Nosocomial fungal bloodstream infections (BSI) are increasing significantly in hospitalized patients and *Candida parapsilosis* has emerged as an important pathogen responsible for numerous outbreaks. The objective of this study was to evaluate *C. parapsilosis sensu lato* infection scenarios, regarding species distribution and strain relatedness. One hundred isolates of *C. parapsilosis sensu lato* derived from blood cultures and catheter tips were analysed by multiplex microsatellite typing and by sequencing D1/D2 regions of the ribosomal DNA. Our results indicate that 9.5 % of patients presented infections due to *C. parapsilosis* and *Candida orthopsilosis,* 57.1 % due to *C. parapsilosis*, 28.3 % due to *C. orthopsilosis* and 4.8 % due to *Candida metapsilosis*. Eighty per cent of the *C. parapsilosis* BSIs were due to a single strain that was also identified in the catheter, but in 10 % of the cases *C. parasilosis* was identified in the catheter but the BSI was due to *C. orthopsilosis*. There is a significant probability that *C. parapsilosis* isolates collected from the same patient at more than 3 months interval are of different strains (P=0.0179). Moreover, several isolates were identified persistently in the same hospital, infecting six different patients. The incidence of polyfungal BSI infections with *C. parapsilosis* and *C. orthopsilosis* is reported herein for the first time, emphasizing the fact that the species identified in the catheter is not always responsible for the BSI, thus impacting the treatment strategy. The observation that strains can remain in the hospital environment for years highlights the possible existence of reservoirs and reinforces the need for accurate genotyping tools, such as the markers used for elucidating epidemiological associations and detecting outbreaks.

INTRODUCTION

The incidence of candidaemia continues to increase, particularly in hospitalized patients. Due to the substantial morbidity and mortality associated with these infections it is clear that fungal diseases have emerged as important public health problems (Pfaller & Diekema, 2007). While *Candida albicans* remains the most common causative agent of candidaemia, the incidence of *Candida parapsilosis* has increased significantly, outranking *C. albicans* in some studies, depending on the period and geographical area (Aittakorpi *et al.*, 2012; Lagrou *et al.*, 2007; Lockhart *et al.*, 2012; Maganti *et al.*, 2011; Nucci *et al.*, 2013; Parmeland *et al.*, 2013; Tragiannidis *et al.*, 2012; Wu *et al.*, 2011; Xess *et al.*, 2007). Candidaemia risk factors include the use of broad-spectrum antibiotics, cancer chemotherapy, immunosuppressive agents and indwelling medical devices (Tumbarello *et al.*, 2007). Nosocomial fungaemia due to *C. parapsilosis* is mainly associated with the presence of a central venous catheter, and with the use of parenteral nutrition (Barchiesi *et al.*, 2004). Although the primary reservoir in the hospital setting is unknown, *C. parapsilosis* carriage on the skin of healthy individuals, particularly on the hands of health care workers, and hospital environmental surfaces has been consistently observed (Lupetti *et al.*, 2002; Sabino *et al.*, 2011; Vaz *et al.*, 2011). Although frequently associated with neonates and the use of

The GenBank/EMBL/DDBJ accession numbers for the D1/D2 region of the 28S rRNA gene sequence of the isolates described in this study are KJ817066 to KJ817165.

parenteral nutrition (Dizbay *et al.*, 2008), *C. parapsilosis* has also been frequently identified in adult intensive care units, surgery and internal medicine departments (Diab-Elschahawi *et al.*, 2012). The discrimination of *C. parapsilosis* strains is fundamental not only for the rapid identification of the strains involved in the infection but also to clarify nosocomial cross-transmission and possible routes of transmission in hospital settings (van Asbeck *et al.*, 2009). Since the description of a microsatellite multiplex strategy for *C. parapsilosis* strain differentiation (Sabino *et al.*, 2010), this method has been applied in several studies mainly regarding outbreaks (Diab-Elschahawi *et al.*, 2012; Romeo *et al.*, 2013; Vaz *et al.*, 2011) and is described as the most discriminatory method for *C. parapsilosis* strain differentiation. Herein, we used this method to genotype presumed *C. parapsilosis* isolates involved in fungaemia episodes from three hospitals in Brazil and to determine the patterns of relatedness of the isolates, including the pair identified in the bloodstream/catheter.

METHODS

Strains. During the period August 2002 to April 2006 at Hospital dos Servidores do Estado (HSE), 76 strains were isolated from 42 patients and were identified as *C. parapsilosis sensu lato*. For comparison, an additional 20 strains from Hospital Universitário Pedro Ernesto (HUPE) isolated before the year 2000 were also studied, although no patient's information was available, as well as four isolates from Hospital Samaritano (SAM). In total, 100 isolates of *C. parapsilosis sensu lato* derived from blood cultures and catheter tips from patients admitted at three different hospitals in Rio de Janeiro, Brazil, between 1998 and 2006, were analysed (Table 1). These isolates were stored in 40 % (v/v) glycerol at −80 °C at the yeast stock collection of the Laboratório de Micologia do Instituto Nacional de Infectologia (INI) da Fundação Oswaldo Cruz (Fiocruz), Rio de Janeiro, Brazil.

Species identification. The isolates were phenotypically identified *as C. parapsilosis sensu lato* at the hospital of origin using VITEK 2 and API 20 C AUX systems (bioMérieux) following the manufacturer's instructions. Molecular identification at the species level was performed by sequencing the D1/D2 region of the 28S rRNA gene (Asadzadeh *et al.*, 2009). Sequences were edited with the Sequencer version 4.9 software package (Genes Codes Corporation), aligned with MEGA version 4.0.2 software and compared by BLAST with sequences available from NCBI GenBank.

Microsatellite multilocus PCR amplification and fragment size determination. Isolates identified as *C. parapsilosis* were further discriminated by multilocus microsatellite amplification. Cultures were grown at 30 °C for 2 days on YPD agar plates. Cells for colony PCR were prepared as described by Vaz *et al.* (2011). The primers, PCR amplification conditions and the allele size determination by GENESCAN (version 3.7) analysis after a run on an ABI PRISM 310 genetic analyser (Applied Biosystems) were as described previously (Sabino *et al.*, 2010) with some modifications as described by Vaz *et al.* (2011), namely the redesign of one primer. Fragment sizes were determined automatically using GENESCAN 3.5 analysis software. The discriminatory power (DP) of the method was calculated as described by Hunter & Gaston (1988).

Data analysis. A distance matrix was generated using the Cavalli-Sforza & Edwards method (Cavalli-Sforza & Edwards, 1967) with Populations software (version 1.2.28) and the dendrogram was constructed by the unweighted pair group method in NTSYSpc software (version 2.02; Applied Biostatistics). Categorical data were analysed using Fisher's exact test, unless stated in the text. Results were considered statistically significant when *P*-values were lower than 0.05.

RESULTS

Identification of *C. parapsilosis sensu lato* isolates and epidemiology

A total of 100 isolates from *C. parapsilosis sensu lato* fungaemia were analysed in this study. The majority of the isolates were derived from the HSE (76 %) while 20 % were derived from the HUPE and only 4 % from the SAM. Isolates included 83 from blood cultures and 17 from catheter tips (Table 1). Genotyping isolates with the microsatellite multiplex failed to amplify all markers in 39 isolates. Since this multiplex strategy is specific to *C. parapsilosis sensu stricto* (Sabino *et al.*, 2010), all the isolates were sequenced. Sequencing showed that 37 strains were *Candida orthopsilosis*, two were *Candida metapsilosis* and the remaining 61 were *C. parapsilosis* (Table 1). All sequences showed 100 % identity. The majority of the *C. orthopsilosis* isolates (29 isolates) derived from the HSE, while the eight isolates remaining were obtained from patients attending the HUPE. These isolates were obtained from 19 adult patients and seven children. All *C. metapsilosis* isolates were identified in patients from the HSE. Thus, considering all isolates, 61 % were *C. parapsilosis*, 37 % were *C. orthopsilosis* and 2 % were *C. metapsilosis*.

Considering only the isolates from the HSE, we determined that 57.1 % (24 from 42) of patients presented fungaemia due to *C. parapsilosis*, 28.6 % (12 from 42) due to *C. orthopsilosis* and 4.8 % (2 from 42) due to *C. metapsilosis*. Curiously, in the HSE *C. parapsilosis* and *C. orthopsilosis* were isolated from the same patient in 9.5 % (4 from 42) of patients. All cases of polyfungal infection were observed in male patients, but no significant difference ($P>0.05$) in species distribution was observed between the two sexes. Three of these polyfungal infections occurred in children and one in an adult patient. Likewise, no significant difference was observed ($P>0.05$) regarding species isolation considering the different years of isolation (from August 2002 to April 2006). It was not possible to perform these analyses with isolates from the HUPE since patient information was incomplete. All patients under 18 years old (nine children) were from the HUPE and 78 % were infected with *C. orthopsilosis* (Table 1).

Microsatellite multiplex genotyping of *C. parapsilosis* isolates

Genotyping of all *C. parapsilosis sensu stricto* isolates with the microsatellite markers identified 39 multilocus genotypes of which 24 were observed only once (Table 1). The most prevalent genotype, MG1, was found in five isolates

and was retrieved from two patients. Considering only independent isolates (the first *C. parapsilosis* strain isolated from each patient), the combined DP of the multiplex was 0.99, which is in agreement with previous studies (Diab-Elschahawi *et al.*, 2012; Sabino *et al.*, 2010). In this study, isolates with the same allelic combination at all microsatellite markers correspond to genetically similar strains and were defined as identical, while isolates with distinct allelic combinations at more than one locus correspond to genetically dissimilar strains and were considered different strains. The remaining cases, with minor changes in only one locus, were considered as micro-variations.

In order to analyse strain relatedness, the multiple isolates collected from the same patient were grouped (Table 2). First, we observed that 12 of these patients were infected exclusively with *C. parapsilosis*, five with *C. orthopsilosis* and four with both *C. parapsilosis* and *C. orthopsilosis*. These two species were isolated on the same day in all four patients except patient 11, so the majority of these infections may be considered polyfungic. Curiously, in patients infected only with *C. orthopsilosis* (patients 12, 17 and 35), this species was also isolated from the catheter; however, when *C. parapsilosis* was also present (patients 11, 13, 14 and 19) the species isolated from the catheter was always *C. parapsilosis*.

Analysing *C. parapsilosis* strain relatedness from patients with catheter and blood cultures isolates, we observed that five patients showed identical bloodstream and catheter strains (patients 6, 13, 18, 27 and 36), three showed micro-variations in the pair bloodstream/catheter strains (patients 33, 39 and 42) and two presented different strains (patients 11 and 27). If the identical and microvariant cases are grouped, 80 % of *C. parapsilosis* bloodstream/catheter pairs showed similar strains. Indeed, there is a statistical probability ($\chi^2=4.00$, $P=0.04$) that the strain observed in the catheter will also be present in the blood culture. However, when Yates' correction was applied this association was no longer significant ($\chi^2=1.78$, $P=0.18$). Although the cases of microvariation observed in this study were associated with the presence of a catheter, the isolation dates were the same so it was impossible to determine whether microvariation occurred in the catheter strain.

Regarding the relatedness of *C. parapsilosis* strains isolated at different collection dates, regardless of the presence or absence of a catheter in patients that maintained the infecting strain (patients 4, 6, 13, 18 and 44), the collection dates were always within 1 month (Table 2). On the contrary, in all cases in which a strain replacement was observed (patients 11, 27 and 29) the collection dates were always greater than 3 months. We observed that the probability of strain replacement within 3 to 6 months was statistically significant ($P=0.0179$), suggesting that in these infections *C. parapsilosis* strains were mainly acquired from the environment. One example was patient 11: a *C. parapsilosis*-positive catheter culture was collected on day 1 with no positive blood culture, in the following 2-month period two blood cultures were positive for *C. orthopsilosis* and a third blood culture was positive for a completely different *C. parapsilosis* strain; these two *C. parapsilosis* strains were collected 3 months apart. The presence of *C. orthopsilosis* (patients 11 and 13), did not affect this correlation.

Clustering of *C. parapsilosis* isolates

When strains were compared regardless of their origin, we observed that different patients shared similar strains (Fig. 1). Patient 6 presented a positive blood culture with isolate 057 and one month later the same strain was present in the catheter and again in the blood (Table 1). More than a month after this episode, patient 5, from the same hospital, was infected with a similar strain (001). Other patients from the same hospital, patients 14 and 11, also presented strains with the same multilocus genotype (MG-10), collected approximately 7 months apart (023 and 098). Similarly, patients 19 and 15 from the same hospital shared strains with MG-23 (010 and 025), collected almost 18 months apart (23 August 2004 and 1 February 2006). Curiously, patients 42 and 32, from different hospitals, also showed strains with the same multilocus genotype (MG-22; isolates 009 and 031) collected 5 months apart (6 September 2005 and 1 Febuary 2006). Interestingly, MG-22 and MG-23 differ only at locus CP4a and are considered microvariants. In addition, MG-24 observed in isolate 022 from patient 41 and MG-21 in isolate 030 from patient 42 may also be considered microvariants of MG-22 and MG-23 (Table 1). These observations suggest that isolates with multilocus genotypes similar to isolate 25 (MG-23), the first to be isolated, have been persistently isolated in hospital settings over the period August 2004 to February 2006, affecting six different patients (Fig. 1). Similar cases of micro-variation in different patients from the same hospital were observed: isolate 029 from patient 21 (MG-3) and one month later in isolate 032 from patient 30 (MG-2), and isolate 062 from patient 29 (MG-26) and 14 months later the microvariant MG-27 in isolate 085 from patient 18. Considering that the patients in this study are not related, we cannot exclude the hypothesis of cross-contamination of patients by the hands of healthcare personnel, as extensively reported in other studies (Lupetti *et al.*, 2002; Vaz *et al.*, 2011). Isolates 039 and 040 or 041 are also considered microvariants. However, due to the lack of information regarding patients' identity these may not be considered as possible cross-contaminants.

DISCUSSION

The incidence of *Candida* in bloodstream infections has been reported to be higher in Brazil than in the USA or Europe, where *C. parapsilosis* has now become, respectively, the second and third most common aetiological agent of these infections after *C. albicans* (Colombo *et al.*, 1999; Dizbay *et al.*, 2008; Hajjeh *et al.*, 2004). However, more recently some European regions, including southern

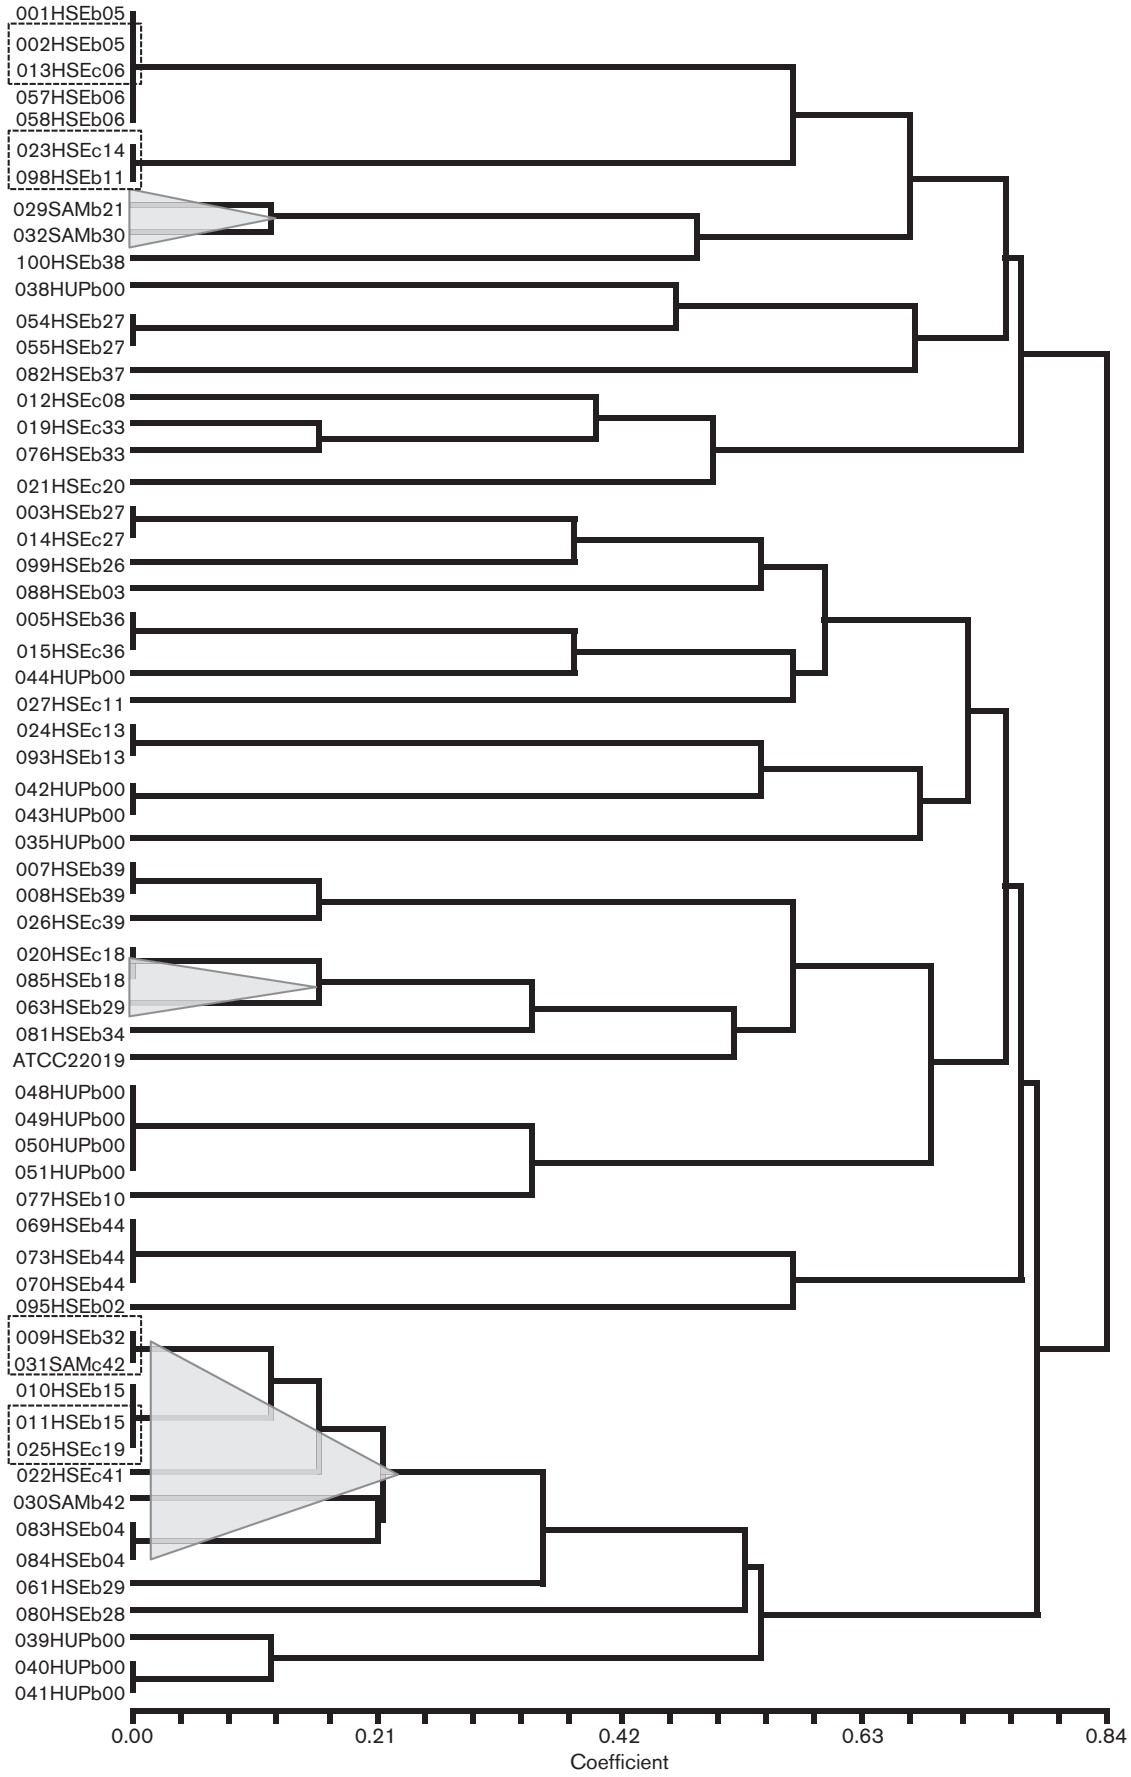

Fig. 1. Dendrogram showing relationships among 61 *Candida parapsilosis* isolates based on multilocus microsatellite genotypes. Dashed boxes represent strains from different patients sharing the same multilocus genotypes, and triangles represent microvariant strains from different patients. The isolates are represented by a code that includes the isolate number (000–100), followed by the hospital of origin (HSE, HUP or SAM), by the letter b (for blood) or c (for catheter), and finally the patient number (01–44; 00 denotes no information available).

Italy, have reported bloodstream incidences for *C. parapsilosis* infection of around 60 %, similar to those observed in Brazil (Delfino *et al.*, 2014). Moreover, the distribution of *C. orthopsilosis* and *C. metapsilosis* as agents of invasive infections has marked variability. In this study, we report an overall prevalence of 37 % for *C. orthopsilosis* and 2 % for *C. metapsilosis* among *C. parapsilosis sensu lato* isolates. The majority of the patients analysed in this study were from the HSE and in this hospital the incidence was 28.6 % for *C. orthopsilosis* and 4.8 % for *C. metapsilosis*. These values are higher than those described in a multi-centre surveillance study conducted in Brazil between 2003 and 2004 (*C. orthopsilosis* was 9 % and *C. metapsilosis* was 3 %; Gonçalves *et al.*, 2010), and those in a Spanish multi-centre study that reported 8.2 % of *C. orthopsilosis* and 1.1 % of *C. metapsilosis* (Cantón *et al.*, 2011). Our values are relatively similar to those recorded in a Spanish study in which 23.5 % of *C. orthopsilosis* and 2.1 % of *C. metapsilosis* were found (Garcia-Effron *et al.*, 2012). Nevertheless, it is known that the incidence of *C. parapsilosis sensu lato* infections varies according to multiple factors, such as the age and underlying disease of patients, geographical location of the hospitals studied and climatic and socio-economic conditions.

A significant finding of this study was the observation that the same patient can simultaneously have *C. parapsilosis* and *C. orthopsilosis*. Indeed in 9.5 % of patients from the HSE, both *C. parapsilosis* and *C. orthopsilosis* were isolated and only in one case were the two species isolated on different dates. To our knowledge, there are few studies reporting polyfungic infections involving *C. parapsilosis sensu lato* species, and none from systemic infections. It has previously been reported that in superficial infections, 7.5 % those that identified *C. parapsilosis* complex species were polyfungal (Feng *et al.*, 2012). However, all combined *C. parapsilosis* and *C. albicans* with *Candida tropicalis* or *Candida guilliermondii*. A previous study reported two cases of polyfungal infections (*C. albicans* and *Candida glabrata*) in 20 hospitalized patients with catheter-related candidaemia; however, none of the *C. parapsilosis* complex species was involved in polyfungal infections (Escribano *et al.*, 2014). It has been reported that polymicrobial BSIs are strongly associated with increased mortality (Kim *et al.*, 2013). Although there is no study to date regarding the survival of patients infected with *C. parapsilosis* and *C. orthopsilosis*, the identification of BSI due to more than one species is of extreme importance.

C. parapsilosis is notorious for the ability to form biofilms on catheters and other implanted devices (Tumbarello *et al.*, 2007), more so than the closely related species *C. orthopsilosis* and *C. metapsilosis* (Lattif *et al.*, 2010). This may explain why in all cases of polyfungal infection the species identified in the catheter was *C. parapsilosis* and never *C. orthopsilosis*. This was not due to the fact that *C. orthopsilosis* was not able to form biolfim, because when *C. orthopsilosis* was the only species present, in both blood culture and catheter, biofilm was identified in the catheter. This highlights the fact that the species identified in the catheter is not always that responsible for the BSI. In the last decade, antifungal susceptibility among *C. parapsilosis sensu lato* strains has been considered a matter of concern worldwide. The identification of one species in the catheter and another in the bloodstream gives a different perspective on the evaluation and use of antifungals. This may have been the case for our patient 11 that showed multiple BSIs due to *C. orthopsilosis* and *C. parapsilosis*, but the catheter was initially colonized with *C. parapsilosis*.

In the case where multiple isolates from the same patient were recovered, we observed that 80 % of *C. parapsilosis* bloodstream/catheter pairs showed similar strains (identical and microvariants strains), indicating a high probability that the *C. parapsilosis* strain observed in the catheter will also be present in the blood culture. The occurrence of genetic changes in a strain has been described in catheter-colonizing isolates rather than in blood isolates, for *C. parapsilosis* (Romeo *et al.*, 2013) as well as for *C. albicans* (Shin *et al.*, 2004). However, regardless of their origin (blood or catheter), there was a statistically significant correlation between the identity of the isolate and the date of collection (P=0.0179). In samples that were collected less than 1 month apart the isolates were genetically related (identical or microvariants), while samples collected at more than 3 months′ interval were genetically distinct. These observations suggest that *C. parapsilosis* BSI strains are mainly acquired from the environment. The identification in this study of genetically related isolates, persistently isolated from BSI occurring in different patients in the same hospital, sometimes over several years, further reinforces the environmental acquisition of these infections. The temporal persistence of single *C. parapsilosis* strains over long periods of time in the same hospital or ward has been described in other studies, and was also associated with outbreaks (Ásmundsdóttir *et al.*, 2008; Romeo *et al.*, 2013; Viviani *et al.*, 2006).

In conclusion, taking all our results together, five main scenarios for *C. parapsilosis* fungaemia were identified in this study: (i) monofungal infections due to all three species of the complex; (ii) polyfungal, always including *C. parapsilosis*; (iii) maintenance of the *C. parapsilosis* infecting strain when collection dates are less than three months apart;

(iv) replacement of the *C. parapsilosis* infecting strain when collection dates are more than three months apart; and (v) micro-variation in the pair bloodstream/catheter *C. parapsilosis* strains.

Although the detection of BSIs with *C. parapsilosis* should include alerts regarding security breaks in catheter care and infection control procedures, as previously reported, the identification of polyfungal infections and their consequences for treatment should also be considered an alert. The observation that strains can remain in the hospital environment for years is also an alerts for the possible existence of specific reservoirs and reinforces the need for accurate genotyping tools, such as the microsatellite markers used, for both elucidating epidemiological associations and the detection of outbreaks.

ACKNOWLEDGEMENTS

Financial support was provided by CAPES Foundation (BEX 19194/12-9), Ministry of Education of Brazil, Brasília (DF 70.040-020), by FEDER through POFC–COMPETE and by Portuguese funds from FCT (PEst-OE/BIA/UI4050/2014). R. M. Z.-O. is supported in part by CNPq (350338/2000-0) and FAPERJ E (26/103.157/2011). We are grateful to Ronaldo Rozembaun from HSE and SAM and Andréa Pussenti Derossi from HUPE for providing the *Candida* isolates and technical assistance in sampling. Automated sequencing was done using the genomic platform/DNA sequencing platform at Fundação Oswaldo Cruz, PDTIS/FIOCRUZ (RPT01A), Brazil. The authors declare that they have no conflict of interest.
