components would be necessary. In this Chapter, we illustrate some examples of chemical reagents, including A β -targeting agents, metal chelators, and multifunctional chemical tools.

Chapter 2.

Tuning Structures and Properties for Developing Novel Chemical Tools
 towards Distinct Pathogenic Elements in Alzheimer's Disease

I thank Dr. Hyuck Jin Lee for the studies of TEM, gel/Western blot, and cells; Kyu Yeon Kim and Professor Junghyun Chae for the synthesis of the small molecules (1–3); Dr. Shin Jung C. Lee for helping the analysis of mass spectrometric data. I carried out the experiments using cyclic voltammetry, UV–visible spectroscopy, biochemical assays (PAMPA–BBB, DTNB assay, and TEAC assay), analyses of mass spectrometry, gel/Western blot, and living cells along with data analyses.

2.1 Introduction

Various pathological factors [*e.g.*, amyloid- β (A β), metal ions, metal-bound A β (metal-A β), reactive oxygen species (ROS)] are reported to be involved in the pathogenesis of Alzheimer's disease (AD).¹⁻¹⁰ A β peptides, produced *via* the proteolytic cleavage of amyloid precursor protein (APP), tend to aggregate into oligomers, protofibrils, and fibrils.^{1,2,8-10} Recently, soluble A β oligomers are suggested to be major toxic species that cause neuronal atrophy and death.^{2,10-13} Additionally, highly concentrated metals (*e.g.*, copper, zinc, iron) found in senile plaques are observed to directly interact with A β generating metal-A β complexes, which can facilitate A β aggregation and stabilize toxic A β oligomers.^{8,13-15} Moreover, complexes of A β and redox-active metal ions, including Cu(I/II), are presented to overproduce ROS *via* Fenton-like reactions leading to damage of nucleic acids, lipids, and cellular organelles.^{2,16-18} Due to the complex link among multiple pathological elements to AD pathology, however, a cure for the disease has not been still discovered.^{8,19}

In order to gain a better understanding of the pathogenesis of AD, chemical tools capable of targeting and modulating pathogenic factors have been devised.²⁰⁻³⁹ A variety of anti-amyloidogenic compounds that interact with metal-free A β species and mediate peptide aggregation have been constructed.²⁰⁻²² Small molecules, exhibited to specifically modify the aggregation of metal-A β over metal-free A β , have also been invented.²³⁻²⁵ In addition, several antioxidants have been shown as chemical tools against ROS-induced oxidative stress.^{26,27} Moreover, given that the individual elements have been detected to be intertwined with each other in the AD-affected brain, the design of small molecules as multifunctional tools for regulating the inter-connections among AD pathogenic components has currently received attention.²⁸⁻³⁹ For example, some small molecules, including (*E*)-5-(4-hydroxystyryl)quinolone-8-ol (**10c**),³² *N,N*-dimethyl-*p*-phenylenediamine (**DMPD**),³⁷ and *N*¹-((1*H*-pyrrol-2-yl)methyl)-*N*⁴,*N*⁴-dimethylbenzene-1,4-diamine (**4**),³⁹ were shown to alter the aggregation of metal-free A β and metal-A β as well as quench free radicals. Taken together, the efforts on engineering chemical tools able to target and control single or multiple pathogenic components(s) and control their activities have been made to provide molecular-level insights into the pathology of AD. The development of such tools, however, has been challenging.

Herein, we report new small molecules (**1–3**; Figure 2.1) that distinguishably interact and react with the pathological targets found in AD (*i.e.*, metal-free A β , metal-A β , and free radicals). Our compounds, **1–3**, were designed *via* a rational structure-property-directed strategy. As depicted in Figure 2.1, through an extremely minor structural variation [*i.e.*, change of only one nitrogen (N) or sulfur (S) donor atom in the backbone], we are able to tune the properties of compounds (*e.g.*, oxidation potentials, interactions with metal-free and metal-bound A β) and subsequently afford reactivities against disparate pathological features. Overall, our studies demonstrate that small molecules as chemical tools for modulating distinct pathological components of AD can be rationally

constructed through a structure-property-based design strategy. Such design tactics would be further applied for devising chemical reagents utilized for other neurodegenerative disorders.

Figure 2.1. Rational design of the small molecules (1–3) able to have distinct properties and reactivities with pathological factors found in AD. (a,b) Structures of **DMA** and the bidentate ligands used for construction of 1–3. (c) Structural variations of 1–3, obtained *via* a change of only one N or S donor atom in the framework, and the difference in their oxidation and targets.

2.2 Results and Discussion

2.2.1. Structure-Property-Directed Principle for Designing Chemical Tools Able to Target Distinct Pathological Components of AD

To design the backbone of the new compounds (1–3), we rationally selected two structural moieties, *i.e.*, **DMA** and bidentate ligands composed of N and S donor atoms (Figure 2.1a,b). The conjugation of two structural groups could achieve different redox properties of small molecules and their distinguishable interactions with metal ions, metal-free A β , metal-A β , and free radicals. First, **DMA** (Figure 2.1a) is a structural portion employed for previously reported chemical tools targeting metal-free A β and/or metal-A β .^{34,37,40,41} In addition, the **DMA**-containing structures [*e.g.*, **DMPD**,³⁷ **4**³⁹], incorporated with one N donor atom at the *para* position of the *N,N*-dimethyl group, are known to undergo one- or two-electron oxidation.^{37,39,42,43} Such oxidation is indicated to direct the capabilities of compounds against regulation of metal-free A β , metal-A β , and free radicals.^{37,39,44} Second, in order to interact with metal ions [*i.e.*, Cu(II), Zn(II)] as well as metal ions bound to A β , the bidentate ligands containing N and S donor atoms were introduced into the framework of 1–3 (Figure 2.1b).^{45,46} Lastly, to tune the extent of compounds' oxidation, 1–3 were obtained through the modification of only one N or S donor atom (Figure 2.1c). The oxidation potentials of small molecules have been previously demonstrated to be critical for interactions and reactivities with pathological targets, including metal-free A β , metal-A β , and free radicals.^{39,44} As summarized in Figure 2.1c, our new molecules (1–3), developed *via* a very slight structural variation, are observed to have the differences in their oxidation and coverage of pathological targets for interactions and reactivities (*vide infra*).

2.2.2. Synthesis and Characterization of 1–3

As described in Scheme 2.1, new small molecules (**1–3**) were prepared. Compound **1** was afforded by ring opening of ethylene sulfide with **DMPD**. Compounds **2** and **3** were obtained through copper-catalyzed C–S bond formation between 4-iodo-aniline and the corresponding alkanethiols, followed by conversion of terminal groups into thiol (for **2**) or amino (for **3**) functionality. Synthesis of **1–3** was confirmed by spectroscopic and spectrometric methods (Figures 2.2-2.4). Moreover, our molecules were verified to interact with Cu(II) and Zn(II) (Figure 2.5) as we designed. Furthermore, **1–3** are suggested to be blood-brain barrier (BBB) permeable based on the calculated and experimentally obtained values ($\log\text{BB} > -1.0$ and $-\log P_e < 5.4$; Table 2.1).

Scheme 2.1. Synthetic routes to 1–3.

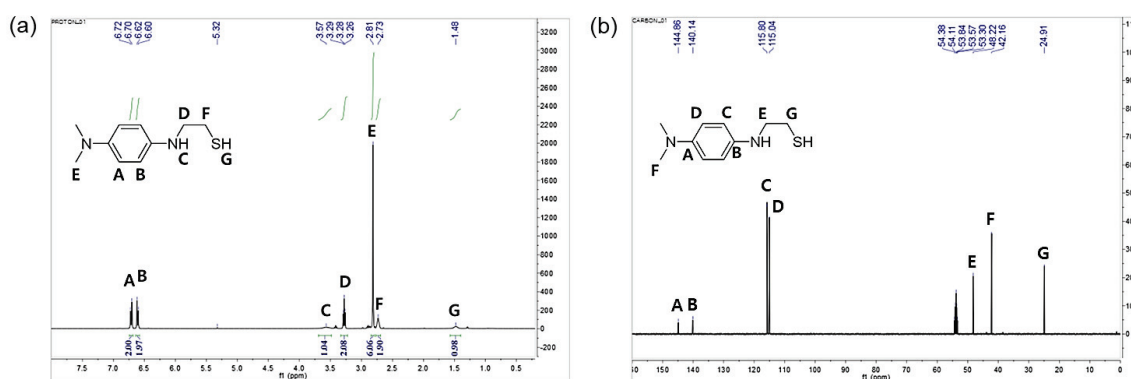

Figure 2.2. ¹H (a, 400 MHz) and ¹³C (b, 100 MHz) NMR spectra of **1** in CD₂Cl₂.

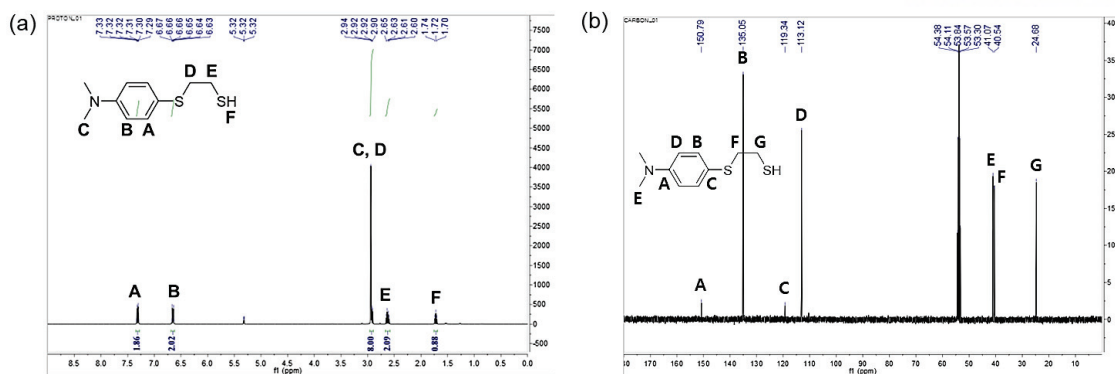

Figure 2.3. ^1H (a, 400 MHz) and ^{13}C (b, 100 MHz) NMR spectra of **2** in CD_2Cl_2 .

Figure 2.4. ^1H (a, 400 MHz) and ^{13}C (b, 100 MHz) NMR spectra of **3** in CD_3OD .

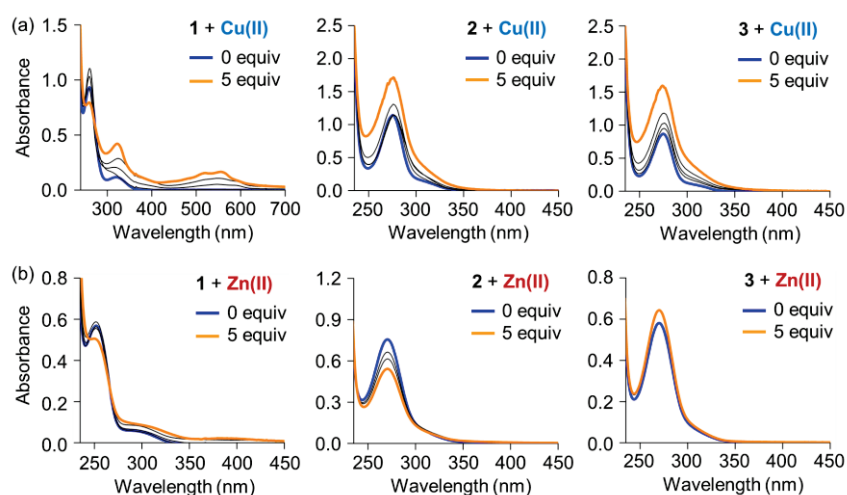

Figure 2.5. Metal binding of **1–3** observed by UV–Vis. Spectral changes of our molecules are monitored upon titration of various concentrations of (a) Cu(II) and (b) Zn(II) . Conditions: $[\text{compound}] = 50 \mu\text{M}$, $[\text{CuCl}_2 \text{ or } \text{Zn(NO}_3)_2] = 0$ (blue), 25, 50, 100, and 250 μM (orange), EtOH [for Cu(II) binding studies] or buffered solution [20 μM HEPES, pH 7.4, 150 μM NaCl, for Zn(II) binding studies], room temperature, incubation for 10 min.

Table 2.1. Values (MW, $c\log P$, HBA, HBD, PSA, logBB, and $-\log P_e$) of **1–3**.

	1	2	3	Lipinski's rules and others
MW ^a	196	213	196	≤ 450
$c\log P$ ^b	2.16	3.22	1.91	≤ 5.0
HBA ^c	2	1	2	≤ 10
HBD ^d	1	0	2	≤ 5
PSA (Å ²) ^e	15.3	3.24	29.3	≤ 90
logBB ^f	0.232	0.580	-0.0130	< -1.0 (poorly)
$-\log P_e$ ^g	4.59 ± 0.02 (CNS+)	4.52 ± 0.07 (CNS+)	4.45 ± 0.01 (CNS+)	$-\log P_e < 5.4$ (CNS+) $-\log P_e > 5.7$ (CNS-)

^aMW, molecular weight, ^b $c\log P$, calculated log of water-octanol partition coefficient, ^cHBA, hydrogen bond acceptor atoms, ^dHBD, hydrogen bond donor atoms, ^ePSA, polar surface area, ^flogBB = 0.152 × $c\log P$ - 0.0148 × PSA + 0.139, ^g $-\log P_e$, the values obtained using the parallel artificial membrane permeability assay adapted for the BBB (PAMPA–BBB) were calculated by the PAMPA Explorer software v. 3.5. Compounds assigned to be CNS+ are able to penetrate the BBB and thus be available in the central nervous system (CNS), compounds assigned to be CNS– compounds have poor BBB permeability and thus their availability in the CNS are considered minimal.

2.2.3. Redox Properties of 1–3

To determine whether a minor structural variation of compounds could lead to distinguishable compounds' oxidation potentials as we designed (Figure 2.1), their redox properties were investigated by cyclic voltammetry (CV) and UV–visible spectroscopy (UV–Vis). The oxidation potentials of each compound were measured by CV (Figures 2.6 and 2.7). The lower value of the anodic peak potential (E_{pa}) indicates that the compound is relatively easy to be oxidized.⁴⁷ The E_{pa} value of **1** containing a moiety of **DMPD** is *ca.* 0.22 V [*versus* Ag/Ag(I)], significantly lower than those of **2** and **3** (E_{pa} = *ca.* 0.54/0.80 and 0.75 V, respectively) composed of a 4-(dimethylamino)-benzenethiol (**BT**) group (Figure 2.6 and Table 2.2). Although the E_{pa} values of **2** and **BT** could not be measured in H₂O due to their limited solubility, **1** has a much lower E_{pa} value than **3** in H₂O, similar to the observation in DMSO (Figure 2.7 and Table 2.3). Based on the E_{pa} values of **DMPD** and **BT** (*ca.* 0.23 and 0.93 V, respectively), the structural portion of **DMPD** would be mainly responsible for the lower E_{pa} value of **1**.

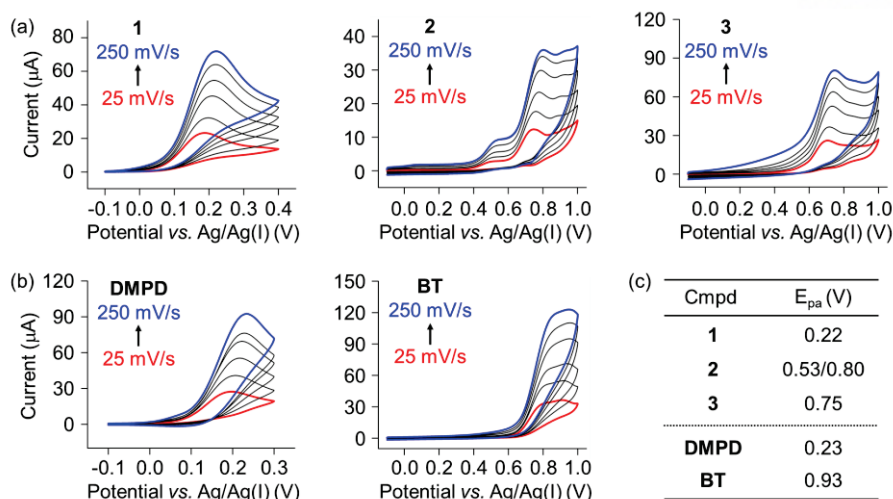

Figure 2.6. Redox potentials of **1–3** measured in DMSO. The oxidation of (a) **1–3** and (b) their structural portions was monitored by cyclic voltammetry. The E_{pa} values at 250 mV/s are summarized in (c). Conditions: [compound] = 1 mM; 0.1 M *tetra-N*-butylammonium perchlorate (in DMSO); various scan rates [25 (red), 50, 100, 150, 200, and 250 mV/s (blue)]; room temperature; three electrodes composed of the glassy carbon working electrode, platinum counter electrode, and Ag/Ag(I) reference electrode.

Table 2.2. Quantitative data of cyclic voltammograms of **1–3** in DMSO.

In addition to the moieties of **DMPD** and **BT**, the oxidation of the thiol groups in **1** and **2** was monitored by the DTNB assay [DTNB = 5,5'-dithio-*bis*-(2-nitrobenzoic acid)] with *L*-cysteine as a positive control (Scheme 2.2 and Figure 2.8). A new absorption band at *ca.* 412 nm was exhibited

upon reaction of the thiol groups in **1** and **2** with the disulfide bond in DTNB, indicative of the formation of 2-nitro-5-thiobenzoic acid dianion (TNB²⁻) (Figure 2.8). The different intensity of the optical bands of TNB²⁻, resulted from the interactions of DTNB with compounds, presents that the thiol group in **1** is less oxidizable than that in **2**.

Scheme 2.2. Reaction scheme of the DTNB assay

Figure 2.8. Oxidation of thiol groups in *L*-cysteine (*L*-Cys) and compounds, monitored by the DTNB assay. *L*-Cys was used as a positive control in the DTNB assay. Conditions: [DTNB] = 50 μ M; [compound] = 50 μ M; buffered solution (pH 8.0); room temperature; incubation for 10 min.

Based on the redox properties of **1–3**, analyzed through CV and the DTNB assay, their oxidation was additionally traced for 24 h by UV–Vis (Figure 2.9). The absorption band of **1** decreased at *ca.* 254 nm and increased at *ca.* 300 nm upon incubation, indicative of oxidation producing the delocalized electron(s) on the phenyl ring.^{37,39} Different from **1**, the intensity of the optical band of **2** was slightly reduced at *ca.* 280 nm, whereas the peak intensity was enhanced in the range of *ca.* 290 to 400 nm. The spectral changes of **3** were not detected even for 24 h (Figure 2.9), suggesting that the compound was not easily oxidizable under our experimental conditions. Therefore, the moiety of **DMPD** in **1** is suggested to be more associated with ligand oxidation than the **BT** portion found in **2** and **3**, which is consistent with the results of CV (Figure 2.6). More importantly, the different degree of the compounds' oxidation is demonstrated to be achieved *via* a minor structural difference (*i.e.*, replacement of only one donor atom in the backbone; Figure 2.1c). These distinct redox properties of compounds are observed to direct their distinguishable interactions as well as modulating reactivities towards metal-free A β , metal–A β , and free radicals (*vide infra*).

Figure 2.9. Oxidation of **1–3** monitored by UV–Vis. Conditions: [compound] = 50 μM ; 20 μM HEPES, pH 7.4, 150 μM NaCl; room temperature; incubation for 24 h.

2.2.4. Interactions of **1–3** with Metal-free $\text{A}\beta$

To verify how the distinct redox properties of **1–3** could influence their reactivities towards $\text{A}\beta$ aggregation, the interactions of **1–3** with metal-free $\text{A}\beta$ species were identified at the molecular level employing electrospray ionization mass spectrometry (ESI–MS) and tandem MS (ESI–MS²) (Figure 2.10). Upon incubation of metal-free $\text{A}\beta_{40}$ with or without the compounds, the +3-charged $\text{A}\beta_{40}$ monomer ($[\text{A}\beta_{40} + 3\text{H}]^{3+}$) was detected at 1444 m/z in the ESI–MS spectra (red peaks; Figure 2.10a). Among our small molecules, **1** was observed to oxidize metal-free $\text{A}\beta_{40}$ showing the peak at 1449 m/z corresponding to $[\text{A}\beta_{40} + \text{O} + 3\text{H}]^{3+}$ (red asterisk; Figure 2.10a), while such peptide modification was not monitored in the case of metal-free $\text{A}\beta_{40}$ treated with both **2** and **3**.

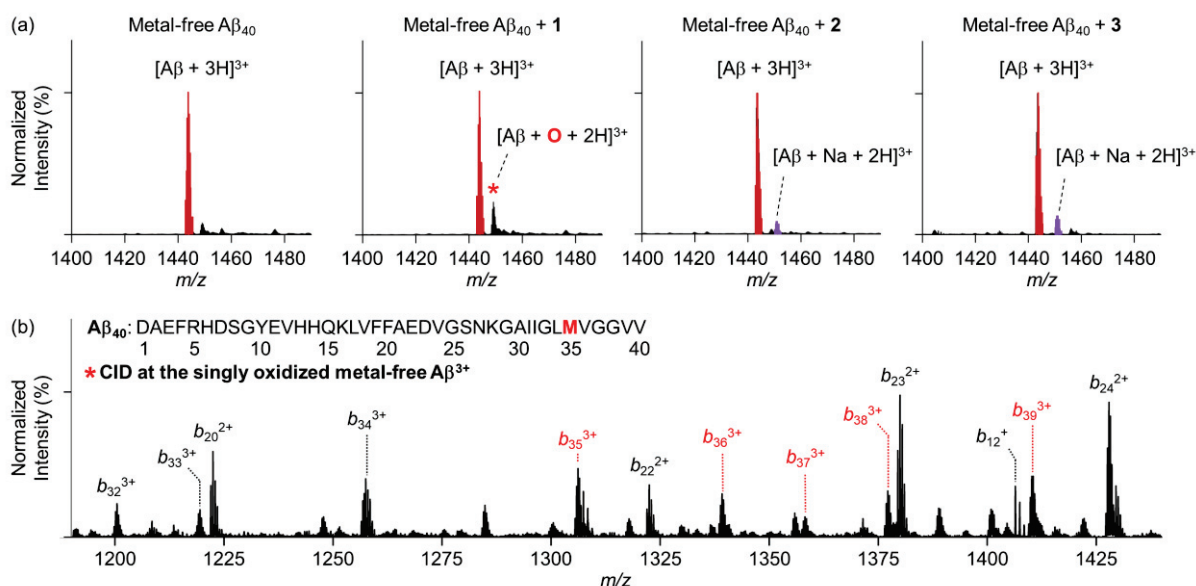

Figure 2.10. Interactions of **1–3** with metal-free $\text{A}\beta_{40}$, analyzed by ESI–MS and ESI–MS². (a) The +3-charged $\text{A}\beta_{40}$ monomers in the samples incubated with **1–3** in the absence of $\text{Cu}(\text{II})$ were detected in the ESI–MS spectra. Metal-free $\text{A}\beta_{40}$ is denoted as red peaks. The oxidized ions are indicated by the red asterisks. (b) The oxidized amino acid residue of $\text{A}\beta_{40}$ incubated with **1** was identified through

ESI-MS². Conditions: [A β ₄₀] = 100 μ M; [compound] = 500 μ M; incubation for 3 h; 20 mM ammonium acetate, pH 7.2; 37 °C; no agitation. All samples were diluted with ddH₂O by 10 fold before injection to the mass spectrometer.

Furthermore, we determined which amino acid residues of metal-free A β ₄₀ were plausibly oxidized upon treatment of **1** through ESI-MS² (Figure 2.10b). The ESI-MS² spectrum of **1**-added A β ₄₀ displayed that the methionine 35 (M35) residue in A β ₄₀ was oxidized (*e.g.*, methionine sulfoxide).^{48,49} In the previous studies, the oxidation of M35 in A β has been suggested to modify A β aggregation pathways.^{50,51} Together, among our molecules (**1–3**), **1** with the lowest E_{pa} value is capable of oxidizing metal-free A β ₄₀, implying that the interactions of compounds with metal-free A β ₄₀ could be linked to their redox properties.

2.2.5. Interactions of **1–3** with Cu(II)-A β

In addition to metal-free A β ₄₀, the interactions of **1–3** with Cu(II)-treated A β ₄₀ species were investigated (Figure 2.11). Note that compounds' interactions with Zn(II)-A β could not be studied since Zn(II)-bound A β species were not observed under our MS conditions. Upon incubation of A β ₄₀ in the presence of Cu(II), Cu(II)-added A β ₄₀ (*i.e.*, [A β ₄₀ + Cu(II) + H]³⁺) was revealed at 1465 *m/z*, along with metal-free A β ₄₀ at 1444 *m/z* (red and light blue peaks; Figure 2.11). Compound **1** with the lowest oxidation potential was shown to degrade and oxidize Cu(II)-treated A β ₄₀ (orange peaks and red asterisks, respectively; Figure 2.11). The degraded A β ₄₀ by 89 Da could be induced by oxidative cleavage of the aspartate 1 (D1) residue forming isocyanate.⁵²⁻⁵⁴ The D1 residue was reported to be preferentially oxidized through alkoxy radical pathways,⁵²⁻⁵⁴ which could impact the structural rearrangement of Cu(II) coordination in A β . In addition to the degraded A β ₄₀ (at 1415 *m/z*), the peak at 1409 *m/z* could be assigned as the degraded A β ₄₀ with further loss of one water (H₂O) molecule. In a similar manner, the peaks at 1421 *m/z* and 1427 *m/z* (peptide species bound to one and two H₂O, respectively) might indicate the degradation of A β ₄₀.

The oxidation sites in the amino acid sequence of Cu(II)-added A β ₄₀ induced by **1** were determined by ESI-MS² (Figure 2.11b). Under Cu(II)-present conditions, histidine 13 and 14 (H13 and H14) were shown to be oxidized, along with M35, previously reported as the plausibly oxidizable residues in A β .^{48,50,51,55,56} Since Cu(II) is known to be bound to H13 and H14 in A β ,^{3,5,45} their oxidation (*e.g.*, 2-oxo histidine)⁵⁷ upon incubation of A β with **1** might explain the low abundance of Cu(II)-A β ₄₀ in the spectra (Figure 2.11b). Additionally, the oxidation of H13, H14, and M35 in A β is previously reported to alter A β aggregation pathways.^{50,51}

Figure 2.11. Interactions of **1–3** with Cu(II)-treated A β_{40} , analyzed by ESI-MS and ESI-MS². (a) The +3-charged A β_{40} monomers in the samples incubated with **1–3** in the presence of Cu(II) were detected in the ESI-MS spectra. Cu(II)-A β_{40} is denoted as light blue peaks, respectively. The oxidized ions are indicated by the red asterisks. The number of the asterisks represents the number of the oxygen atoms incorporated into A β_{40} . The degraded A β_{40} with 89 Da loss (orange peaks) was presented from the **1**-treated samples in the presence of Cu(II). (b) The oxidized amino acid residues of A β_{40} incubated with **1** and Cu(II) were identified through ESI-MS². Conditions: [A β_{40}] = 100 μ M; [CuCl₂] = 100 μ M; [compound] = 500 μ M; incubation for 1 h; 20 mM ammonium acetate, pH 7.2; 37 $^{\circ}$ C; no agitation. All samples were diluted with ddH₂O by 10 fold before injection to the mass spectrometer.

Compound **2**, which possesses the higher oxidation potential than **1** (Figure 2.6), indicated different interactions with Cu(II)-treated A β_{40} , compared with **1**. In detail, **2** significantly reduced the intensity of peaks at 1465 m/z corresponding to $[A\beta_{40} + Cu(II) + H]^{3+}$, suggesting that the coordination of Cu(II) to A β_{40} was modified by incubation with **2** (Figure 2.11). Distinct from **1**, **2** was not able to degrade and oxidize A β even in the presence of Cu(II). In order to further analyze the interaction of **2** with Cu(II)-A β , we additionally employed Cu(II)-treated A β_{42} , another isoform of A β (Figure 2.12).¹² When **2** was incubated with Cu(II) and A β_{42} , the peak of Cu(II)-A β_{42} disappeared, supporting that this molecule might also disrupt Cu(II) binding to A β_{42} (blue peaks; Figure 2.12a). Moreover, compound **2** was observed to be transformed to **BT**⁵⁸ (153 Da) or the oxidized **BT** (**BT**_{ox}; 304 Da) under Cu(II)-present conditions. These transformed compounds from **2**, **BT** and **BT**_{ox}, were shown to subsequently form the non-covalent adduct with the A β_{42} dimer at 1868 m/z (green peaks; Figure 2.12a). Moving forward, we applied ion mobility mass spectrometry (IM-MS) to monitor the effects of **2** on conformation of the A β_{42} dimer (Figure 2.12b). The arrival time distribution (ATD) of

the A β_{42} dimer, monitored after addition of **2** into the sample of Cu(II)-treated A β_{42} , was enhanced at 11.57 ms, implying that **2** could trigger the conformational compaction of the dimeric form. Thus, **2** is able to specifically interact with Cu(II)-treated A β over metal-free A β , especially showing the non-covalent complexation between the compound and the A β_{42} dimer with conformational changes when Cu(II) is present. These interactions of **2** with Cu(II)-A β_{42} are exhibited to be related to its modulating activity towards the aggregation of Cu(II)-A β_{42} (*vide infra*).

Figure 2.12. Interactions of **2** with Cu(II)-treated monitored A β_{42} monitored by ESI-MS and IM-MS. (a) The +5-charged Cu(II)-treated A β_{42} dimer in the samples incubated without (left) or with **2** (right). The non-covalent complex formation of **BT** (153 m/z) or **BT_{ox}** (304 m/z) with A β_{42} was detected in the ESI-MS spectra (green peak, 1868 m/z). (b) The altered arrival time distributions (ATDs) of Cu(II)-A β_{42} upon incubation with **2** indicate the conformational change of the peptide. Ions selected for the IM-MS analysis are marked with gray and orange circles in the ESI-MS spectra. Conditions: [A β_{42}] = 100 μ M; [CuCl₂] = 100 μ M; [**2**] = 500 μ M; incubation for 1 h; 20 mM ammonium acetate, pH 7.2; 37 °C; no agitation. All samples were diluted with ddH₂O by 10 fold before injection to the mass spectrometer.

Lastly, the hardly oxidizable compound **3**, relative to **1** and **2**, displayed no significant interaction with Cu(II)-treated A β_{40} . For example, **3** was not able to degrade and oxidize A β as well as generate non-covalent complexes with peptides (Figure 2.11b). In summary, the easily oxidized compound, **1**, is observed to considerably interact with both metal-free and Cu(II)-treated A β . Compound **2** (with the higher E_{pa} value than **1**) specifically affects Cu(II) binding to both A β_{40} and A β_{42} and produces a non-covalent adduct with the A β_{42} dimer showing structural compaction. The least oxidizable compound, **3**, among our molecules could not interact with both metal-free A β and Cu(II)-A β . Taken

together, our MS studies support that the interactions between our compounds and metal-free or Cu(II)-treated A β could be differentiated depending on their redox properties which were rationally tuned *via* a very minor structural variation (Figure 2.1c).

2.2.6. Regulatory Abilities of 1–3 against Metal-free A β and Metal–A β Aggregation

To confirm the compounds' regulatory activities against metal-free A β and metal–A β , the capability of 1–3 to control peptide aggregation with and without metal ions was evaluated. The resultant A β species upon treatment with compounds were analyzed by gel electrophoresis/Western blotting (gel/Western blot; for size distribution) with an anti-A β antibody (6E10) and transmission electron microscopy (TEM; for morphology). In the inhibition experiments (Figure 2.13), freshly prepared A β was introduced with our compounds in the absence and presence of metal ions [*i.e.*, Cu(II) and Zn(II)] for 24 h. In the disaggregation experiments (Figure 2.14), the compounds were added to preformed metal-free or metal-added A β aggregates, generated by 24 h incubation, and the resultant samples were additionally incubated for 24 h. The larger A β aggregates (*e.g.*, fibrils), generated from both experiments, are known to limit their penetration through the gel matrix; thus, they are in general visualized by TEM.^{59,60} When A β aggregation is varied with the treatment of compounds producing small-sized A β species, smearing bands in the gel/Western blot are presented.^{59,60}

Figure 2.13. Reactivities of 1–3 to inhibit metal-free A β and metal–A β aggregation. (a) Scheme of the inhibition experiments. (b) Analysis of the size distributions of the resultant A β_{40} and A β_{42} species from (a) by gel/Western blot using 6E10. (C) [A β \pm Cu(II) or Zn(II)]; (1) [(C) + 1]; (2) [(C) + 2]; (3) [(C) + 3]. Conditions: [A β] = 25 μ M; [CuCl₂ or ZnCl₂] = 25 μ M; [compound] = 50 μ M; pH 6.6 [for Cu(II) samples] or pH 7.4 [for metal-free and Zn(II) samples]; 37 $^{\circ}$ C; constant agitation. (c) TEM images of the samples from (b). The inset image represents the minor species. Scale bar = 200 nm.

Figure 2.14. Reactivities of 1–3 against the preformed metal-free and metal-induced A β_{40} /A β_{42} aggregates. (a) Scheme of the disaggregation experiments. (b) Analysis of the size distributions of the resultant A β_{40} and A β_{42} species from (a) by gel/Western blot using 6E10. (C) [A β \pm Cu(II) or Zn(II)]; (1) [(C) + 1]; (2) [(C) + 2]; (3) [(C) + 3]. Conditions: [A β] = 25 μ M; [CuCl₂ or ZnCl₂] = 25 μ M; [compound] = 50 μ M; pH 6.6 [for Cu(II) samples] or pH 7.4 [for metal-free and Zn(II) samples]; 37 $^{\circ}$ C; constant agitation. (c) TEM images of the resultant A β_{40} /A β_{42} aggregates from the 24 h incubated samples from (b). Scale bar = 200 nm.

When metal-free A β_{40} /A β_{42} and metal–A β_{40} /A β_{42} were incubated with 1, noticeable smearing bands of the resultant A β_{40} and A β_{42} species with lower molecular weights were observed in the gel/Western blots (Figure 2.13b). These results suggest that 1 is able to significantly modulate A β aggregation pathways in the absence and presence of metal ions. In addition, 1 is shown to disaggregate preformed metal-free A β_{40} /A β_{42} and metal–A β_{40} /A β_{42} aggregates or affect their further

aggregation (Figure 2.14b). TEM images of the A β aggregates formed upon treatment of **1** in both inhibition and disaggregation studies were amorphous and smaller sized instead of larger and fibrillar aggregates observed from compound-free A β samples (Figures 2.13c and 2.14c).

In the case of **2**, this molecule could not regulate metal-free A β_{40} and metal-A β_{40} aggregation in both inhibition and disaggregation experiments (Figures 2.13b and 2.14b). Different from A β_{40} , smearing bands of Cu(II)-A β_{42} aggregates, larger than 140 kDa, were observed upon incubation with **2**, which could indicate its specific reactivity towards the aggregation of Cu(II)-A β_{42} over metal-free A β_{42} and Zn(II)-A β_{42} (Figures 2.13b and 2.14b). In accordance with the results of gel/Western blot, shorter-sized A β aggregates were shown only in the samples containing **2** and Cu(II)-treated A β_{42} in both inhibition and disaggregation experiments (Figures 2.13c and 2.14c). Lastly, **3** could not modify the aggregation of metal-free A β_{40} /A β_{42} and metal-A β_{40} /A β_{42} based on the results of gel/Western blot (Figures 2.13b and 2.14b). No noticeable morphological changes of **3**-added A β aggregates, produced with and without metal ions, were visualized (Figures 2.13c and 2.14c).

The reactivities of **1–3** against the aggregation of metal-free A β and metal-A β are consistent with the trend of their E_{pa} values (Figure 2.6) as well as the observation for the interactions with metal-free and metal-bound A β species (Figures 2.10-2.12). Compound **1** with the lowest E_{pa} value could trigger the oxidation of metal-free A β (at M35) as well as the degradation (at D1) and oxidation (at H13, H14, and M35) of Cu(II)-A β . Such interactions could lead to modifying metal-free and metal-induced A β aggregation by **1**. Compound **2** with the higher E_{pa} value than **1** could disrupt the coordination of Cu(II) to A β and generate a non-covalent complex with the A β_{42} dimer showing structural compaction with Cu(II) being present; thus, the molecule could noticeably control Cu(II)-A β_{42} aggregation. In the case of **3** with the highest E_{pa} value among our molecules, the compound was not able to interact with metal-free A β and Cu(II)-A β , which could support no reactivities of the molecule towards the aggregation of both metal-free A β and metal-A β . Taken together, the ability of compounds to modulate the aggregation of A β_{40} and A β_{42} with or without metal ions is demonstrated to be highly relevant to their characteristics, including redox properties and interactions with the targets.

2.2.7. Antioxidant Capabilities of **1–3** against Free Radicals

To determine if the redox properties of compounds can direct their regulatory activity against free radicals, the ability of **1–3** to quench free radicals was evaluated by the Trolox equivalent antioxidant capacity (TEAC) assay employing the lysates of Neuro-2a (N2a) neuroblastoma cells (Figure 2.15a). The TEAC assay verifies the capability of compounds to scavenge free radicals, such as ABTS^{•+} [ABTS = 2,2'-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid)], relative to that of an analog of vitamin E, Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid).^{39,61-63} The quenching

ability of Trolox against free radicals is well characterized; thus, small molecules with the TEAC values higher than 1.0 are regarded as potent antioxidants than Trolox.⁶¹ Compound **1** is presented to have the TEAC value as 1.6 (± 0.1), suggesting this molecule as a better scavenger against free radicals than Trolox (Figure 2.15). Compound **2** also quenches free radicals [the TEAC value as 0.33 (± 0.04)] but its activity is much lower than **1** and Trolox. As expected, **3** with the highest oxidation potential exhibits the lowest TEAC value [0.03 (± 0.01)]. Collectively, the trend of the TEAC values of **1–3** is observed to be well matched with the degree of their oxidation (Figures 2.6 and 2.7).

Figure 2.15. Scavenging capability of **1–3** against free organic radicals in N2a cell lysates, determined by the TEAC assay. The TEAC values of compounds are summarized in (b). *n.d., not determined. The TEAC values of ethanamine (**EA**) and ethanethiol (**ET**) were not able to be obtained due to their limited activity.

In order to identify which structural portions contribute to the antioxidant capability of our compounds (especially, **1** and **2**), we further investigated the ability of structural components of **1–3** [*i.e.*, **DMPD**, **BT**, ethanamine (**EA**), ethanethiol (**ET**); Figure 2.15] to scavenge free radicals. The TEAC value of **DMPD** is 1.0 (± 0.03), much higher than that of **BT** [0.02 (± 0.03)], which could explain the better antioxidant capability of **1** containing **DMPD**, compared to **2** and **3** possessing **BT**. In the case of **EA** and **ET**, their TEAC values could not be measured due to their limited activity against free radicals. In addition to the individual parts, the entire structure of the compounds might be shown to be important for their antioxidant capacity (**1 versus DMPD**; Figure 2.15b). Overall, the antioxidant capability of compounds is confirmed to be associated with their chemical structures that consequently differentiate their oxidation potentials.

Figure 2.16. Toxicity of compounds in SH-SY5Y (5Y) cells. (a) Cell survival of compounds (1–3) in the absence of metal ions. (b) Cell survival of compounds (*i.e.*, 1 and 2) in the presence of metal ions. (c) Cell survival of compounds (*i.e.*, 1 and 2) in the presence of A β ₄₀ or A β ₄₂ and metal ions. Conditions: [A β] = 10 μ M, [CuCl₂ or ZnCl₂] = 5 μ M, [compound] = 10 μ M.

2.3. Conclusions

Novel small molecules, composed of **DMA** and bidentate ligands, were newly constructed for regulating distinct factors linked to AD pathology to different extents. The development of such compounds was achieved *via* our rational structure-property-directed design principle employing a very straightforward structural modification. The distinguishable characteristics of the small molecules, including redox properties and interactions with pathological components, were obtained through our simple structural variation. The relatively easily oxidizable compound, **1**, is demonstrated to effectively modify multiple pathogenic factors, *i.e.*, metal-free and metal-bound A β as well as free radicals. In addition, **2**, which is less easily oxidized than **1**, presents the specific reactivity towards the aggregation of Cu(II)–A β ₄₂, along with less scavenging ability against free radicals than that of **1**. The hardly oxidizable compound, **3**, could not influence the actions of all pathogenic components, *i.e.*, metal-free A β , metal–A β , and free radicals. Therefore, our studies reveal that a very minor structural change could successfully tune their properties (especially, oxidation potentials) as well as regulatory reactivities towards distinct pathogenic elements found in AD.

In order to evaluate biological applications of our small molecules, their cytotoxicity was examined employing human neuroblastoma SH-SY5Y cells through the MTT assay [MTT = 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] (Figure 2.16). Compound **1** was observed to have no cytotoxicity up to 10 μ M (cell viability, *ca.* 100%; Figure 2.16). In the case of **2** and **3**, the

compounds were less toxic up to 25 μM (cell viability, *ca.* 80-100%) (Figure 2.16). When the cells incubated with $\text{A}\beta$ and **1** (the compound with regulatory reactivities towards multiple pathological factors) in the absence and presence of metal ions, the cell survival was enhanced by *ca.* 10 to 20% (Figure 2.16). To improve the utilization of such molecules in biological systems, further structural optimization would be necessary. To conclude, our structure-property-directed design demonstrates the feasibility of building up novel structural entities useful for devising chemical tools towards modulation of single or multiple pathogenic factor(s) found in AD.

2.4. Experimental Section

2.4.1. Materials and Methods

All reagents were purchased from commercial suppliers and used as received unless otherwise noted. Cyclic voltammograms were recorded under N_2 (g) with a CHI620E model potentiostat (Qrins, Seoul, Republic of Korea). A three-electrode setup is composed of an Ag/Ag(I) reference electrode [RE-1B Reference electrode [Ag/Ag(I); Qrins], a Pt wire auxiliary electrode (SPTe Platinum electrode; Qrins), and a glassy carbon working electrode (Qrins). $\text{A}\beta_{40}$ and $\text{A}\beta_{42}$ ($\text{A}\beta_{42}$ = DAEFRHDSGYEVHHQKLVFFAEDVGSNKGAIIGLMVGGVVIA) were purchased from Anaspec (Fremont, CA, USA). Trace metal ions were removed from the solutions used in the studies by treating the solutions with Chelex overnight (Sigma-Aldrich, St. Louis, MO, USA). Optical spectra were recorded using an Agilent 8453 UV-Vis spectrophotometer. Absorbance values for biological assays, including the PAMPA-BBB, TEAC, and MTT assays, were measured using a Molecular Devices SpectraMax M5e microplate reader (Sunnyvale, CA, USA). TEM images were taken by a JEOL JEM-2100 transmission electron microscope [UNIST Central Research Facilities (UCRF), Ulsan, Republic of Korea]. ESI-MS and IM-MS analyses were performed using a Waters Synapt G2-Si quadrupole time-of-flight (Q-ToF) ion mobility mass spectrometer (Waters, Manchester, UK) equipped with an ESI source [DGIST Center for Core Research Facilities (CCRF), Daegu, Republic of Korea]. ^1H and ^{13}C NMR spectra were recorded using a 400 MHz Agilent NMR spectrometer (UCRF). The high-resolution mass spectra of compounds were obtained through a Q exactive plus orbitrap mass spectrometer (Thermo Fisher Scientific, Carlsbad, CA, USA).

2.4.2. Preparation of **1**

Ethylene sulfide (150 μL , 2.5 mmol) was added dropwise into a solution of dimethyl-4-phenylenediamine (690 mg, 5 mmol) in EtOH (3 mL) and the reaction mixture was heated to 100 $^\circ\text{C}$ under N_2 (g). After 2 h, ethylene sulfide (100 μL , 1.7 mmol) was added dropwise. After 1 h, the solvent was removed under vacuum. The residue was dissolved in water and extracted with ethyl acetate (EtOAc; 3x). The combined organic layer was dried over anhydrous magnesium sulfate

(MgSO₄) and concentrated under the vacuum. The crude compound was purified by column chromatography (SiO₂; EtOAc:hexanes = 1:3) yielding a product (white oil; 140 mg, 0.71 mmol, 29%). ¹H NMR [400 MHz, CD₂Cl₂, δ (ppm)]: 6.71 (2H, d, *J* = 8.8 Hz), 6.61 (2H, d, *J* = 8.8 Hz), 3.57 (1H, br), 3.28 (2H, t, *J* = 6.4 Hz), 2.81, (6H, s), 2.73 (2H, m), 1.48 (1H, m). ¹³C NMR [100 MHz, CD₂Cl₂, δ (ppm)]: 144.9, 140.1, 115.8, 115.0, 48.2, 42.2, 24.9. HRMS (*m/z*): [M + H]⁺ Calcd. for C₁₀H₁₆N₂S, 197.1107; found, 197.1102.

2.4.3. Preparation of 2

4-Iodoaniline (660 mg, 3.0 mmol), 2-mercaptoethanol (0.42 mL, 6.0 mmol), copper sulfate pentahydrate (CuSO₄·5H₂O; 38 mg, 0.15 mmol), and KOH (840 mg, 15 mmol) were added into a test tube containing DMSO/H₂O (2 mL/0.2 mL) with a magnetic stir bar. After flushing with Ar (g), the mixture was stirred in a preheated oil bath at 90 °C for 20 h and then cooled to room temperature. The reaction was quenched with water and extracted with EtOAc (4x). The organic layer was washed with water (1x) and brine (1x) and then concentrated under vacuum. The crude product was purified by column chromatography (SiO₂; EtOAc:hexanes = 1:1) yielding a primary amine product (yellow oil; 360 mg, 2.1 mmol, 70%).

A mixture of 3 M sulfuric acid (H₂SO₄; 1.2 mL, 3.4 mmol) and formaldehyde (aq, 37% w/w, 0.64 mL, 8.4 mmol) was cooled to 0 °C. A slurry of 2-((4-aminophenyl)thio)ethanol (360 mg, 2.1 mmol) and sodium borohydride (NaBH₄; 480 mg, 13 mmol) in tetrahydrofuran (THF; 5 mL) was added dropwise into the solution. After stirring the solution for 1 h, the reaction mixture was basified with 1 N sodium hydroxide (NaOH; aq) and then extracted with EtOAc (3x). The combined organic phase was washed with brine (1x), dried over anhydrous MgSO₄, and concentrated under vacuum. The crude compound was purified by column chromatography (SiO₂; EtOAc:hexanes = 1:1) yielding a tertiary amine product (white solid; 330 mg, 1.7 mmol, 79%).

A solution of 2-((4-(dimethylamino)phenyl)thio)ethanol (340 mg, 1.7 mmol) and thiourea (140 mg, 1.9 mmol) in HCl (aq) (0.6 mL) was stirred at 100 °C for 6 h. The reaction mixture was cooled to 50 °C. A solution of NaOH (aq; 20% w/w, 0.39 mL) was slowly added to the reaction solution, and then white solid precipitates were obtained. The reaction mixture was stirred at 70 °C for 1 h until the white precipitates disappeared. The reaction was quenched with water and extracted with EtOAc (3x). The organic layer was washed with brine (1x), dried over anhydrous MgSO₄, and concentrated under vacuum. The crude product was purified by column chromatography (SiO₂; EtOAc:hexanes = 1:2) yielding a thiol product (140 mg, 0.65 mmol, 12%). ¹H NMR [400 MHz, CD₂Cl₂, δ (ppm)]: 7.31 (2H, d, *J* = 8.1 Hz), 6.65 (2H, d, *J* = 8.8 Hz), 2.94 (6H, s), 2.91 (2H, m), 2.62 (2H, m), 1.72 (1H, t, *J* = 8.1 Hz). ¹³C NMR [100 MHz, CD₂Cl₂, δ (ppm)]: 150.8, 135.0, 119.3, 113.1, 41.1, 40.5, 24.7. HRMS (*m/z*): [M + H]⁺ Calcd. for C₁₀H₁₅NS₂, 214.0719; found, 214.0714.

2.4.4. Preparation of 3

4-Iodo-*N,N*-dimethylaniline (490 mg, 2.0 mmol), 2-(Boc-amino)ethanethiol (680 μ L, 4.0 mmol), copper acetate dihydrate [Cu(OAc)₂·2H₂O; 40 mg, 0.2 mmol], and potassium carbonate (K₂CO₃; 1.1 g, 8.0 mmol) were added into a test tube containing DMSO/H₂O (3 mL/1 mL) with a magnetic stir bar. After flushing with Ar (g), the mixture was stirred in a preheated oil bath at 90 °C for 24 h. After cooling the solution to room temperature, the reaction was quenched with EtOAc. The reaction solution was washed with water (3x) and brine (1x). The organic layer was dried over anhydrous MgSO₄ and concentrated under vacuum. The crude product was purified by column chromatography (SiO₂; EtOAc:hexanes = 1:10) yielding a product (white solid; 210 mg, 0.71 mmol, 34%).

tert-Butyl 2-(4-(dimethylamino)phenylthio)ethylcarbamate (400 mg, 1.4 mmol) was added into the solution of HCl/dioxane (4.0 M, 10 mL) at 0 °C under Ar (g). The reaction mixture was stirred at room temperature for 24 h. The solvent was removed under vacuum and the residue was washed with diethyl ether (Et₂O). The sticky compound was basified with 1 N NaOH (aq) and extracted with EtOAc (3x). The combined organic layer was washed with brine (1x), dried over anhydrous MgSO₄, and concentrated under vacuum. The crude compound was purified by column chromatography (SiO₂; CH₂Cl₂:CH₃OH = 7:1). A product (white powder; 50 mg, 0.25 mmol, 18%) was obtained by addition of Et₂O to the yellow liquid product. ¹H NMR [400 MHz, CD₃OD, δ (ppm)]: 7.35 (2H, m), 6.72 (2H, d, *J* = 8.8 Hz), 2.94 (10H, m), 1.90 (2H, s). ¹³C NMR [100 MHz, CD₃OD, δ (ppm)]: 152.2, 136.0, 119.2, 114.2, 40.6, 39.8, 35.5. HRMS (*m/z*): [M + H]⁺ Calcd. for C₁₀H₁₆N₂S, 197.1107; found, 197.1103.

2.4.5. Metal Binding Studies

The interactions of compounds with metal ions [Cu(II) and Zn(II)] were determined using UV–visible spectroscopy (UV–Vis). The solutions of compounds (50 μ M; 1% v/v DMSO) were prepared in EtOH for [Cu(II) samples] or buffer [20 μ M HEPES, pH 7.4, 150 μ M NaCl; for Zn(II) samples]. Various concentrations of CuCl₂ or Zn(NO₃)₂ (25, 50, 100, and 250 μ M) were titrated to the solutions of the compound. The UV–Vis spectra were recorded after 10 min incubation for every titration at room temperature.

2.4.6. Cyclic Voltammetry (CV)

Cyclic voltammograms were recorded under N₂ (g) with a CHI620E model potentiostat (Qrins) with three electrodes composed of an Ag/AgCl reference electrode [RE-1B Reference electrode (Ag/AgCl); Qrins], a Pt wire auxiliary electrode (SPTE Platinum electrode; Qrins), and a glassy carbon working electrode (Qrins). Electrochemical analyses of compounds (dissolved in DMSO; final concentration, 1 mM) were recorded in 0.1 M *tetra-N*-butylammonium perchlorate (in DMSO) and 1 M NaCl (in

ddH₂O; 1% v/v DMSO) at various scan rates (25, 50, 100, 150, 200, and 250 mV/s) at room temperature.

2.4.7. DTNB Assay

The oxidation of a thiol group in our compounds was evaluated through the DTNB assay [DTNB = 5,5'-dithio-bis-(2-nitrobenzoic acid)]. The solutions of DTNB (50 μM) were prepared in 0.1 M sodium phosphate buffer, pH 8.0, 1 mM EDTA, followed by treatment of *L*-cysteine, as a positive control, and small molecules (50 μM; 1% v/v DMSO). The DTNB molecule can react with the thiol groups in small molecules, yielding a product containing a newly formed disulfide bond and a yellow-colored compound, 2-nitro-5-thiobenzoic acid dianion (TNB²⁻).⁶⁴ After 15 min incubation at room temperature, the absorbance of TNB²⁻ at 412 nm was measured.

2.4.8. Stability of Compounds

The oxidation of compounds was traced by UV–Vis. The solutions of compounds (50 μM; 1% v/v DMSO) were prepared in buffer (20 μM HEPES, pH 7.4, 150 μM NaCl). The compound was incubated for 24 h at room temperature without agitation.

2.4.9. TEAC Assay

The assay employing Neuro2a (N2a) cell lysates was conducted following the previously reported methods.^{34,63} Cell lysates were prepared following a previously reported procedure with modifications.⁶⁵ N2a cells were seeded in a six-well plate and grown to approximately 80-90% confluence. Cells were washed once with cold phosphate buffered saline (PBS, pH 7.4, GIBCO, Grand Island, NY, USA) and harvested by gently pipetting off adherent cells with cold PBS. The cell pellet was generated by centrifugation (2,000 g for 10 min at 4 °C) and sonicated on ice (5 s pulses, 3x with 20 s intervals between each pulse) in 2 mL of cold buffer (5 mM potassium phosphate, pH 7.4, containing 0.9% NaCl and 0.1% glucose). The cell lysates were centrifuged at 5,000 g for 10 min at 4 °C. The supernatant was removed and stored on ice until use. To prepare the standard and samples in 96 well plates, 10 μL of the supernatant of cell lysates was delivered followed by the addition of compound (10 μL), metmyoglobin (55 μM, 10 μL), 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS; 220 μM, 150 μL), and H₂O₂ (412 μM, 40 μL) in order. The final concentrations (2.14, 4.28, 6.43, 8.57, 10.7, and 15.7 μM) of compounds and Trolox were used. After 5 min incubation at room temperature, the absorbance at 750 nm was recorded. The percent inhibition was calculated according to the measured absorbance [% inhibition = 100 × (A₀ – A)/A₀, where A and A₀ are the absorbance of the supernatant of cell lysates with and without compound treatment, respectively] and was plotted as a function of compound concentration. The TEAC values of

compounds for each time point were calculated as a ratio of the slope of the compound to that of Trolox. The measurements were conducted in triplicate.

2.4.10. A β Aggregation Experiments

A β ₄₀ or A β ₄₂ was dissolved in ammonium hydroxide [NH₄OH (aq); 1% v/v]. The resulting solution was aliquoted, lyophilized overnight, and stored at -80 °C. A stock solution of A β was then prepared by dissolving the lyophilized peptide using NH₄OH (1% v/v, 10 μ L) and diluting with ddH₂O. All A β samples were prepared by following the previously reported procedures.^{34,37,66,67} The concentration of the peptide solution was determined by measuring the absorbance of the solution at 280 nm (ϵ = 1,450 M⁻¹cm⁻¹ for A β ₄₀; ϵ = 1,490 M⁻¹cm⁻¹ for A β ₄₂). The peptide stock solution was diluted to a final concentration of 25 μ M in the Chelex-treated buffer [20 μ M HEPES, pH 6.6 [for Cu(II) samples] and pH 7.4 [for metal-free and Zn(II) samples], 150 μ M NaCl]. For inhibition studies, compounds (final concentration, 50 μ M; 1% v/v DMSO) were added to the samples of A β (25 μ M) in the absence and presence of a metal chloride salt (CuCl₂ or ZnCl₂; 25 μ M) followed by incubation at 37 °C with constant agitation for 24 h. For disaggregation studies, A β (25 μ M) was incubated with and without a metal chloride salt (CuCl₂ or ZnCl₂; 25 μ M) for 24 h at 37 °C with constant agitation to generate preformed A β aggregates. The resulting peptide aggregates were then treated with compounds (50 μ M) and incubated with constant agitation for an additional 24 h.

2.4.11. Gel Electrophoresis with Western Blotting (Gel/Western Blot)

The A β resultant species from *in vitro* experiments were analyzed through gel electrophoresis with Western blotting (gel/Western blot) using an anti-A β antibody (6E10).^{34,37,66,67} The samples (10 μ L) were separated on a 10-20% Tris-tricine gel (Thermo Fisher Scientific). Following separation, the proteins were transferred onto nitrocellulose membranes and blocked with bovine serum albumin (BSA, 3% w/v, Sigma-Aldrich) in Tris-buffered saline (TBS) containing 0.1% Tween-20 (TBS-T) for 2 h (at room temperature) or overnight (at 4 °C). The membranes were incubated with the anti-A β antibody (6E10) (1:2,000, Covance, Princeton, NJ, USA) in a solution of 2% BSA (w/v in TBS-T) for 4 h (at room temperature) or overnight (at 4 °C). After washing with TBS-T (3x, 10 min), a horseradish peroxidase-conjugated goat anti-mouse secondary antibody (1:5,000 in 2% w/v BSA in TBS-T; Cayman Chemical Company) was added for 1.5 h at room temperature. A homemade ECL kit^{63,68,69} was used to visualize gel/Western blot data on a ChemiDoc MP Imaging System (Bio-Rad, Hercules, CA, USA).

2.4.12. Transmission Electron Microscopy (TEM)

Samples for TEM were prepared according to previously reported methods.^{34,37,63,66-68} Glow-

discharged grids (Formvar/Carbon 300-mesh, Electron Microscopy Sciences, Hatfield, PA, USA) were treated with A β samples (25 μ M, 5 μ L) for 2 min at room temperature. Excess sample was removed using filter paper followed by washing twice with ddH₂O. Each grid, incubated with uranyl acetate (1%, ddH₂O, 5 μ L) for 1 min, was blotted off and dried for 15 min at room temperature. Images for each sample were taken on a JEOL JEM-2100 transmission electron microscope (200 kV; 25,000x magnification; UCRF).

2.4.13. MTT Assay

The SH-SY5Y (5Y) cell line was purchased from the American Type Culture Collection (ATCC, Manassas, VA, USA). The cell line was maintained in media containing 50% minimum essential medium (MEM) and 50% F12 (GIBCO) and supplemented with 10% fetal bovine serum (Sigma-Aldrich), 100 U/mL penicillin, and 100 mg/mL streptomycin (GIBCO). Cells were grown and maintained at 37 °C in a humidified atmosphere with 5% CO₂. The cells used for our studies did not indicate mycoplasma contamination. Cell viability upon treatment with compounds was determined by the MTT assay [MTT = 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide]. Cells were seeded in a 96 well plate (15,000 cells in 100 μ L per well) and treated with A β (10 μ M) with or without CuCl₂ or ZnCl₂ (5 μ M), followed by addition of compounds (10 μ M, 1% v/v DMSO). After 24 h incubation, MTT [25 μ L of 5 mg/mL in PBS (pH 7.4, GIBCO)] was added to each well, and the plate was incubated for 4 h at 37 °C. Formazan produced by cells was solubilized using an acidic solution of DMF (pH 4.5, 50% v/v, aq) and sodium dodecyl sulfate (SDS; 20% w/v) overnight at room temperature in the dark. The absorbance was measured at 600 nm by the microplate reader. Cell viability was calculated relative to cells containing an equivalent amount of DMSO.

2.4.14. Electrospray Ionization Ion Mobility Mass Spectrometry (ESI-IM-MS)

The experiments were performed according to previously reported methods.^{63,68,70} A β ₄₀ and A β ₄₂ (100 μ M) were incubated with compounds (500 μ M; 1% v/v DMSO) and/or CuCl₂ (100 μ M) in 20 mM ammonium acetate (pH 7.2) at 37 °C without agitation. Incubated samples were diluted by 10 fold with water and then injected into the mass spectrometer. A Waters Synapt G2-Si quadrupole time-of-flight (Q-Tof) ion mobility mass spectrometer (Waters) equipped with ESI source (CCRF) was used for the experiments. The capillary voltage, sampling cone voltage, and source temperature were set to 2.8 kV, 70 V, and 40 °C, respectively. The backing pressure was adjusted to 2.7 mbar. Ion mobility wave height and velocity were adjusted to 10 V and 300 m/s, respectively, and gas flow for the helium and ion mobility cell was set to 120 and 30 mL/min, respectively. Tandem MS (ESI-MS²) analyses were additionally performed on the singly oxidized A β and complexes of A β with compounds. The ESI parameters and experimental conditions were the same as above. Collision-induced dissociation

(CID) was conducted by applying the collision energy in the trap and adjusting the low mass (LM) resolution to 10 or 15 depending on the samples. More than 200 spectra were obtained for each sample and were averaged for the analyses. To estimate the collision cross section (CCS) values of IM–MS data, the calibration was also carried out base on the previously reported methods.⁷¹

2.4.15. Parallel Artificial Membrane Permeability Assay Adapted for the Blood-brain Barrier (PAMPA–BBB)

PAMPA–BBB experiments were conducted using the PAMPA Explorer kit (*p*ION Inc., Billerica, MA, USA) using previously reported protocols.^{2,5,6} The compounds (25 μ M, 200 μ L) in Prisma HT buffer (pH 7.4, *p*ION) were added to the wells of a donor plate (number of replicates = 12). The polyvinylidene fluoride (PVDF, 0.45 μ M) filter membrane on the acceptor plate was coated with BBB-1 lipid formulation (5 μ L, *p*ION). The acceptor plate was then placed on the top of the donor plate. Brain sink buffer (BSB, 200 μ L, *p*ION) was added to each well of the acceptor plate and was incubated for 4 h at room temperature without agitation. UV–Vis spectra of the solutions in the reference, acceptor, and donor plates were measured using the microplate reader. The PAMPA Explorer software v. 3.5 (*p*ION) was used to calculate the $-\log P_e$ values for compounds. CNS \pm designations were assigned by comparison with compounds that were identified in previous reports.^{72,73}

2.5. Acknowledgments

This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government [NRF-2016R1A5A1009405 and NRF-2017R1A2B3002585 (to M.H.L.); NRF-2015R1D1A1A01060188 (to J.C.)]; the DGIST R&D Program (17-BD-0403) (to J.C.).

Chapter 3.

Detection of Metal Ions in Living Cells by Fluorescence-based Chemosensors

The results presented in this chapter were published; (1) Jo, T. G.; Bok, K. H.; Han, J.; Lim, M. H.; Kim, C. *Dyes Pigm.* **2017**, *139*, 136–147; (2) Jeong, H. Y.; Lee, S. Y.; Han, J.; Lim, M. H.; Kim, C. *Tetrahedron* **2017**, *73*, 2690–2697; (3) Jo, T. G.; Jung, J. M.; Han, J.; Lim, M. H.; Kim, C. *RSC Adv.* **2017**, *7*, 28723–28732. I conducted the imaging experiments in order to monitor fluorescent responses of chemosensors for metal ions in living cells.

3.1. Introduction

Dyshomeostasis of transition metal ions has been suggested to be involved in the pathogenesis of neurodegenerative diseases including Alzheimer's disease (AD) and Parkinson's disease (PD).^{1,2} Particularly, aluminum, the third most prevalent metallic elements in the earth, can be accumulated in the regions of the brain, *i.e.*, the cortex and hippocampus, both of which are notably vulnerable at the early stage of AD.^{1,2} Recent studies have revealed that a trace amount of Al(III), transported to the brain *via* blood-brain barrier (BBB), can either intrude metal-mediated signaling pathways [*e.g.*, Ca(II) exchange] or replace essential biometals in transporters (*e.g.*, iron carrier transferrin), which induces neurotoxicity.^{3,4} In addition, Al(III) can interfere the activities of iron-sulfur clusters in mitochondrial respiratory systems, disrupting the energy production.^{5,6} Moreover, Al(III) has been reported to directly bind A β and stabilize structured oligomers.^{5,6} In order to quantify the concentration of Al(III) and monitor its compartmentalization in the brain, various chemosensors able to specifically detect this metal ion would be valuable.^{2,7,8} In this Chapter, we described three chemical tools capable of targeting Al(III) in living cells.

3.2. Results and Discussions

3.2.1. Fluorescent Responses of AIC-Jul to Al(III) in Living Cells

Scheme 3.1. Proposed structure of the **AIC-Jul**–Al(III) complex.

AIC-Jul was rationally designed through the incorporation of imidazole and julolidine (Scheme 3.1).⁹ This molecule functions as a turn-on and turn-off fluorescent sensors against Al(III) and pyrophosphate ($\text{P}_2\text{O}_7^{4-}$, PPI), the product of during hydrolysis of adenosine triphosphate (ATP), respectively. Upon incubation of **AIC-Jul** (20 μM , DMSO 1%, *v/v*) with 5 and 10 equiv of Al(III) for 10 min, significant fluorescent responses were monitored employing the green fluorescence protein (GFP) channel [excitation 470 (\pm 11) nm; emission 510 (\pm 21) nm; Figure 3.1a]. Furthermore, the **AIC-Jul**–Al(III) complex was shown to specifically detect PPI among various anions (*e.g.*, Cl^- , F^- , N_3^- , and NO_3^-) in the cellular environment. When PPI was treated to cells, pre-incubated with **AIC-Jul** and Al(III), the Al(III)–PPI complex was subsequently formed, indicative of detaching Al(III) from the complex. The quenching process achieved *via* complexation of Al(III)–PPI was monitored using the GFP channel (Figure 3.1b). Our experiments demonstrate the potential of **AIC-Jul** as a sensor for

both Al(III) and PPI in living cells.

Figure 3.1. Fluorescent responses of **AIC-Jul** to Al(III) in HeLa cells in the absence and presence of PPI. (a) Cells were pre-incubated with **AIC-Jul** for 10 min prior to addition of various concentrations of Al(III). (b) Cells incubated with **AIC-Jul** (for 5 min) followed by addition of Al(III) for 10 min were treated with various concentrations of PPI. Conditions: [**AIC-Jul**] = 20 μM ; [Al(III)] = 0, 100, and 200 μM ; [PPI] = 0, 100, and 200 μM ; 37 $^{\circ}\text{C}$; 5% CO_2 . The scale bar is 50 μm .

3.2.2. Fluorescent Responses of TP-DAS to Al(III) in Living Cells

Scheme 3.2. Proposed structure of the **TP-DAS**–Al(III) complex.

TP-DAS was newly designed by introduction of diethylaminophenol and thiophene into a framework (Scheme 3.2).¹⁰ Based on competition experiments, Co(II), Ni(II), and Zn(II) could not interfere the interactions between **TP-DAS** and Al(III), while Cu(II) and Fe(II/III) were shown to intrinsically quench the fluorescent responses from the **TP-DAS**–Al(III) complex. Our compound (5 μM , DMSO 1%, v/v) was incubated with Al(III) in HeLa cells for 10 min at various concentrations (Figure 3.2). The fluorescent responses of **TP-DAS** as a function of the concentration of Al(III) were gradually enhanced, monitored at the channel of 4',6-diamidino-2-phenylindole (DAPI) channel [excitation 357 (\pm 22) nm; emission 447 (\pm 30) nm]. Our experimental results reveal that **TP-DAS** could be a detector for Al(III) in biological systems.

Figure 3.2. Fluorescent responses of **TP-DAS** to Al(III) in HeLa cells. Cells were pre-incubated with **TP-DAS** for 10 min prior to addition of various concentrations of Al(III). Conditions: [**TP-DAS**] = 5 μM ; [Al(III)] = 0, 100, 200, and 300 μM ; 37 $^{\circ}\text{C}$; 5% CO_2 . The scale bar is 50 μm .

3.2.3. Fluorescent Responses of Sul-Nap to Al(III) in Living Cells

Scheme 3.3. Proposed structure of the **Sul-Nap**–Al(III) complex.

Sul-Nap was rationally designed by integrating a water-soluble sulfonic acid group to the naphthol moiety, a widely utilized fluorophore (Scheme 3.3).¹¹ **Sul-Nap** was presented to selectively recognize Al(III) in a 1:1 ratio, followed by a significant change in fluorescence emission in aqueous media. In order to examine the potentials of **Sul-Nap** to be used for sensing Al(III) in biological systems, fluorescence imaging experiments were performed (Figure 3.3). HeLa cells were incubated with **Sul-Nap** (20 μM , DMSO 1%, v/v) for 10 min, prior to treatment of 5 equiv of Al(III) for additional 10 min. The fluorescence responses of **Sul-Nap** in the presence of Al(III) were detected at the GFP channel [excitation 470 (\pm 11) nm; emission 510 (\pm 21) nm]. Note that due to the poor cell permeability of the molecule, the concentration-dependent fluorescent responses of **Sul-Nap** to Al(III) could not be monitored (Figure 3.3).

Figure 3.3. Fluorescent responses of **Sul-Nap** in HeLa cells in the (a) absence and (b) presence of Al(III). Cells were pre-incubated with **Sul-Nap** for 10 min prior to addition of Al(III). Conditions: [**Sul-Nap**] = 20 μM ; [Al(III)] = 100 μM ; 37 C; 5% CO₂. Scale bar = 50 μm .

3.3. Conclusions

Impaired homeostasis of metal ions is found in the AD-affected brain.^{1,2} In the recent studies, Al(III) has been suggested as an additional risk factor in AD, which can facilitate A β aggregation and interfere the activities of metalloenzymes.^{3,4} In order to gain a better understanding of Al(III) in AD, the design of small molecules able to trace this metal ion would be desirable. In this Chapter, we developed three chemical probes, **AIC-Jul**, **TP-DAS**, and **Sul-Nap**, able to detect Al(III) based on fluorescence in living cells. In the future, we will further optimize the structures of the molecules in order to improve their metal specificity and cytotoxicity.

3.4. Experimental Sections

3.4.1. Imaging Experiments in Living Cells

HeLa cells (ATCC, Manassas, USA) were maintained in media containing Dulbecco modified eagle medium (DMEM), 10% fetal bovine serum (FBS, GIBCO, Grand Island, NY, USA), 100 U/mL penicillin (GIBCO), and 100 mg/mL streptomycin (GIBCO). The cells were grown in a humidified atmosphere with 5% CO₂ at 37 °C. Cells were seeded onto 6 well plate (SPL Life Sciences Co., Ltd., South Korea) at a density of 150,000 cells per 1 mL and then incubated at 37 °C for 16 h. For imaging experiments, cells were first treated with compound [dissolved in DMSO; 1% v/v final DMSO concentration; 5 μM (for **TP-DAS**) or 20 μM (for **AIC-Jul** and **Sul-Nap**); at room temperature]. After 10 min, aluminum nitrate (dissolved in water; 1% v/v final concentration; 0-300 μM) is introduced to cells for 10 min. In case of fluorescence quenching experiments for **AIC-Jul**, cells were first treated with the compound (dissolved in DMSO; 1 % v/v final DMSO concentration; 20 μM ; at room temperature). After 5 min, aluminum nitrite (dissolved in water; 200 μM ; 1% v/v) was incubated with cells 10 min. Various concentrations of PPI (dissolved in bis-tris buffer; 1% v/v) were introduced to cells for 5 min and the cells were washed with 3 mL of bis-tris buffer three times. Imaging experiments were performed with an EVOS FL fluorescence microscope (Life Technologies) using a

DAPI light cube [for **TP-DAS**; excitation 357 (\pm 22) nm; emission 447 (\pm 30) nm] or GFP light cube [for **AIC-Jul** and **Sul-Nap**; excitation 470 (\pm 11) nm; emission 510 (\pm 21) nm].

Acknowledgement

I appreciate all the people who have contributed to the completion of the work described in this thesis.

First and foremost, I would love to express my sincere gratitude to my advisor, Professor Mi Hee Lim for guidance and encouragement that she has provided during my M.S. course. She has continuously given me a great confidence to make a progress in research. Despite her busy schedules, she readily spent her valuable time for supervision, discussion, and inspiration regarding my project. Her advice was always helpful for me to establish the research goals and move forward as an independent researcher. Without her notable mentorship, motivation, and immense knowledge, I would not be able to accomplish my M.S. degree.

Additionally, I thank my committee members, Professors Tae-Hyuk Kwon and Jung-Min Kee, for investing their precious time for providing insightful advice.

I want to also acknowledge my collaborators who have continuously helped me carry out the works described in this thesis. Particularly, I would like to express appreciation to Professor Junghyun Chae, Kyu Yeon Kim, Dr. Shin Jung Lee, and Professor Jaeheung Cho for cooperation regarding the preparation of small molecules and discussion regarding experimental results.

Importantly, thank all of the Lim Lab group members, Dr. Hyuck Jin Lee, Juhye Kang, Geewoo Nam, Eunju Nam, Yonghwan Ji, Misun Lee, Mingeun Kim, Nahye Park, Jong-Min Suh, Yelim Yi, Gunhee Kim, and Juri Lee, and our previous group members (Michael W. Beck and Jeffrey S. Derrick) for their assistance and lively scientific discussion. In addition, I thank our lab manager, Mi Sook Lim, for her administration and support for our laboratory. I was considerably inspired by their consideration, knowledge, sincerity, and diligence. It was a great honor for me to work with our group members at UNIST.

Lastly, I would love to appreciate my parents, Woong Ku Han and Jeong Ha Kim, and my brother, Seok Woo Han, with their strong support and encouragement that have allowed me to focus on achieving my research goals during my M.S. course.
