## ABSTRACT

The Potenza Valley Survey project investigates since 2000 the settlement dynamics in the Central Adriatic Potenza valley, with particular attention to the period from the Iron Age to early Medieval times (900 BC-AD 900). Part of this research focuses on the Roman abandoned towns of *Potentia* and *Trea* by performing an integrated, geoarchaeological study of their townscape. This largely non-invasive research consists of remote sensing analysis, geophysical surveys (magnetometry, electrical resistivity and Ground Penetrating Radar) and geomorphological fieldwork such as microtopographic measurements and hand augerings. The chosen techniques depend on the nature of each town and are integrated with more traditionally achieved research data. This paper presents the main interdisciplinary results of these two Roman towns and highlights the importance of obtaining complementary data and performing hand augering as a stratigraphic control of the remote sensing and geophysical results. An insight in the character and layout of the cities, the structural influence on the surrounding area and the human-environment interactions and dynamics through time of both Roman cities could be obtained. Moreover, the results offer guidelines for conservation strategies of these abandoned towns and their *suburbium*, which are necessary to protect them from present-day threats such as agriculture and tourism.

Geoarchaeology, Abandoned towns, Roman period, Italy

## 1. INTRODUCTION

From the 1980s onwards archaeologists working on ancient urban sites started to realize that the systematic application of non-invasive field techniques held out the promise of making a major contribution to our understanding of ancient urbanism. Advancement of knowledge would now not anymore come from the often large and successful towns with almost uninterrupted and full habitation continuity until our time, where archaeological excavations and traditional topographic work in urban environments typically centered on the more monumental or visible structures. But especially the category of ancient urban sites, which today are partly or often even fully abandoned, now came much more into the picture. This happened especially in the Mediterranean area where preservation conditions are best, a multitude of very well built classical cities existed, and where many urban centers show settlement discontinuity in Medieval or modern times. Spurred by seminal projects such as the study of Boeotian towns by Bintliff and Snodgrass (1985, 1988), as well as by the refinement of geophysical techniques and aerial photography that could

1  
2  
3 be used for the fine-grained analysis required to bring out details of urban layout (Barber, 2011;  
4 Bourgeois & Meganck, 2005; Doneus, 2004; Guaitoli, 2003; Scollar, Tabbagh, Hesse, & Herzog,  
5 1990), a new age of urban studies in the field emerged. Partly helped by the power of GIS-  
6 technology and other techniques currently used in the geosciences this evolution created, since  
7 the turn of the millennium, a boom in the non-invasive destructive survey of urban sites,  
8 especially of the classical Greek and Roman periods (Christie, 2012; Johnson & Millett, 2012;  
9 Vermeulen, Burgers, et al., 2012). This has also led to a revolution in how archaeologists  
10 approach urban sites, with survey techniques being used increasingly often to generate a plan of a  
11 town site prior to excavation, while cultural heritage management authorities have also benefited  
12 from this approach, with urban surveys providing them with a very effective tool for gauging the  
13 degree of archaeological survival on major urban sites in their care and choosing appropriate  
14 conservation strategies.

15  
16  
17  
18  
19  
20 Most recently, research has begun to reveal the advantages of intensively integrating a range of  
21 different non-destructive techniques on urban sites, choosing those suites that are most  
22 appropriate for the nature of the town in question (Corsi, Slapšak, & Vermeulen, 2013), such as is  
23 well demonstrated at several ancient urban sites (Vermeulen, 2013a, 2013b). The variety of  
24 techniques can be quite impressive, such as the application of different geophysical instruments  
25 (for georadar, magnetometer or earth resistance survey, etc.), different aerial photography  
26 approaches (such as flying with traditional airplanes, drones or balloons, or using multispectral  
27 techniques of photography), LiDAR scanning of the sites, and other geomorphological and  
28 geomatic approaches (augering, erosion modelling, DEM production etc.). Therefore, the concept  
29 of integrated, non-invasive multi-method survey relates to a much wider range of techniques, and  
30 the overall methodology envisages a reasoned deployment of them all, or of a choice of them for  
31 systematic data acquisition at the site studied, by testing, sampling or total coverage (Vermeulen,  
32 2013a, 2013b).

33  
34  
35  
36  
37  
38  
39 But the picture tends to be complex, and the tools to address this complexity are normally diverse  
40 and adapted to each case under study. The approaches depend on a variety of factors specific to  
41 the local area such as the natural setting and geomorphological changes through time, the scale of  
42 the site and its depth of monumentality and stratigraphy, the post-urban population presences and  
43 needs, the degree of Medieval to modern efforts to rob or reclaim the terrain and its materials,  
44 and sometimes earlier archaeological intrusions. Furthermore, some sites are far more visible or  
45 more accessible than others, while some have landmarks which guide readings as to what is  
46 missing and some have been more damaged than others (Christie, 2012, p. 285). So flexibility  
47 rather than uniformity will be the rule, and that requires a thorough understanding of the options  
48 at hand and of the problems we can realistically explore by non-invasive geoarchaeology.

60 In this paper, we wish to briefly present two case studies in an Italian context where non-invasive  
survey approaches to study ancient abandoned towns have met with good success. The examples  
from the towns of *Potentia* and *Trea*, both located in the central Adriatic region of Marche  
(Figure 1), illustrate some of the research options at hand and highlight the potential of the

interdisciplinary approach inherent to the geoarchaeology of Classical Antiquity, as already advocated by two of us some 15 years ago (Vermeulen & De Dapper, 2000). At the same time they lay bare some of the typical problems of such fieldwork in past urban contexts, as well as the limits of the possible at the current stage of methodological development, while at the same time offering some avenues for a more soil science based type of urban survey.

**Figure 1** Location of the study area.

## 2. A SUITE OF APPROACHES FOR URBAN SURVEY

Intensive fieldwork and remote sensing operations at both chosen urban sites started in 2000, as part of the archaeological *Potenza Valley Survey* project, which focuses on the *longue durée* settlement dynamics in a typical central Italian valley between the Apennines and the Adriatic sea. Over the years this long term project gave special priority to the intensive study of four partly or fully abandoned Roman town sites and their immediate hinterland, equally dispersed along the valley corridor of the River Potenza. *Potentia*, a newly founded colonial city of Roman citizens (foundation date 184 BC) situated in the valley bottom at the river mouth, and *Trea*, an urban settlement that had since c. 50 BC gradually developed and is located on a small plateau near the central part of the valley, have been studied most elaborately since 2004. Both sites had known only very punctual topographic research before these new investigations, while the few excavations done there had remained very punctual and had not provided insight in such crucial matters as: the exact extent of the urban areas, their street grids and public structures, their housing organization, the character and location of suburban sectors, and the structural impact on the surrounding landscape of roads, cemeteries, field systems and economic exploitation areas. To reveal these elements of the Roman urbanization system in the area, and to answer a whole set of related historical and archaeological questions, a fundamentally integrated new approach was needed. The most diagnostic of these operations comprised the following steps.

The first part of the intensive study of both urban settlements through time, between the Roman Late Republic and their gradual abandonment in the course of the Early Middle Ages (7<sup>th</sup>-9<sup>th</sup> centuries AD), involved the evaluation and re-study of earlier field observations and material collections, and the organization of new and systematic intra-site field walking to collect artifact scatters brought to the surface. As both sites are today still mostly in use as agricultural land these surface concentrations are in part the result of ploughing activities. The field walking provided diachronically subdivided distribution maps of artifact densities and of qualities of archaeological material, which allowed to assess among others certain spatial evolutions of the sites between their Roman and Early Medieval history, functional zoning during the life of the cities (workshops, houses, cemeteries, public buildings...), and the archaeological and geomorphological erosion factors and post-depositional processes.

A second group of new and old data was acquired from a wide array of remote sensing sources. Throughout the now 15 year old project, detailed and significant knowledge about spatial aspects of the urban and suburban areas could be derived from increasingly available aerial photography

1  
2  
3 of both sites and their immediate surrounding landscapes. Among existing imagery, normally  
4 taken at higher altitudes for other purposes than archaeology, this is in the first place certain  
5 historical photography pre-dating more modern landscape changes, such as the excellent imagery  
6 of the coastal area around *Potentia* by RAF flights at the end of WWII and several other series of  
7 aerial photos covering parts of the second half of the last century. Of particular importance for  
8 details on buried structures of this coastal town, often visible through crop marks in the covering  
9 agricultural vegetation, are also the now widely available and high resolution aerial and satellite  
10 views from applications such as Google Earth or Bing, and recently also some good LiDAR  
11 imagery from the Italian Ministry of Environment.  
12  
13  
14  
15

16 The bulk of the remote sensing information for both sites was however acquired via an intensive  
17 and long term program of photography flights by the Belgian team, intensively monitoring the  
18 local archaeology from different aerial platforms. The spectacular discovery of many buried  
19 structures of both towns and their suburban landscapes has over the years allowed a very detailed  
20 mapping of a wide range of features bringing exact knowledge of defensive systems, the quasi  
21 full street grids, most of the public buildings and monuments (forum, temples, market halls,  
22 theatres/amphitheatres, ...), house-plans, cemeteries, etc. The sheer size and character of these  
23 Roman population centers and of certain architectural creations, the systematic choice of durable  
24 building materials and the sometimes quite impressive impact on the local topography of a place,  
25 all contribute well to this present-day vision obtained from the air, even if both town sites have  
26 today left almost no traces of their existence above ground. As it was seldom possible to  
27 photograph the buried traces totally and during one flight only, it was a crucial part of the  
28 monitoring strategy to do regular follow up flights of the area during different seasons and in  
29 different weather conditions. This active aerial photography has been applied as well from a  
30 “classic” manned aircraft (mostly bi- to four-sitters) as from several low-altitude unmanned  
31 platforms (a helikite and a radio-controlled multi-copter drone) (Vermeulen, 2004, 2012;  
32 Vermeulen & Verhoeven, 2004; Vermeulen, Verhoeven, & Semey, 2005). The remarkable speed  
33 and image quality of aerial imagery obtained from such increasingly low-cost solutions make the  
34 latter platforms potent instruments for reconnaissance. They have also allowed and stimulated the  
35 further exploitation of new imaging techniques, such as close-range near-infrared photography  
36 (Verhoeven, 2008, 2012) and near-ultraviolet imaging (Verhoeven & Schmitt, 2010; Verhoeven,  
37 Smet, Poelman, & Vermeulen, 2009). The now more readily available software solutions to  
38 orthorectify these oblique images (e.g. PhotoScan) (Verhoeven, Doneus, Briese, & Vermeulen,  
39 2012), even in the more undulating middle-Potenza landscape around *Trea*, has in recent years  
40 also facilitated the topographically more exact interpretative mapping needed for this survey  
41 method.  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51

52 As in many surveys of large urban sites elsewhere in the Mediterranean and beyond, the project  
53 strategy also comprised the intensive use of geophysical prospections for mapping structural  
54 buried features. Because magnetic surveys generally detect most types of archaeological features  
55 within Roman urban sites, other geophysical survey techniques are only seldom applied on a  
56  
57  
58  
59  
60

1  
2  
3 large scale, as they are more time consuming and hence expensive. However, feature detection  
4 through multiple parameters enhances interpretative validity (Neubauer & Eder-Hinterleitner,  
5 1997; Neubauer, Eder-Hinterleitner, & Melichar, 2002). In addition, recent developments, such  
6 as DGPS equipped multi-instrument platforms and towed arrays, allow relatively rapid collection  
7 of more extensive but also more intensive geophysical datasets. It is clear that for the total survey  
8 of buried Roman towns sites we need to apply as much as possible all relevant geophysical  
9 approaches: so apart from geomagnetic survey, also earth resistance and georadar prospections  
10 are used if available and possible, to name but the most effective today. We, therefore, arranged  
11 to apply these three methods together to obtain not only an almost full coverage of the formerly  
12 inhabited intra-mural areas of our two Potenza valley towns (*Potentia*: 18 ha, *Trea*: 12 ha), but  
13 also to cross their data in the most productive ways in view of the interpretation of the evidence.  
14 This was especially successful on the site of *Trea*, even if on both sites the high clay composition  
15 of the soils caused GPR-results to be very poor (Vermeulen, Slapšak, & Mlekuž, 2012).  
16 Furthermore, a program of covering some of the extra-mural spaces of both sites has also been  
17 initiated, including targeted use of a multi-electrode resistivity meter survey for deeper sounding  
18 and palaeo-landscape mapping, as covering of the buried Roman and Medieval archaeology by  
19 recent deposits proved very disturbing for both aerial and normal geophysical detection.  
20  
21  
22  
23  
24  
25  
26

27  
28 This brings us to a sequence of field operations that we judge to be crucial in such large scale and  
29 non-invasive field operations on the essentially greenfield sites of former Roman towns. They are  
30 the more geomatic and specifically geomorphologically based approaches that in association with  
31 the archaeological questionnaire form the core of real ‘geoarchaeology’. From the onset of the  
32 field operations the need was felt to produce a high-resolution Digital Elevation Model (DEM) of  
33 the areas under investigation in order to relate the urbanization effort and use of the urban site by  
34 the ancients with the physical landscape of the past and today. This is needed not only to  
35 contextualize better the underground (and above ground) features detected with aerial and  
36 geophysical survey, but also to understand the “phenomenology” of complex sites and  
37 landscapes. The DEM is needed not only to support the volumetric and 3D reconstructions, but  
38 also to allow spatial analysis with a full understanding of post-depositional processes. DEMs can  
39 also play a role when studying the effects of processes affecting the representativeness and  
40 conservation of the archaeological record. Furthermore, they may be very useful to assess the  
41 reliability of the results of surface surveys and the preservation of archaeological deposits  
42 (Martinez del Pozo & Mayoral Herrera, 2013). For the relative flat bottom-valley site of *Potentia*  
43 the currently still most common method of topographic survey with total station and DGPS  
44 proved to be of enough relevance, even if recently available LiDAR data for the area adds a new  
45 dimension to the results (see below). For sites with more relevant micro-topography and lying in  
46 a more undulating and expressive topographic environment, such as *Trea*, our excellent and  
47 repeated aerial photography allowed for the production of relevant photogrammetric DEM’s  
48 (Verhoeven, Loenders, Vermeulen, & Docter, 2009).

1  
2  
3 Of the same order of importance, but still somewhat undervalued in many field projects is the  
4 insertion of a series of geoarchaeological field operations, which specifically target the deeper  
5 palaeo-morphology and a better understanding of the sometimes deeply buried archaeology.  
6  
7 Apart from the already mentioned resistivity surveys, which have been very useful to reveal  
8 palaeo-channels of the River Potenza and the palaeo-coastline near the colony city of *Potentia*,  
9 especially the use of manual augerings seems adapted for fully integrated ground-truthing of  
10 much relevant data from non-invasive survey operations and landscape observations. For the  
11 augering survey hand auger equipment of Eijkelkamp (7 cm diameter) was used, consisting of an  
12 Edelman auger, stony soil auger, spiral auger, soft soil auger, riverside auger, stone catcher,  
13 handles, extension rods and bayonet connections. The applied auger depends on the dominant  
14 texture of the sediment; in perfect soil conditions the maximum achievable depth of the hand  
15 auger is around 15 meters (Berendsen, 2005). The different soil layers were described based on  
16 the texture, color, compaction, boundary characteristics and presence of archaeological material.  
17 In what follows we will elaborate a bit more on these geomatic and geomorphological field  
18 techniques, which need a constant dialogue between the geoscientists and the archaeologists in  
19 the field.

### 26 3. THE URBAN AND WESTERN SUBURBAN SETTING OF *POTENTIA*

#### 27 3.1 City Layout

28  
29  
30  
31  
32 The site of *Potentia*, situated in the south of the present town of Porto Recanati at a distance of 100  
33 m from the Adriatic coastline, was discovered in the 1940s. In the following decades several small-  
34 scale excavations were performed in and around the town, but it was only in the frame of the PVS-  
35 project that the Roman colony and the relation with its environment were fully investigated and a  
36 detailed plan of the town was obtained (Vermeulen & Verhoeven, 2006). Remote sensing analysis,  
37 based on oblique aerial, vertical aerial and satellite images, was achieved from 2000 onwards. Part  
38 of the obtained images revealed crop and soil marks indicating subsurface archaeological features  
39 such as the street network, town walls and traces of large buildings (Vermeulen, Monsieur, et al.,  
40 2005; Vermeulen & Verhoeven, 2006). In addition, several campaigns of grid field walking were  
41 done for qualitative and quantitative data acquisition of the subsurface archaeological features  
42 (Vermeulen, De Dapper, et al., 2009).  
43  
44  
45  
46

47  
48 In 2004 and 2005, large scale geophysical surveys were executed to locate the subsurface  
49 archaeological relicts detected by remote sensing analysis and grid walking and to identify more  
50 details about the city layout (Vermeulen & Verhoeven, 2006). The positive NNW-SSE oriented  
51 anomalies of the magnetic surveys could easily be interpreted as parts of the street grid. A  
52 rectangular anomaly in the center of the town, bordered by many linear anomalies, represents the  
53 forum square with surrounding shops (*tabernae*), a portico and several large public buildings,  
54 including a Late Republican sanctuary found by previous excavations. In addition, positive  
55 anomalies of the city walls and two gates (west and south) could be defined (Vermeulen,  
56  
57  
58  
59  
60

1  
2  
3 Monsieur, et al., 2009; Vermeulen & Verhoeven, 2006) (Figure 2). The magnetic survey was  
4 combined with the complementary resistivity technique to gain more information about the  
5 nature of the magnetic anomalies. In this way, the street pattern with housing blocks (*insulae*) of  
6 different sizes and several monumental buildings could be identified (Vermeulen & Verhoeven,  
7 2006). To verify the presence of the western gate assumed by the remote sensing and geophysical  
8 surveys, and to uncover its construction and relation with the surrounding area, an excavation  
9 was executed between 2007 and 2010 (Vermeulen, De Dapper, et al., 2009; Vermeulen et al.,  
10 2011; Vermeulen, Monsieur, et al., 2009).

### 3.2 Topographic Setting of the Urban Area

For the detection of micro-topographical features, a series of total station measurements were taken during field campaigns between 2005 and 2007, and a Digital Elevation Model (hereafter DEM) was created (Vermeulen & Verhoeven, 2006). The DEM (Figure 3a) shows a slightly higher position of the town, which is due to the presence of an ancient beach ridge on which the town had settled since it offered protection against flooding. At that time, the ancient river course ran immediately south of the city wall, as was well shown by a series of geoarchaeological operations (Goethals, De Dapper, & Vermeulen, 2009). During the post-Roman period, the beach ridge was cut in the southeast by the Potenza river channel. This phenomenon is mainly visible on the LiDAR DEM (Figure 3b). It was also present on remote sensing images and could be verified by hand augerings and geoelectrical resistivity profiles. The forum square in the center of *Potentia* (Figure 3a and b, black box) appears to be lower than the other parts of the town. This and other micro-topographical differences are more visible in the DEM obtained from total station measurements than in the LiDAR DEM. It can also be observed that the area west of *Potentia* lies more or less at the same height as the town center. Hand augerings showed this is mainly due to the deposition of clayey and silty sediments during flooding in the 14<sup>th</sup> and 15<sup>th</sup> century AD. Hence, this area was lower and more sensitive to flooding in Roman times (Goethals et al., 2009).

**Figure 3** Digital Elevation Model (DEM) of *Potentia* based on micro-topographical measurements from the PVS-campaigns (a) and the DEM of LiDAR data from the Italian Ministry of Environment, created in 2009 (b).

The geomorphological evolution of the area is very efficiently defined by hand augering (HA), a rather simple and inexpensive technique. The deepest layer could be reached by the use of many extension rods and represented a beach deposit on which the beach ridge was formed (see below Figure 6, hand augering 1). The formation of this beach ridge must have occurred between 1500 and 300 BC and was a consequence of the deforestation during the Bronze and Iron Age (circa 2200-300 BC), which caused a higher sediment load in the Potenza river (Coltorti, 1989, 1997). The beach ridge has a steep seaward and more gentle landward slope. Several augerings were carried out to reconstruct the landward slope of the beach ridge on top of which the Roman town

of *Potentia* was built (boreholes 1, 9, 14 and 18) (Vermeulen et al., 2013). Based on augerings 9, 14 and 18 (Figure 4), the inland slope of the beach ridge could be calculated. From augering 9 to 14, the landward slope is 2.2 %. The beach ridge created a natural barrier inducing the formation of a lagoon behind the ridge. In time, sedimentation took place transforming the area during the first centuries of Roman occupation (circa 200 BC – 200 AD) from a marshy to dryer area with seasonal floods. This phenomenon was testified by thinly laminated silty sediments. The upper sedimentological units consist of alluvial material from post-Roman periods. The aggradation of the topsoil was stimulated by increasing deforestation for agriculture and cattle raising during the late and post-medieval period causing an increased erosion on the surrounding hillslopes (Coltorti, 1991; Goethals, De Dapper, & Vermeulen, 2005).

### 3.3 Subsurface Archaeological Features in the Western Suburbium

Additional crop and soil marks were detected outside the formerly walled area on oblique aerial photographs and satellite images during the campaigns from 2004 to 2012. These traces revealed the presence of three Roman roads entering *Potentia* at its northern, western and southern gates. The road coming from Rome and entering the town in the west is the *decumanus maximus* of the town. *Extra Muros*, this road connected *Potentia* with its regularly divided field system (*centuriatio*) in the valley bottom and with the nearby inland Roman town of *Ricina* (Vermeulen et al., 2009). Crop marks of subsurface structures along both sides of this road are visible on the images. These structures are interpreted as Roman funerary monuments based on former excavations and research along the north-south oriented coastal road (*cardo maximus extra muros*) leaving *Potentia* from the northern and southern gates, and by the presence of a still standing funerary monument along the *decumanus maximus extra muros* (hereafter *dmem*) at the site of Torraccio (Figure 2), about 500 m west of the western gate (Vermeulen, De Dapper, et al., 2012; Vermeulen, De Dapper, et al., 2009; Vermeulen & Verhoeven, 2006).

To achieve more detailed information about the extension of the funerary area and to locate and map the sub-surface archaeological relicts, a geomagnetic survey was done in this western sector (Vermeulen, De Dapper, et al., 2012; Vermeulen, De Dapper, et al., 2009). This survey detected 250 m long linear traces of the *dmem*, before they are blurred by the presence of buried metal pipes causing large dipole anomalies (Figure 4, yellow zone ). Along both sides of the road, small, positive magnetic anomalies were detected, which coincide with the crop marks from the aerial images and thus most likely represent archaeological relicts (Figure 4, blue marks). In addition, anomalies of modern structures and of a geological or geomorphological nature occurred (Vermeulen, De Dapper, et al., 2012).

**Figure 4** Results and interpretation of the geomagnetic surveys (2012-2013) by Eastern Atlas and the location of the hand augerings (2013).

Consequently, geoelectrical resistivity surveys were conducted to understand the subsurface structures in depth, which is not possible with geomagnetic surveys (Vermeulen et al., 2013). A

1  
2  
3 south-north oriented resistivity transect of 74.25 m long, crossing the *dmem* around 45 m, was  
4 laid out (Figure 4, white line). The resulting 2D-profile reveals vertical and lateral variations,  
5 which are related to the impact of archaeological structures near the surface and to the difference  
6 in type of sediments (Figure 5). The relatively high resistivity values, higher than 20  $\Omega$ m,  
7 correspond with Roman structures and are spread over a zone in the profile of 39 to 57 m.  
8 Another high resistivity area is present around 59 to 60 m. Underneath the topsoil, a highly  
9 conductive layer with a depth around 2 m could be identified, which indicate a clayey soil with  
10 highly conductive groundwater such as brackish water or salt water intrusions (Vermeulen et al.,  
11 2013). The third applied geophysical technique was the Ground Penetrating Radar (GPR) survey  
12 during the 2013 campaign. This method creates 3D images and served to obtain complementary  
13 information on the earlier detected magnetic anomalies (Vermeulen, De Dapper, et al., 2009).  
14 However, the results were limited since only the *dmem* could be detected at an estimated depth of  
15 55-60 cm. No archaeological monuments were visible on the 3D images, which may be due to the  
16 high clay content of the soil and/or the depth of the funerary structures (Vermeulen et al., 2013).  
17 Hand augerings showed an average depth of 1 m for most archaeological structures.

18  
19  
20  
21  
22  
23  
24  
25 **Figure 5** 2D-profile of the resistivity transect crossing the Roman road (*dmem*), executed by Eastern Atlas (2013),  
26 and location of the hand augerings.

27  
28 A total of 23 augerings in the western *suburbium* of *Potentia* were carried out in the 2012 and 2013  
29 campaigns of the PVS-project. During 2013, a NNW-SSE transect of 13 augerings, perpendicular  
30 to the Roman *dmem*, was set out to verify the Roman road and its subsurface structure, and to  
31 gather historical and archaeological landscape information. This transect largely coincides with  
32 the resistivity transect in order to combine the stratigraphy from the resistivity imaging with soil  
33 samples. The location of some of these hand augerings was also based on anomalies detected by  
34 the geophysical surveys. The presence of the Roman road was verified at a depth of 50 to 64 cm  
35 below the surface. Moreover, three positive magnetic anomalies were identified as archaeological  
36 structures (see numbered pink circles in Figure 4). In the first anomaly (Figure 4, HA 21)  
37 archaeological material is present from a depth of 205 cm, in the second from 100 cm deep  
38 onwards (Figure 6, HA 3) and in the augerings performed on the location of the third magnetic  
39 anomaly, from 90 to 115 cm. The archaeological layer consisted of brick fragments, mortar,  
40 sandstone, charcoal and ceramics. The ceramics in these layers were studied by P. Monsieur and  
41 could be attributed to the Roman period. It cannot, however, be stated with complete certainty  
42 that these subsurface structures are funerary monuments but based on the aerial photographs and  
43 the funerary relict in the landscape this may be reasonably assumed (Vermeulen et al., 2013).  
44 Based on these results, other slightly positive magnetic anomalies along the *dmem* are also  
45 interpreted as archaeological anomalies (see dark blue marks in Figure 4).  
46  
47  
48  
49  
50  
51  
52

53  
54 The second objective of hand augering was obtaining more insight in the construction of the road  
55 and of the raised platform on which it was likely built. The center of this platform lies near HA 1  
56 and 5, where it has a maximum thickness of 100 cm (Figure 6). The platform had a width of at  
57 least 7 m and was constructed with flattened, elongated and rounded gravel, which indicates the  
58  
59  
60

1  
2  
3 use of beach ridge material. The augerings contained several fragments of ceramics; the ones  
4 from augering 21 (located at a magnetic anomaly) can be dated in the Late Republican and/or  
5 Early Imperial Age (ca. 180 BC – 40 AD), coinciding with the first two centuries of life at  
6 *Potentia*. Ceramics found at a depth of 310 cm in augering 22 are possibly Protohistoric, but a  
7 finer dating in the Bronze or Iron age cannot be obtained (Pincé, 2013).  
8  
9

10  
11 The results of the resistivity survey can be compared with the hand augerings to explain the  
12 differences in conductivity visible on the 2D-profile. The highly resistant features between 43 to  
13 52 are clearly related to the Roman road (*dmem*) and the relatively high resistivity spot around 60  
14 m, coinciding with augering 10, consists of an anthropogenic layer from 85 to 130 cm  
15 (Vermeulen et al., 2013). The anomaly from the magnetic survey that could be verified in  
16 augering 3 (Figure 6) is not visible in the resistivity model. The highly conductive layer at a  
17 depth from 1 to 3 m coincides with clayey silt sediments (Vermeulen et al., 2013).  
18

### 25 **3.4 Coastal and Fluvial Changes in the *Suburbium***

26  
27

28 Coastal and fluvial alternations were predominant in this landscape during ancient times. These  
29 environmental changes had implications on the town since it influenced the location of the  
30 harbor, the extension of the city towards the east and the orientation and form of the Roman street  
31 grid. Moreover, it affects the usability of the applied techniques (Goethals et al., 2009). To  
32 elucidate the environmental situation in parts of the town's *suburbium*, the combination of aerial  
33 photography analysis, geomorphological fieldwork, geoelectrical resistivity surveys and hand  
34 augerings was suitable (Goethals et al., 2009; Vermeulen & Verhoeven, 2006). Based on the  
35 integration of these techniques, the river diversions of the Potenza and the coastline progression  
36 since Roman times could be reconstructed.  
37  
38  
39

40  
41 During the Roman period, the Potenza channel was located directly south of the colonial town of  
42 *Potentia*, flowing in the middle of the valley and under the Casa dell' Arco bridge (Goethals et al.,  
43 2009; Vermeulen, 2003; Vermeulen, Monsieur, et al., 2005; Verreyke, 2007 p. 155-157) (Figure 2).  
44 Radiocarbon datings showed the Potenza followed this course until the 14<sup>th</sup> century AD. However,  
45 the location of the estuary probably changed in the Early Middle Ages to the southeastern corner of  
46 *Potentia*, which possibly contributed to the final abandonment of the town area. It must also have  
47 erased the presumed structures of a small river mouth port located near the southern gate. From the  
48 14<sup>th</sup> to the 16<sup>th</sup> century AD, the Potenza changed its courses several times, as well by natural as by  
49 man-made causes, gradually filling the valley plain with a thick veneer of alluvial sediment. Even  
50 with a more stabilized river course at the northern edge of the plain since early modern times,  
51 regular floods continued to shape the more and more flattish valley bottom near the coast  
52 (Vermeulen, Monsieur, et al., 2005; Verreyke, 2007 p. 157).

#### 4. INTRA-MURAL AUGERINGS AT *TREA*

##### 4.1 The Site and its Investigation

The site of the Roman urban settlement of *Trea* is situated on a plateau 1 km northwest of modern Treia, in the middle valley of the Potenza river. The plateau, situated 308 m a.s.l. and 70-80 m above the present-day valley bottom, is part of a Middle-Pleistocene alluvial terrace composed of a thick layer of gravel with alternating thin layers of silt and clay. The site offers several benefits: a wide view over the river plain, defence due to the elevation and the steep slopes partly bordering the rims and an excellent drainage thanks to the gravel content of its soil. Moreover, a nearby source located at the footslope of the uphill provides a permanent water supply. Due to the loose sedimentary characteristics of the superficial geological formations, the area is suitable for agriculture. As a consequence, however, the soil is also vulnerable for landslides and erosion (Costantini, Urbano, & L'Abate, 2004). Except for the monastery of SS. Crocifisso and a couple of rural houses, the plateau is nowadays fully used for agriculture. From the 16<sup>th</sup> century onwards, *Trea* was studied by various interested parties. In 1812, F. Benigni published a report on his 'excavations', which meant a first breakthrough in the investigations of the city (Moscatelli, 1988). In the 1970s the University of Marcerata based their research on vertical aerial photography and topographical studies and in the 1980s the same university excavated some parts of the plateau under supervision of G. M. Fabrin. These studies made it possible to obtain a preliminary understanding of the town (Marengo, 2000; Vermeulen, Slapšak, et al., 2012). It was only in 2003 that the town could be mapped in detail, thanks to the exceptionally clear crop marks on the oblique aerial images taken during the PVS-project (Vermeulen & Verhoeven, 2006). In 2007, geophysical prospections, based on the previous results and the new aerial photographs, were carried out in the frame of the PVS-project especially focusing on the central town area (Vermeulen, De Dapper, et al., 2009). The geoelectrical resistivity method revealed many buried stone structures and other human made anomalies. By using the magnetic method with an induced type of magnetization, an even wider range of remains was detected such as structures of brick and tile, kilns and hearths. The combined results of these measurements made it possible to enhance the archaeological interpretation and to distinguish stone built structures from brick ones. In addition, an extensive Ground Penetrating Radar (GPR) survey was tried in 2013, but the terrain conditions at *Trea* were not favourable; because of the high percentage of clay in the soil the results of the GPR survey were blurred. Next to these remote sensing techniques and geophysical measurements, intensive artifact surveys were carried out during several field campaigns to further improve qualitative and chronological detail (Vermeulen, De Dapper, et al., 2009). Everything included, these now established approaches of urban survey created an excellent documentation of a small Roman town, which was fully provided with an impressive forum and series of public buildings, a basic street grid, a full defence system with gates and towers, areas of intra-mural housing and commercial zones since its municipalisation of around 50 BC (Figure 7). Most of these urban structures could now be mapped, and even some data on transformations of the urban space through time were obtained without excavation.

1  
2  
3 **Figure 7** Interpretation of city layout based on remote sensing analyses and geophysical prospections. The dotted  
4 lines are less certain interpretations.  
5

6 To verify these non-invasive techniques even further, a geoarchaeological augering survey was done  
7 during the PVS-campaign of 2013 based on the results of previous investigations. This survey  
8 provides a better context for the suggested archaeological interpretations of the previous work. In  
9 addition, information was obtained about the state of conservation of the archaeological materials  
10 and an insight into the on-site geomorphology of the Roman town was acquired.  
11  
12

#### 13 **4.2 Results of the Augering Campaign**

14  
15

16 The intra-mural area of the site was divided into six zones of interest and 54 hand augerings were  
17 conducted (Figure 8). In what follows, the relationship between the different prospection results and  
18 the most remarkable results will be described (Weekers, 2015). This comprises first the specific  
19 archaeological results and second a series of results regarding the geomorphology of the site.  
20  
21

22 **Figure 8** Orthophoto based on oblique low altitude photography over the abandoned town site of *Trea*, showing a  
23 multitude of crop marks that reveal urban structures. The locations of the hand augerings are indicated.  
24

25 The monumental center of the site was investigated by a transect of 18 augerings (Figure 8, zone 1).  
26 On the aerial photographs and geoelectrical data, the forum square is clearly distinguishable but the  
27 augerings could not prove the existence of any remnants of a large pavement. The percentage  
28 archaeological material in these samples was not exceptional and the preservation depth underneath  
29 the square is approximately 1 m, which is not remarkably deeper than in any other area of the site.  
30 Most probably the paving of the square has disappeared as the result of spoliation after the  
31 abandonment of the town, but we cannot exclude that the plaza never received a stone paving, as  
32 was not unusual in smaller towns. The crop marks south of the forum square are less clear in  
33 comparison to the ones at the northern border. Despite this, the augerings attested a thick layer of  
34 preserved material with an outstanding number of mosaics. The zone north of the forum seems to be  
35 build in more massive/permanent building materials such as limestone, sandstone and gravel. This  
36 can explain the better visibility of the cropmarks north of the square. Noteworthy are the two  
37 structures in the northwestern corner of the forum, because they are not visible on the geomagnetic  
38 data (Figure 9b). The augering survey could confirm these structures must mainly consist of gravel-  
39 based foundations, which would explain their absence on the magnetic image.  
40  
41  
42  
43  
44  
45

46 **Figure 9** Detailed mapping of (a) aerial photography, (b) geomagnetic and (c) geoelectrical resistivity data with hand  
47 augering locations in the northwestern part of the forum area. (d) Augering profiles with gravel based foundations.  
48

49 The study of the archaeological material recovered from these soil samples dates predominantly in  
50 the 1<sup>st</sup> and 2<sup>th</sup> century AD. However, in the zone south of the square twelve coins were found 60 cm  
51 beneath the surface, which can be dated in the Late Antique period (4<sup>th</sup> – 5<sup>th</sup> century AD). Another  
52 remarkable fact is that in the zone south of the forum and underneath the *basilica* Republican  
53 material was discovered in some augerings at a depth of approximately 1 m. The existence of  
54 differently orientated structures in this area, visible on the aerial images (Figure 8, hatched zone),  
55 could also be related to this (possibly older) material. These Republican fragments might indicate an  
56  
57  
58  
59  
60

1  
2  
3 older occupation layer, and therefore an earlier phase of urbanization in this part of the settlement.  
4 The results of the on-going C-14 analyses of the charcoal fragments could shed some more light on  
5 this important chronological issue.  
6

7  
8 Until now, there is no proof of the existence of preserved prehistoric occupation layers at *Trea*.  
9 This does not exclude the presence of prehistoric occupation, as suggested by the new finds, but  
10 further research is necessary. A Republican building phase prior to the construction of the mainly  
11 Early Imperial monuments must be confirmed, corroborating the hypothesis of an older  
12 habitation layer predating the monumental forum phase.  
13  
14

15  
16 In the zone west of the forum complex (Figure 8, zone 3) seven augerings were executed, which all  
17 attest that the archaeological layer in this area is quite well preserved. For instance, the presence of  
18 the *basilica* on the western short side of the forum square is not only clearly visible on the aerial  
19 images and in geoelectric and magnetic data, but this suggested preservation quality can now also be  
20 confirmed (Vermeulen, Monsieur, et al., 2005) through the augering survey. In addition, the area east  
21 of the monumental center is quite well known thanks to the prospection images and is interpreted as  
22 a zone dominated by wealthy houses of the *domus*-type. The four augerings conducted in this area  
23 confirm the quite good conservation of the remains and prove the impenetrable characteristics of the  
24 soil due to the presence of archaeological material.  
25  
26  
27  
28

29 In the northwestern corner of the town (Figure 8, zone 4), the magnetic survey results show a few  
30 very visible anomalies (Figure 10b). In the sample of the augering (HA 49), metal slag and some  
31 overfired tiles were recognised, which might relate to the existence of kilns or other strongly burnt  
32 materials in this zone. The northern edge of the plateau is bordered by an elongated irregular  
33 cropmark visible on the aerial photographs (Figure 8). The geophysical prospection did not extend  
34 until this edge so further examination of this anomaly was done by augering at two different  
35 locations (Figure 8, zone 2 and 4). The sediment profiles did prove this cropmark to be strictly  
36 natural and it can now be seen as part of the Pleistocene river terrace. No traces of levelling or  
37 modelling of the plateau by the Romans could be recognised in these soil profiles, which of course  
38 does not exclude a landscape modification elsewhere in the town.  
39  
40  
41  
42

43 **Figure 10** Detailed mapping of (a) aerial photography, (b) geomagnetic and (c) geoelectrical resistivity data with  
44 hand augering locations in the northwestern part of the intra-mural town area.  
45

46 Next to the study of the archaeological traces and material, the augerings could also provide insight  
47 in the (geomorphological) degradation of the site. The edges of the site seem to be quite vulnerable  
48 to erosion. In the north (Figure 8, zone 2) a steep slope of 10 % was attested, which can indicate  
49 slope erosion. It can be noted that the concentration of archaeological material<sup>1</sup> at the edges of the  
50 town only amounts 0.5 %, where in the center of the site an average of 5 % was attested.  
51  
52  
53

54 At the northwestern border of the site (zone 4), the effect of slope erosion is less distinct, the slope  
55 gradient is only 2 %, but the percentage of archaeological material is also quite low. Augering 48  
56

57  
58 <sup>1</sup> These percentages are measured by weighing the archaeological material in each sample.  
59  
60

(Figure 10) can be seen as an exception: in this sample much material was found (at least until a depth of 190 cm) dating from the Bronze / Iron Age (2200-300 BC) to the Late Antique / Early Middle Ages. It is very probable that this context must be interpreted as a waste deposit, instead of a colluvial layer.

The northeastern corner of the site (Figure 8, zone 6) is clearly disturbed. The aerial photographs are empty of cropmarks (Figure 11a) and the traces on the geophysical images are very disordered (Figure 11b and 4c). A transect of augerings was carried out to investigate this difficult interpretable area (Figure 12). The study of the soil profiles points to the presence of a landslide. In this zone the plough layer is succeeded by a very clayey impervious layer (HA 38, 39, 36 and 34), which prevents water infiltration and quickly ensues top soil saturation after heavy or prolonged rainfall. In case of steep slopes (here 11 %) the right conditions for landsliding, a quite common geomorphological process in this hilly region of Italy, are present (Costantini et al., 2004). The soil profile clearly shows the occurrence of erosion and the accumulation of archaeological material downhill. Augering 37 shows an exceptionally thick layer (2.1 m) with archaeological material, the low percentage (1 %) and the mixed nature of the material confirmed the colluvial characteristics. It is likely that in this sector erosion took place on a higher level.

**Figure 11** Detailed mapping of (a) aerial photography, (b) geomagnetic and (c) geoelectrical resistivity data with hand augering locations in the northeastern part of the intra-mural town area.

**Figure 12** Hand augering profile showing possible landslide

## 5. CONCLUSION

It is particularly clear from recent research in many parts of the Roman Mediterranean world that non-invasive survey is crucial in the process of revealing and studying ancient urban contexts. Especially when this type of archaeological detection can be continued over a span of several years, making good use of the diversity of seasons and methods. The case studies presented here show very distinctly the need for geoarchaeological approaches if we want to deal with the sometimes very high stratigraphic complexity of the surveyed urban sites and the very dynamic landscapes they are part of. In-site geoarchaeological analysis first and foremost focuses on the genesis of the archaeological sites, which are the formation processes on the scale of the sites themselves and on the factors leading to the fossilization, preservation or reworking of the archaeological remains (Rapp & Hill, 1998). It is thus complementary with the purely archaeological, traditional stratigraphic approach. It allows to establish the origin of the archaeological sediment and their evolution by highlighting what is linked with the anthropogenic, cultural and bio-pedological processes as well as the geological depositional (sedimentary) and/or post-depositional factors, which are so important in abandoned Roman towns sites.

Both presented case studies illustrate very well the need for complementing now already established ways of non-invasive archaeological survey with a more in-depth geoarchaeological

1  
2  
3 strategy. The remote sensing and geophysical techniques were very useful to uncover new data  
4 about subsurface archaeological features in and around the city of *Potentia* and about coastal and  
5 fluvial changes. However, the implementation of hand augerings appeared to be vital for the  
6 study of depositional environments such as those of the lower Potenza valley and for the  
7 verification of geophysical and remote sensing results. Moreover, this method allowed an insight  
8 in the dynamic processes of the urban landscape through time. The spatial resolution of these  
9 augerings was in function of the research questions and the results of other non-invasive  
10 techniques. More augerings could have been useful to verify other magnetic anomalies. However,  
11 the augerings were strategically chosen in order to achieve a thoughtful interpretation of these  
12 anomalies. The geoarchaeological techniques are combined with artifact studies, grid field  
13 walking, study of historical sources and excavations to elucidate the settlement history of  
14 *Potentia* and its relationship with the surrounding landscape. It must be stressed that the  
15 implementation of these geoarchaeological survey methods was mainly possible here thanks to  
16 the largely agricultural function of the area today. However, the increasing coastal tourism in and  
17 around Porto Recanati exerts huge pressure on the area of the former Roman town and its  
18 *suburbium*. To meet the needs of the tourists, a new commercial complex was recently planned in  
19 the southern *suburbium*, which would partly destroy the Roman estuary of the Potenza, the  
20 possible harbor and many other buried, archaeological structures and traces. However, our  
21 archaeological research prevented these destructive interventions, making way for a wider  
22 protection of the ancient site and its buffering landscape. The use of non-destructive,  
23 interdisciplinary techniques for the study of the former urban area is thus important for heritage  
24 management since, based on their results, guidelines for urban planning can now be established  
25 here.  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35

36 The case study of the abandoned urban site of *Trea* shows well that intensive and focused  
37 augering survey is a useful tool in a detailed non-invasive study of former intra-mural areas and  
38 their landscape transformations. Firstly, the depth of the preserved archaeological strata and  
39 structures can be quite accurately estimated, without costly excavation work. In *Trea*, the  
40 archaeological layer has a thickness of approximately 1 m, with the exception of some particular  
41 zones where the material only reaches a depth of 30 cm. These results demonstrate the  
42 importance of the technique for focused archaeological heritage management. The amplification  
43 of modern agriculture at *Trea* and the unawareness of the wider public about this 'hidden'  
44 archaeological patrimony are a direct threat to the archaeological record. Modern agricultural  
45 activities can harm the archaeological record and may lead to the fading or disappearance of the  
46 temporarily visible cropmarks and the archaeological layer. The intensification of agriculture will  
47 also cause an increase of tillage erosion, especially at the steepest borders of the plateau. To  
48 recommend the required measures for heritage management, augerings are an efficient tool.  
49 Furthermore, it is clear that the material in the augering sequences allows better insight in  
50 previous occupation layers than offered by simple surface control. The augering survey allowed  
51 also to verify the nature of many cropmarks and to explain the characteristics of certain  
52 anomalies. In addition, the relation between different prospection images could now be clarified  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 based on the material in the soil samples. The study of post-depositional processes provides an  
4 important insight in the degradation and preservation of a site. It can be noted that erosion  
5 processes caused an accumulation of colluvium downhill; the steeper the slope the more material  
6 is accumulated. Furthermore, the augerings in the northeast sector of the site point to a landslide,  
7 to be confirmed by further research. Based on these results, it can be stated that the chosen  
8 frequency of the augerings on the site was appropriate.  
9  
10

11  
12 Both study cases demonstrated that the integrated mapping of buried urban structures also needs  
13 to be undertaken at different levels, i.e. at different scales, ranges of precision and with variety in  
14 the depiction of interpreted detail. Only with a better comprehension of the current and the buried  
15 geomorphology of the site can non-invasive survey evidence, such as from aerial archaeology or  
16 geophysical prospection data, reveal their full potential for the archaeology of former (and  
17 current) urban contexts. Today, still only very few non-invasive survey projects based on aerial  
18 photography and systematic geophysical prospections involve regular observation of soil profiles  
19 as a means of direct calibration and control (Jordan, 2013). Also the objective evaluation of soil  
20 moisture is rarely undertaken at such instances while, especially for aerial photography results  
21 but also for certain geophysical methods (e.g. GPR and earth resistance survey), this kind of  
22 information is crucial. As it is now clear that no prospection method detects all archaeological  
23 remains under all circumstances, we need to understand more fully the structure and behavior of  
24 remains and their environments. Together with a better assessment of the depth, nature and  
25 preservation of the archaeological structures, the combination of an air photograph or geophysical  
26 prospection image with the more systematic use of the auger-hole (and possibly the soil test-pit),  
27 holds the promise for substantial advances in geoarchaeological understanding of urban  
28 archaeological landscape  
29
