# California's Carbon Market and Energy Prices: A Wavelet Analysis

Luís Aguiar-Conraria\*      Maria Joana Soares†      Rita Sousa‡

December 18, 2017

## Abstract

Carbon price is a key variable in management and risk decisions in activities related to the burning of fossil fuels. Different major players in this market, such as polluters, regulators, and financial actors have different time horizons. Using innovative multivariate wavelet analysis tools, including partial wavelet coherency and partial wavelet gain, we study the link between carbon prices and final energy prices in the time and frequency dimensions in California's carbon market, officially known as the California cap-and-trade program. We find that gasoline prices lead an anti-phase relation with carbon prices. This result is very stable at lower frequencies (close to one-year period cycles), and it is also present before mid-2015 in the 20 ~ 34 weeks frequency-band. Regarding electricity, we find that at about 1 year frequencies, a rise in carbon prices is reflected in higher electricity prices. We conclude that the first five years of compliance of the California cap-and-trade program supports the idea that emissions' trading is a significant measure for climate change mitigation, with visible rising carbon prices. The quantitative financial analytics we present here supports the continuation of the program after 2020.

**Keywords:** Multivariate wavelet analysis; partial wavelet gain; partial wavelet coherency; carbon market; energy prices; California ETS.

# 1 Introduction

In the current economic context with climate change concerns, variations of energy prices, and numerous emission trading schemes that have multiplied around the world, there is an urge to develop quantitative tools to model and understand the origins of variations in carbon prices and its effects in energy prices. Information on the movement of these variables has operational and political implications highly relevant to the main players in the market: polluters, regulators, and financial actors. While the latter are mostly interested in knowing daily connections between commodities prices, the polluting industries and regulators are also interested in longer cycles tendencies.

Previous work on carbon prices proliferated after 2008 and focused on the European Emission Trading Scheme (EU ETS). Studies of the Californian ETS were mostly concerned with market design features; [1, 2, 3, 4, 5]. The exceptions are Bushnell [6], and Sousa and Aguiar-Conraria [7], who looked into the impact on daily electricity prices.

This paper adds two critical perspectives to the current research on carbon price dynamics. First, we study the California carbon market, a recent example. Second, we study relations between variables in cycles of different periodicities.

The emission trading scheme in California is one of the World's latest emerging greenhouse gas (GHG) markets, created under the Assembly Bill 32 (AB32), as intended by the Western Climate Initiative (WCI), signed in 2007. It is operational since 2012, and it is an important instrument to meet the goal of reaching the state's 1990 GHG levels by 2020. The California market has significant structural differences from the EU ETS that should allow to control previously encountered EU market misconceptions. Namely, volatility of prices and overallocation are dealt with cost containment mechanisms, which include a price floor, for auctions, and an allowance price containment reserve. There is another relevant difference between EU ETS and the California ETS features, which regards the sectors included. The California program includes electricity importers, and, since 2015 (second phase), also road sector transport activities, such as suppliers of natural gas, fuel oil, LPG and gasoline. In Europe, GHG emissions from road transport activities are controlled by other carbon pricing

mechanisms.

Whereas there has been extensive research on carbon prices, built mainly on data from Europe, we present an analysis of the California Carbon Allowances (CCA), representing one metric ton of CO<sub>2</sub> equivalent, and their relation to final energy consumers, after 2014, when Québec joined the Californian market.

The above-mentioned second critical perspective, brought by this work, concerns the methodology, where we rely on multivariate continuous wavelet analysis, to understand how carbon and energy prices relate at different cycle lengths.

Initial studies on carbon prices mostly explained the price or volatility of one variable in terms of others. They used Granger causality method to find unidirectional relations between pairs of variables, including daily carbon and energy prices; [8, 9]. More recently, new studies consider effects between variables — also daily energy and carbon prices — but in both directions. They include vector auto-regressive studies, with multivariate analysis, and estimate impulse-response functions that show the daily impact of innovations of a variable, namely carbon; [10, 11, 12, 13, 14]. Other carbon price issues, such as volatility, risk-premia and forecasting, have lately been the focus of attention; e.g [15] and [16].

Following previous studies, we relate CO<sub>2</sub> prices to final energy prices, electricity and gasoline, which connect final consumers to the carbon cost. These are critical variables for carbon markets that include both electricity and transport sectors.

In line with [17], we rely on multivariate wavelet analysis (MWA) and work in the time-frequency domain, estimating how carbon price relationships behave at different frequencies and how they evolve over time. We chose to work with MWA mainly for two reasons. First, it has been shown that energy price dynamics is strongly non-stationary and so it is important to use methods that do not require stationarity; [18]. Second, we note that decisions of market regulators include long term plans, and also, decisions of investment and management strategy in power and transport supply, on a large scale, are neither easy nor quick. Therefore, from both angles, it makes sense to consider the presence of short and long-term decisions, meaning that these relations should be studied simultaneously at different frequencies. This can be easily done with wavelet analysis. The papers [19, 20, 21, 22, 23]

have already relied on wavelets to study the evolution of energy prices, including oil, gasoline, natural gas, biofuels and other commodities. To the best of our knowledge, specifically about carbon markets, the only previous work performed in the time-frequency domain is [17].

The paper proceeds as follows. Section 2 provides a description of the methodology. Section 3 describes our data and the Californian Carbon market. Section 4 contains our empirical results. Finally, Section 5 concludes and discusses some policy implications of our findings.

## 2 Continuous Wavelet Analysis

### 2.1 Continuous wavelet transform

Time-scale wavelets are characterized in reference to a mother wavelet,  $\psi(t)$ , a function of a real variable  $t$ . For a function to qualify to be a mother wavelet it has to satisfy a certain admissibility condition which, in practice, amounts to requiring that the function integrates to zero and also has fast decay towards zero. The fact that  $\psi$  tends quickly to zero means that we can view it as a window function; on the other hand, demanding that  $\psi$  integrates to zero implies that  $\psi$  must be oscillatory, enabling us to associate a certain frequency to this function.

The mother wavelet  $\psi$  provides a source function for generating a family of daughter wavelets,  $\psi_{\tau,s}$ ; these functions are obtained from the mother by performing two operations, scaling by  $s$  and translation by  $\tau$ :

$$\psi_{\tau,s}(t) = \frac{1}{\sqrt{|s|}} \psi\left(\frac{t-\tau}{s}\right), \quad s, \tau \in \mathbb{R}, s \neq 0.^1$$

The scaling parameter  $s$  controls the width of the wavelet and the translation parameter  $\tau$  controls the location of the wavelet along the  $t$ -axis. For  $|s| > 1$ , the windows  $\psi_{\tau,s}$  become larger (hence, correspond to functions with lower frequency) and for  $|s| < 1$ , the windows become narrower (hence, become functions with higher frequency).

Given a time series  $x(t)$ , its *continuous wavelet transform* with respect to the wavelet  $\psi$

is a function of two variables,  $W_x(\tau, s)$ , given by

$$W_x(\tau, s) = \int_{-\infty}^{\infty} x(t) \overline{\psi}_{\tau,s}(t) dt = \frac{1}{\sqrt{|s|}} \int_{-\infty}^{\infty} \overline{\psi}\left(\frac{t-\tau}{s}\right) dt.$$

In the above formula and throughout the paper the over-bar is used to denote complex conjugation.

The specific wavelet we use in this paper is a complex-valued function selected from the so-called *Morlet wavelet* family, first introduced in [24],

$$\psi_{\omega_0}(t) = \pi^{-\frac{1}{4}} e^{i\omega_0 t} e^{-\frac{t^2}{2}},$$

and corresponds to the particular choice of  $\omega_0 = 6$ . Although, strictly speaking, the above function is not a true wavelet, since it has no zero mean, for sufficiently large  $\omega_0$ , namely for the value used in this paper,  $\omega_0 = 6$ , for numerical purposes it can be considered as a wavelet; see [25] and also [26] for some properties of this wavelet which justify our choice.

**Remark 1** *As for the wavelet transform, all the wavelet quantities we are going to introduce below are functions of two variables, time ( $\tau$ ) and scale ( $s$ ). To simplify the notation, we will describe these quantities for a specific value ( $\tau, s$ ) of the argument which will be omitted from the formulas.*

## 2.2 Univariate wavelet tools

In analogy with the terminology used in the Fourier case, the (local) *wavelet power spectrum* of series  $x(t)$ , denoted by  $(WPS)_x$ , is defined as

$$(WPS)_x = W_x \overline{W_x} = |W_x|^2.$$

The wavelet power spectrum (sometimes called *scalogram* or *wavelet periodogram*) gives us a measure of the variance distribution of the time-series in the time-scale (time-frequency) plane.

When the wavelet  $\psi(t)$  is chosen as a complex-valued function, as in our case, the wavelet transform  $W_x$  is also complex-valued and, therefore, it can be separated into its real part,  $\Re(W_x)$ , and imaginary part,  $\Im(W_x)$ ; alternatively, the transform can be expressed in polar form as

$$W_x = |W_x| e^{i\phi_x}, \quad \phi_x \in (-\pi, \pi].$$

The angle  $\phi_x$  is known as the (*wavelet*) *phase*.<sup>2</sup> For real-valued wavelet functions, the imaginary part is zero and the phase is undefined. Therefore, to separate the phase and amplitude information of a time-series, it is necessary to use complex wavelets.

### 2.3 Bivariate wavelet tools

In many applications, one is interested in detecting and quantifying the time-frequency relations between two non-stationary time series. Generalizations of the wavelet tools, appropriate for this purpose, are now briefly described; for more details, the reader is referred to e.g. [26].

Given two time-series,  $y(t)$  and  $x(t)$ , we define their *cross-wavelet transform* (or *cross-spectrum*),  $W_{yx}$ , by

$$W_{yx} = W_y \overline{W_x} \tag{1}$$

where  $W_y$  and  $W_x$  are the wavelet transforms of  $y$  and  $x$ , respectively. The absolute value of the cross-wavelet transform,  $|W_{yx}|$ , will be referred to as the *cross-wavelet power*.

We also define the *complex wavelet coherency* of  $y$  and  $x$ ,  $\rho_{yx}$ , by

$$\rho_{yx} = \frac{S(W_{yx})}{\sqrt{S(|W_y|^2)} \sqrt{S(|W_x|^2)}},$$

where  $S$  denotes a smoothing operator in both time and scale.<sup>3</sup> For notational simplicity, we will denote by  $S_{yx}$  the smoothed cross-wavelet transform of two series  $y$  and  $x$  and also

---

<sup>2</sup>Recall that the phase-angle  $\phi_x$  of the complex number  $W_x$  can be obtained from the formula:  $\tan(\phi_x) = \frac{\Im(W_x)}{\Re(W_x)}$ , using the information on the signs of  $\Re(W_x)$  and  $\Im(W_x)$  to determine to which quadrant the angle belongs to.

<sup>3</sup>As in the Fourier case, smoothing is necessary, otherwise the magnitude of coherency would be identically one.

use  $\sigma_y$  and  $\sigma_x$  to denote, respectively,  $\sqrt{S(|W_y|^2)} = \sqrt{S_{yy}}$  and  $\sqrt{S(|W_x|^2)} = \sqrt{S_{xx}}$ . With these notations, the formula for the complex coherency is written simply as

$$\varrho_{yx} = \frac{S_{yx}}{\sigma_y \sigma_x}.$$

By analogy with the Fourier case, we define the *wavelet coherency*,  $R_{yx}$ , of two series  $y$  and  $x$ , as the absolute value of their complex wavelet coherency, i.e.

$$R_{xy} = \frac{|S_{xy}|}{\sigma_x \sigma_y}.$$

With a complex-valued wavelet, we can compute the wavelet phases of both series and, by computing their difference, we are able obtain information about the possible delays of the oscillations of the two series, as a function of time and frequency. It follows immediately from (1) that the phase-difference, which we will denote by  $\phi_{yx}$ , can also be computed simply as the phase-angle of the cross-wavelet transform. The obtained values for the phase-difference may be interpreted as follows. If  $\phi_{yx} = 0$ , then the series are totally in phase, while if  $\phi_{yx} = \pi$ , the series show a total anti-phase relationship; if  $\phi_{yx}$  lies between 0 and  $\pi/2$ , then the series are in-phase, but the variable  $y$  leads  $x$ ; if  $\phi_{yx}$  is between  $-\pi/2$  and 0, the series are also in-phase, with  $x$  leading; when  $\phi_{yx}$  is between  $-\pi$  and  $-\pi/2$  or between  $\pi/2$  and  $\pi$ , the series show in anti-phase relation and, in the first case,  $y$  leads  $x$ , while in the second case, is  $x$  which leads.

**Remark 2** *The wavelet-phase difference is sometimes defined as the phase-angle of the complex wavelet coherency; although this is not fully consistent with the difference between the individual phases, since it is affected by the smoothing, the results obtained are not substantially different; this alternative definition has the advantage of being simpler to generalize to the multivariate case.*

Finally, we define the *complex wavelet gain* of  $y$  over  $x$ , denoted by  $\mathcal{G}_{yx}$ , by

$$\mathcal{G}_{yx} = \frac{S_{yx}}{S_{xx}} = \varrho_{yx} \frac{\sigma_y}{\sigma_x}$$

and, following Mandler and Scharnagl in [27], we define the *wavelet gain* of  $y$  over  $x$ , which we denote by  $G_{yx}$ , as the modulus of  $\mathcal{G}_{yx}$ . Recalling the interpretation of the Fourier gain as the modulus of the regression coefficient of  $y$  on  $x$  at a given frequency (see, e.g. [28]), it is perfectly natural to interpret the wavelet gain of  $y$  over  $x$  as the modulus of the regression coefficient in the regression of  $y$  on  $x$ , at each time and frequency.

## 2.4 Multivariate wavelet tools

Some wavelet tools specially designed to use when more than two series are involved, namely the so-called partial wavelet coherency and partial phase-difference are also available; see, e.g. [29] for the case of three series and [26] for the more general case. More recently, in [30], the authors introduced the concept of partial wavelet gain, a generalization the wavelet gain for the case of more than two variables. Here, we will only display the formulas for the case of three variables, which are the ones we use in this paper. For the other cases, the reader is referred to the appendices of the aforementioned references [26] and [30].

Given a series  $y(t)$  and two other series  $x(t)$  and  $z(t)$ , the *squared multiple wavelet coherency* between the series  $y(t)$  and the other two series, denoted by  $R_{y(xz)}^2$ , is given by

$$R_{y(xz)}^2 = \frac{R_{yx}^2 + R_{yz}^2 - 2\Re(\varrho_{yx} \varrho_{xz} \overline{\varrho_{yz}})}{1 - R_{xz}^2},$$

and *multiple wavelet coherency*  $R_{y(xz)}$  is defined as the positive square root of the above quantity.

The *complex partial wavelet coherency* between  $y$  and  $x$  after controlling for  $z$ , denoted by  $\varrho_{yx.z}$ , is the quantity given by

$$\varrho_{yx.z} = \frac{\varrho_{yx} - \varrho_{yz} \overline{\varrho_{xz}}}{\sqrt{(1 - R_{yz}^2)(1 - R_{xz}^2)}}.$$

The *partial wavelet coherency* of  $y$  and  $x$  after controlling for  $z$ , denoted by  $R_{yx.z}$ , is simply the absolute value of the complex partial wavelet coherency, and the *partial phase-difference* of  $y$  over  $x$ , given  $z$ , denoted by  $\phi_{yx.z}$ , is the phase-angle of  $\varrho_{yx.z}$ .

The *complex partial wavelet gain* of  $y$  over  $x$  after controlling for  $z$ , denoted by  $\mathcal{G}_{yx.z}$ , is given by

$$\mathcal{G}_{yx.z} = \frac{\varrho_{yx} - \varrho_{yz}\overline{\varrho_{xz}}}{1 - R_{xz}^2} \frac{\sigma_y}{\sigma_x},$$

and the *partial wavelet gain* of  $y$  over  $x$  after controlling for  $z$ , denoted by  $G_{yx.z}$ , is simply the absolute value of  $\mathcal{G}_{yx.z}$ . The partial wavelet gain  $G_{yx.z}$  can be interpreted as the coefficient (in modulus) in the multiple linear regression of  $y$  in the explanatory variables  $x, z$ , at each time and frequency.

## 2.5 Statistical significance

Naturally, it is important to assess the statistical significance of the computed wavelet measures. Torrence and Compo, in their influential paper [31], were among the first authors to discuss this issue. Based on a large number of Monte Carlo simulations, Torrence and Compo concluded that the wavelet power spectrum of a white or red noise process, normalized by the variance of the time-series, is well approximated by a chi-squared distribution. This problem was reconsidered more recently by Zhang and Moore in [32]. For the specific case of the use of a wavelet  $\psi_{\omega_0}$  from the Morlet family, Zhang and Moore established, analytically, that the wavelet power spectrum of a Gaussian white noise with variance  $\sigma^2$  is distributed as

$$|W_x|^2 \curvearrowright \frac{\sigma^2}{2}(1 + e^{-\omega_0^2})X_1^2 + \frac{\sigma^2}{2}(1 - e^{-\omega_0^2})X_2^2,$$

where  $X_1$  and  $X_2$  are independent standard Gaussian distributions. In the case of a Morlet wavelet with parameter  $\omega_0 > 5$ , we have  $e^{-\omega_0^2} \approx 0$ , and so we obtain  $\left| \frac{W_x^2}{\sigma^2} \right| \curvearrowright \frac{1}{2}\chi_2^2$ , confirming, for this specific type of wavelet and particular underlying process, the result obtained by Torrence and Compo. To assess the significance of the wavelet power spectrum we will rely on this theoretical distribution.

References [33, 34, 35] have some important theoretical results on significance testing for the wavelet coherency. The results, however, are for specific ways of smoothing (namely in the time domain only) and do not apply directly to our case. To our knowledge, no work has

been done on significance testing for the partial wavelet coherency. All our significance tests are obtained using surrogates. We fit an ARMA(1,1) model to the series and construct new samples by drawing errors from a Gaussian distribution with a variance equal to that of the estimated error terms. For each time-series (or set of time-series) we perform the exercise 5000 times, and then extract the critical values at 5% and 10% significance.

Related to the phase-difference (or partial phase-difference), there are no good statistical tests. This is so because it is very difficult to define the null hypothesis. In fact, Ge, in [33], argues that one should not use significance tests for the phase-difference. Instead, one should complement its analysis by inspecting coherency, and only focus on phase-differences whose corresponding coherency is statistically significant. The same kind of procedure should be used when interpreting the gain (or partial gain).

### **3 The carbon market in California and our data**

The California cap-and-trade system, called California ETS for simplification, took effect in early 2012 and is linked to Québec's since January 2014. The first period occurred between 2012-2014, with compliance since 2013; the second compliance period started in 2015, and lasts until 2017, including distributors of transportation fuels, natural gas, and other fuels; and finally 2018-2020 will cover the third period. Currently, prospects for post-2020 and linkage to Mexico's carbon pricing are being considered.

California is one of the largest economies in the world. On energy information, the state has a consumption of 7,676 trillion BTU (2015), producing internally around 2,353 trillion BTU of primary energy (crude oil and natural gas account for 49% and 11%, 8% from nuclear electric power and 31% for renewables).<sup>4</sup> California's electricity system generates more than 290 TWh per year. The installed capacity shares in 2016 included approximately 54% natural gas, 18% hydroelectric, 25% other renewables, 3% nuclear. In fact, California produces 70% of the electricity it uses. The remaining amount is imported.<sup>5</sup>

The California challenge on electricity under AB32 is to secure supply with 33% of renew-

---

<sup>4</sup>All energy data and further statistics are available at the Energy Information Association ([www.eia.gov](http://www.eia.gov)).

<sup>5</sup>All electricity data was retrieved from the California Energy Almanac ([www.energy.ca.gov](http://www.energy.ca.gov)).

able sources, while reducing greenhouse gases (GHG) emissions. California has an emission goal of 427 MMTCO<sub>2</sub>e (million metric tonnes of CO<sub>2</sub> equivalent) in 2020, i.e. equalling 1990 estimated emissions, and aims to an 80% reduction in 2050 below 1990 levels. In 2015, California emitted of a total of 440 MMTCO<sub>2</sub>e, from which 39% originates in transportation, 23% from industrial sources and 19% from electricity generation (8% imported plus 11% in state).<sup>6</sup>

California Carbon Allowances, or CCAs, each corresponding to one tonne of CO<sub>2</sub> equivalent, are traded in the Intercontinental Futures Exchange US (The ICE Futures US), a leading trade for commodity markets. Currently, traded products are CCAs Vintage Futures for 2017, and corresponding options on futures, available as product number 6747558 at The ICE.<sup>7</sup> Monthly contract sets for the current year plus 3 years.

An important difference between the California Cap-and-Trade Program and the European Emission Trading Scheme (EU ETS) regards the inclusion of importers of electricity from out of state (through its primary energy source mix), and of distributors of transportation fuels, natural gas, and other fuels, that do not exist in Europe. All other CA trading sectors are, in their essence, energy intensive and/or high emission sectors, such as the EU sectors. Sectors included in the carbon trading since 2013 are: first deliverers of electricity (in-state and imported) and large industrial facilities (such as petroleum refineries; crude petroleum and natural gas extraction; cement; industrial gas; mineral mining and lime; fruit and vegetable canning; glass; paper; dairies; iron, steel, and aluminium; chemical, biological, and pharmaceutical; breweries, wineries, and juice). Distributors of transportation fuels, natural gas, and other fuels are also included since 2015. Sousa and Aguiar-Conraria [7] and the International Carbon Action Partnership ([icapcarbonaction.com](http://icapcarbonaction.com)) provide further comparisons between the EU ETS and the CA ETS.

Considering the above-mentioned CA ETS fundamentals and other previous work on European CO<sub>2</sub> prices causality, namely, [8, 10, 36, 14, 39, 38, 37], our model considers three variables associated to the energy and carbon markets in California: CO<sub>2</sub> (CCA), electricity,

<sup>7</sup>[www.theice.com](http://www.theice.com).

and gasoline prices.

On carbon prices, we use the available series on the CCA Future Vintage for each year released by Climate Policy Initiative S. Francisco of The ICE data at the California Carbon Dashboard program. Data in Figure 1 includes 1452 observations, starting in 2014. The average value was of 12.93 US\$ per CCA, reaching a maximum level of 15.43 US\$ and a minimum of 11.66 US\$. The bottom limit on US\$ axis is intentionally 10 US\$, representing the minimum CCA value at auctions.

Figure 1: California carbon prices, 2014/2017 (Data source: The ICE, retrieved from CPI, California Carbon Dashboard)

The California cap-and-trade program covers nearly 600 emitting facilities, responsible for 85% of CA emissions. Phase one included electric utilities and large industrial facilities that emit more than 25 MtCO<sub>2</sub>/year, and, in phase two, distributors of transportation, natural gas and other fuels were added. We include in this category representative final energy prices, namely electricity and gasoline prices, to analyse the connection from carbon to final consumers.

Regarding the electricity variable, we considered the wholesale day ahead price of SP15 EZ Generation Hub, located in California. Data source is The ICE exchange.<sup>8</sup> Prices are in US\$/MWh and were included from 02/01/2014 to 24/10/2017. Gasoline prices regard the Los Angeles Reformulated RBOB Regular Gasoline Spot Price, also available at the US EIA information page, in Dollars per Gallon.<sup>9</sup>

<sup>8</sup>Retrieved from the US Energy Information Association (EIA) information page for ten major electricity trading hubs in USA ([www.eia.gov/electricity](http://www.eia.gov/electricity)).

<sup>9</sup>[www.eia.gov/petroleum](http://www.eia.gov/petroleum).

Figure 2: California selected energy prices, 2014/2017 (On the left axis we refer to gasoline and the right axis refers to electricity prices. Data sources: US EIA.)

## 4 Our Results

In Figure 3, we do a preliminary analysis with our data. On the left, we plot the monthly returns of CCA, and the monthly rate of price increases of electricity and gasoline. On the right, we plot the wavelet power spectra. Our data is weekly and runs from the beginning of 2014 until the 42<sup>nd</sup> week of 2017 (mid-October).<sup>10</sup>

The wavelet power indicates, for each moment and frequency, the intensity of the variance of the time-series for each frequency of cyclical oscillations. In the plots of the wavelet power, the black conic line identifies the region (usually referred to as the cone-of-influence — COI) where edge effects — unavoidable artefacts appearing when computing the continuous wavelet transform for a finite series — are important; outside this line, the results should be interpreted with caution; see, e.g. [26] for more details. The degree of variability is distinguished by a colour spectrum, ranging from dark blue (low variability) to red (high variability). The white lines in the power spectra indicate local maxima. The black contours signify 5% significance levels, while the grey contours represent 10% significance level. These were computed using the already referred theoretical distribution for the power, assuming a flat spectrum as the null.

<sup>10</sup>Instead of working with daily data, we use weekly averages.

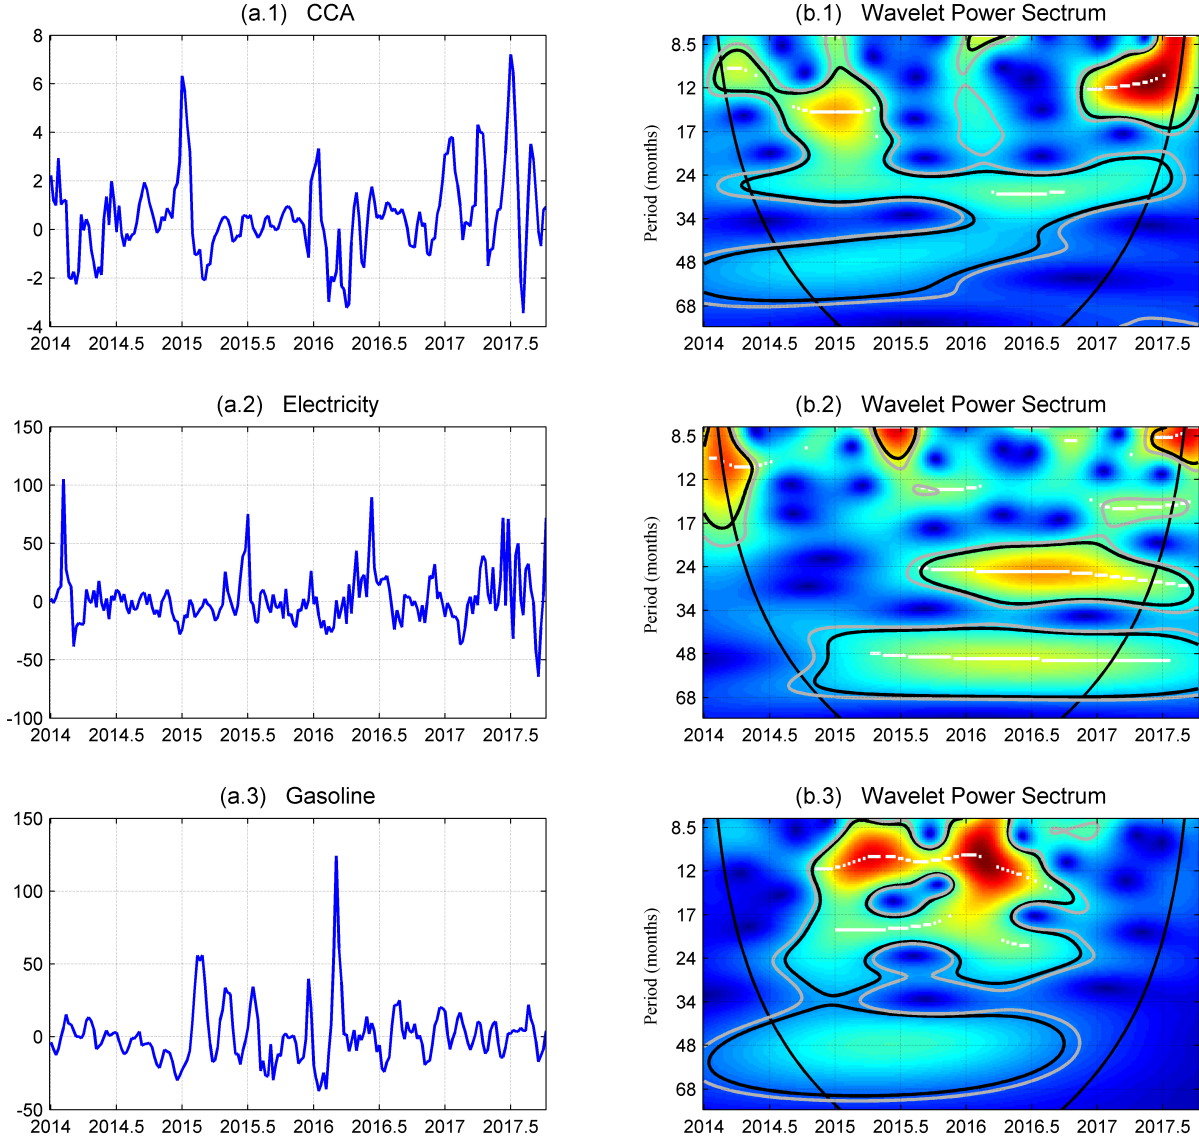

Figure 3: (a) Plot of the monthly rate of return of each time-series. (b) The wavelet power spectrum. The black/gray contour designates the 5%/10% significance level. The cone-of-influence, which is the region affected by edge effects, is indicated with a black line. The color code for power ranges from blue (low power) to red (high power). The white lines show the maxima of the undulations of the wavelet power spectrum.

In the case of carbon prices, the volatility is spread across the sample, but it is stronger at higher frequencies. The red regions correspond to cycles of period smaller than 17 weeks.

It is interesting to note that in the case of electricity prices there are two dominant cycles that coexist at the same time. One cycle has 24 week (about half-year) period and it became apparent in the second half of 2015. There is also a 1-year cycle that appeared in the beginning of 2015.

Finally, in the case of gasoline, most of the volatility is concentrated in the middle of the

sample, between late 2014 and late 2016, especially at high frequencies. However, even for longer frequencies, the wavelet power spectrum is still statistically significant.

Figure 4: Wavelet Multiple Coherency between CO<sub>2</sub> and energy (electricity and gasoline) prices. The black/gray contour designates the 5%/10% significance level. The color code for coherency ranges from blue (low coherency—close to zero) to red (high coherency—close to one).

Based on the preliminary analysis of the wavelet power spectra, it is difficult to discern any inter-relations between these markets. Figure 4 helps us on this task and tell us when and at which frequencies are these inter-relations the strongest. We estimate the multiple coherency between CO<sub>2</sub> and the other two variables, electricity and gasoline. There are no relevant regions of high coherency after 2017. Until then, we identify three main regions with statistically significant coherency. The most important one is located at low frequencies (corresponding to cycles of about one year periodicity) and runs from the beginning of the sample until the third quarter of 2016. In the 20 ~ 34 week frequency-band, there are two regions of statistically significant coherence. One runs from 2014 until the third quarter of 2015. The other, smaller, occurs near mid-2016. Multiple coherency tell us how important strong is the relation between energy prices (electricity and gasoline) and CO<sub>2</sub>. However, just with that information one cannot differentiate the impact of both variables. For that purpose, one must rely on the partial coherency, which we do next.

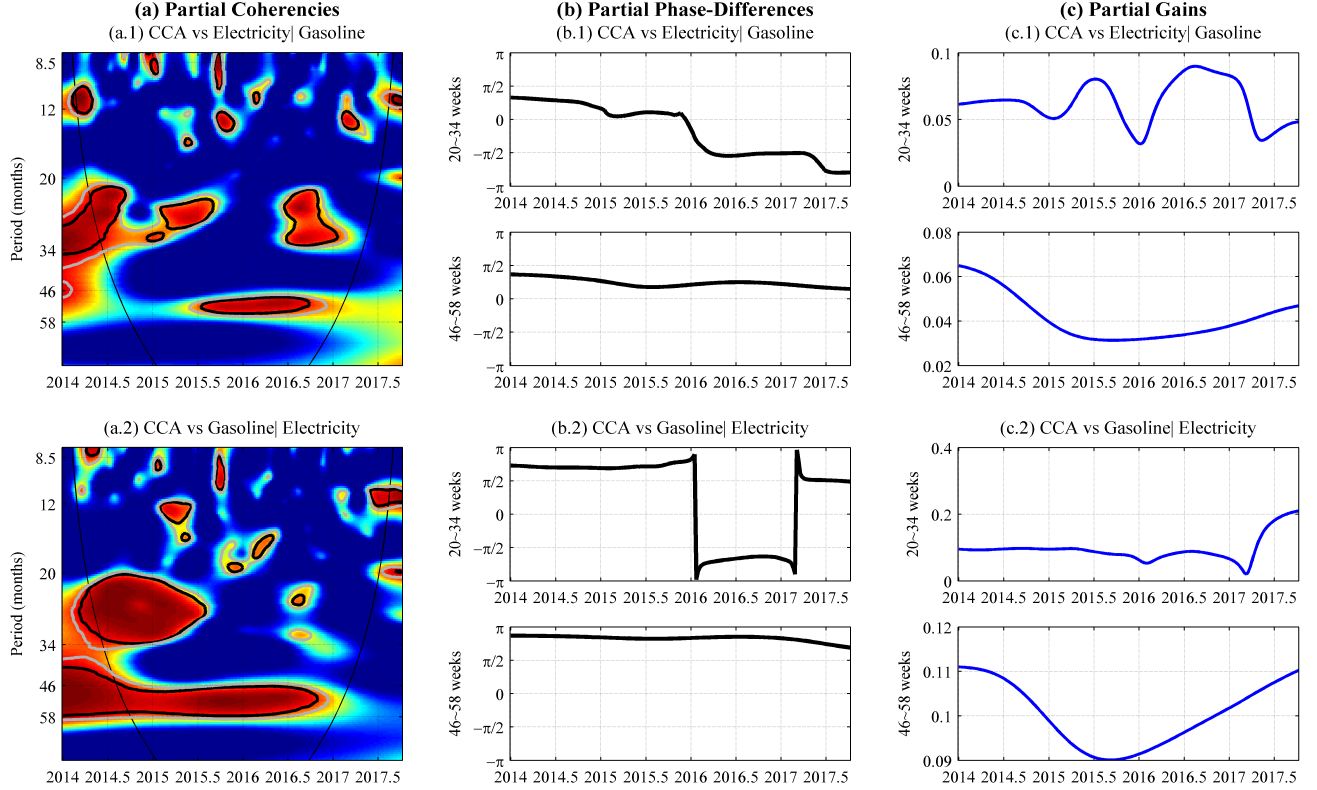

Figure 5: **On the left** – partial wavelet coherence between carbon prices and electricity (top) or gasoline (bottom) prices. The black/gray contour designates the 5%/10% significance level. The color code for coherence ranges from blue (low coherence – close to zero) to red (high coherence – close to one). **In the middle** – partial phase-differences. **On the right** – partial wavelet gain.

In Figure 5, we have our most important set of results. We estimate the partial coherence between  $\text{CO}_2$  prices and each of the energy variables (after controlling for the other), the partial phase difference, and the partial wavelet gain, which will give us information about the magnitude of the impact that a shock in one variable will have on the other.

To facilitate the presentation, we display the mean values for the phase-differences and partial gains corresponding to the two considered frequency bands, namely for cycles of period  $20 \sim 34$  weeks and  $46 \sim 58$  weeks. For the phase-differences, which are measured on a circular scale, the mean is computed as a circular mean, which is the appropriate notion of mean in this case; see, e.g. [40].

In the top of Figure 5, we have the partial coherence between  $\text{CO}_2$  price returns and electricity. There are three important regions of high coherence that overlap with the high coherencies estimated in Figure 4. The first one is located in the  $20 \sim 34$  week frequency-band, and runs from the beginning of the sample until the third quarter of 2015 (in some

areas, it is significant only at 10%). The second is located at lower frequencies (46 ~ 58 week period) and runs from mid-2015 until the end of 2016. In both regions, the phase-difference is between 0 and  $\pi/2$  showing that price returns of both variables are in-phase with CO<sub>2</sub> leading. Finally, there is a third region, again at higher frequencies (in the 20 ~ 34 week frequency-band, to be more precise) in the second half of 2016. In that region, the phase difference is between  $-\pi$  and  $-\pi/2$ . This means that, at this frequency, changes in the CO<sub>2</sub> prices still lead changes in electricity, however the relation is now negative. This result illustrates one of the main advantages of using wavelets in Finance and Economics. Economists have always known that some relations are time-varying. With wavelets, now they can also estimate frequency varying relations.

In the bottom of Figure 5, it is interesting to note the impressive similarity between the partial wavelet coherency of CO<sub>2</sub> and Gasoline and the picture of the multiple wavelet coherency. The two main statistically significant regions that we found in Figure 4 can also be seen in Figure 5.a.2. In those regions of high partial coherency, the partial phase-difference between CO<sub>2</sub> and Gasoline is between  $\pi/2$  and  $\pi$ , suggesting an anti-phase relation with the gasoline prices leading. Economically, that means that, at these frequencies, an increase in the gasoline price is followed by a decrease in CO<sub>2</sub> prices in the financial markets. The partial gain is very stable at both frequency bands, with a value close to 0.1 about twice as large as the partial gain between CO<sub>2</sub> and electricity.

## 5 Concluding remarks and policy implications

In this paper, we presented an analysis of the carbon prices in the California emission market. After describing the main market features, we studied the interaction between carbon prices and final energy prices, gasoline and electricity.

We applied multivariate wavelet analysis (MWA) tools, including the partial wavelet coherency with the purpose of analysing the relation between the various prices at different frequencies, and the partial wavelet gain to assess the magnitude of such relation. Energy price dynamics is non-stationary, so it is important to use methods that do not require

stationarity. MWA tools allow studying cycles of different lengths. In particular, we note that, on the one hand, decisions of power supply investments, on a large scale, are neither easy nor quick, and on the other, regulators actions are also planned for the long-term. So, it makes sense to consider the presence of long-term decisions, or at lower frequencies, i.e., relations in longer temporal cycles. The results we obtain in MWA for lower frequencies are of particular relevance for the above-mentioned actors because they provide a perception of the annual relationships between decision variables.

Previous studies have shown that European carbon prices mostly reflect economic developments, and influence the price of final energy - electricity; [7] and [17]. In contrast, in California, we find the most important result in the relationship between gasoline prices and carbon, with gasoline leading an anti-phase relation. This result is very stable at lower frequencies (close to one-year period cycles), and it is also present before mid-2015 in the 20 ~ 34 weeks' frequency-band.

Regarding electricity, the results may reflect the low price elasticity of electricity in the short run, for a rise in carbon prices is only reflected in higher electricity prices within one year. Conversely, in the relationship between carbon and gasoline, it is the energy that leads the impact, and in the opposite direction, what happens until the middle of 2016, when gasoline prices stabilise at lower values. The reading is that the carbon market counterweights the reduction in prices of energies with high emission levels, such as gasoline, penalising them via carbon prices.

It is evident in the analysis that the weight of the emissions from the transport sector, together with the reduction in gasoline prices, had effects on the carbon price, which were stronger than the effects of the electricity prices in the carbon market. We recall that the transport sector corresponds to 39% of California's total emissions, versus 19% of electricity production and 23% of the industrial sector (2015 data, from the California Air Resources Board). This conclusion is confirmed in the results of multiple coherency and can be the reason for the rise of carbon prices in 2017. As a result, there will be pressure for consumers to seek less emitting products, and, thus, their production and distribution. A proposal to accommodate the results with less economic impacts would be to channel the licenses not

used by the power utilities to the fuels sector, an option that would not tamper with the overall environmental goal.

In conclusion, we suggest that the first five years of compliance of the California-Québec cap-and-trade program advocates emissions' trading as a significant measure for climate change mitigation, with visible rising carbon prices. The quantitative financial analytics we present here supports the development of the program with the considered sectors, in the post-2020.
