18 **ABSTRACT**

19 In this study, we developed a method that provides community-level surface dispersal profiles
20 under controlled hydration conditions from environmental samples and enables us to isolate and
21 uncover the diversity of the fastest bacterial dispersers. The method expands on the Porous
22 Surface Model (PSM), previously used to monitor dispersal of individual bacterial strains in liquid
23 films at the surface of a porous ceramic disc. The novel procedure targets complex communities
24 and captures the dispersed bacteria on a solid medium for growth and detection. The method was
25 first validated by distinguishing motile *Pseudomonas putida* and *Flavobacterium johnsoniae* strains
26 from their non-motile mutants. Applying the method to soil and lake water bacterial communities
27 showed that community-scale dispersal declined as conditions became drier. However, for both
28 communities, dispersal was detected even under low hydration conditions (matric potential: -3.1
29 kPa), previously proven too dry for *P. putida* KT2440 motility. We were then able to specifically
30 recover and characterize the fastest dispersers from the inoculated communities. For both soil and
31 lake samples, 16S rRNA gene amplicon sequencing revealed that the fastest dispersers were
32 substantially less diverse than the total communities. The dispersing fraction of the soil microbial
33 community was dominated by *Pseudomonas* which increased in abundance at low hydration
34 conditions, while the dispersing fraction of the lake community was dominated by *Aeromonas*
35 and, under wet conditions (-0.5 kPa), also by *Exiguobacterium*. The results gained in this study
36 bring us a step closer to assessing the dispersal ability within complex communities under
37 environmentally relevant conditions.

40 **IMPORTANCE**

41 Dispersal is a key process of bacterial community assembly. Yet, very few attempts have been
42 made at assessing bacterial dispersal at the community level as focus has previously been on pure
43 culture studies. A crucial factor for dispersal in habitats where hydration conditions vary, such as
44 soils, is the thickness of the liquid films surrounding solid surfaces, but little is known on how the
45 ability to disperse in such films varies within bacterial communities. Therefore, we developed a
46 method to profile community dispersal and identify fast dispersers on a rough surface resembling
47 soil surfaces. Our results suggest that within the motile fraction of a bacterial community only a
48 minority of the bacterial types are able to disperse in the thinnest liquid films. During dry periods,
49 these efficient dispersers can gain a significant fitness advantage through their ability to colonize
50 new habitats ahead of the rest of the community.

51

52 **KEYWORDS**

53 Community motility, *Pseudomonas putida* KT2440, liquid film, soil, lake water, succession, porous
54 surface model.

55

56 Introduction:

57 Dispersal is essential in order to ensure fitness in a world of limited and heterogeneously
58 distributed resources and is recognized as a key contributor to community dynamics (1, 2). While
59 dispersal has long been studied as an integral part of the ecology of animals and plants, its
60 contribution to microbial ecology has received less attention (3–5).

Accepted Manuscript Posted Online

62 Dispersal is traditionally divided into passive (caused e.g. by weather or human activities) and
63 active, also termed motility, which requires metabolic energy (6). Motility is not limited to
64 environments saturated with water, but is also commonly found on or near surfaces in
65 unsaturated environments, such as the thin liquid films between soil particles or on the surface of
66 leaves (7). Bacteria have evolved diverse mechanisms of active dispersal on surfaces including
67 swimming, swarming, twitching, sliding, and gliding, all of which have been mainly described and
68 studied in pure culture settings (8–11) using agar plates or glass slides for capture of motile cells
69 (8, 9, 11, 12). Hence, it remains unclear how well these methods capture dispersal potential in
70 more natural settings, such as in soils, and how the ability to disperse is distributed within the tree
71 of life and within individual communities. There have been a few efforts to uncover the
72 phylogenetic distribution of flagellar motility (13, 14) and gliding motility (12, 15), but a
73 comprehensive view of how the dispersal abilities vary across and within bacterial phyla is still
74 lacking.
75
76 This gap in our knowledge partly results from the lack of methods for mass assessment of
77 dispersal potential of bacteria in environmental samples. In a community, not all bacteria have
78 equal potential for dispersal; though this is rarely assessed. To assess the dispersal potential of a
79 community one could, in theory, isolate and test all its members but considering that there can be
80 up to 10^9 bacterial cells in a gram of productive soil (16), this would be practically unfeasible. In
81 addition, by studying strains in isolation, the effects of interaction between strains would be
82 missed. Indeed, most past studies of motility have focused on the motion of single strains (8, 17,
83 18) largely neglecting the vast possibilities of interactions which have only recently been
84 uncovered (17). Bacterial co-cultures have been observed swarming together, combining their

85 skills to conquer barriers such as antibiotics (19) or to engage in metabolic cross-feeding (20).
86 Motile bacteria have been demonstrated to carry non-motile bacteria as cargo (21) and inter
87 kingdom cooperation has been described such as bacterial dispersal with the help of fungi and
88 amoeba (22–26). It would seem logical that these complex interactions occur in natural
89 communities but only very few attempts have been made to tackle motile bacteria in
90 environmental samples at the community level (27–31).
91 A few studies did address community-level motility in aquatic environments. Grossart *et al*. (29),
92 Mitchell *et al.* (31) and Fenchel *et al*. (30), assessed swimming motility in ocean samples using
93 microscopy and revealed a large percentage of motile bacteria, but did not identify these. Dennis
94 *et al*. (27) used a syringe based-assay and 16S rRNA gene amplicon sequencing to uncover the
95 identity of motile lake water bacteria showing a chemotactic response towards inorganic
96 substrates. However, to our knowledge, only one study assessed dispersal and identity of
97 dispersing bacteria in a complex natural community under conditions relevant for partially-water-
98 saturated habitats (e.g. surface or vadose zone soils, phyllosphere) (28). Using sand microcosms,
99 Wolf *et al*. revealed that a subset of a soil community consisting mainly of the family
100 *Enterobacteriaceae* and the genera *Undibacterium*, *Pseudomonas* and *Massilia* were able to
101 expand to a distance of more than 2 cm from the inoculation point within 48 h (28). While this
102 study provided important insights into the identity of dispersers and their expansion rate, they
103 only considered one hydration condition (7.5% moisture w/w, i.e., matric potential in the -20 to -
104 50 kPa range based on the particle size (32)). Yet, previous studies have stated that water is one of
105 the primary factors controlling bacterial motility (33).
106 In a non-permanently water saturated habitat such as soil, the ability to disperse is primarily
107 dependent on the thickness of the water film surrounding solid surfaces. The hydration status of

Applied and Environmental Microbiology

108 soil in the vadose zone is highly variable and can increase or decrease rapidly, e.g. following
109 rainfalls or droughts (7, 18, 33). At low matric potential, the thinning of the aqueous films between
110 soil particles will lead to habitat fragmentation into separate micro habitats (34), with strong
111 effect on the bacterial dispersal ability.
112 The Porous Surface Model (PSM) is a 2D model system used for studying bacterial motility on the
113 surface of a porous ceramic disc under controlled hydration conditions that mimics unsaturated
114 soil surfaces. Studies of fluorescently tagged pure cultures using the PSM have demonstrated
115 that flagellar motility is restricted to a relatively narrow range of water potential (0 to -2kPa) (18,
116 34). However, it remains unclear how this knowledge on specific flagellated bacterial isolates can
117 be translated at the scale of complex environmental communities.
118
119 Hence, the aims of the current study were to (i) further develop the PSM for its use to assess
120 bacterial dispersal of natural (untagged) bacterial communities and (ii) apply the method to a soil
121 and a lake community to obtain community-level surface motility profiles under controlled
122 hydration conditions and uncover the diversity of the fastest dispersers.
123
124
125 **Results**

126 **Developing and validating the novel method with pure cultures.**

127 The Porous Surface Model (PSM) has previously been used to monitor bacterial dispersal under
128 controlled hydration conditions (35). The challenge of the current study was to expand the
129 method from being solely usable with fluorescently tagged cultures to evaluate dispersal of a
130 broader range of complex natural communities, tracking the movement from the inoculation point
131 at the center towards the edge of the ceramic disc. To achieve this goal, we devised a procedure

Downloaded from http://aem.asm.org/ on January 30, 2018 by TECH KNOWLEDGE CTR OF DENMARK

Accepted Manuscript Posted Online

132 to get an imprint of dispersal on the ceramic disc by pressing agar plates onto the PSM surface
133 (see method overview in the supporting information, Fig. S1). This step resembles the agar lift
134 method used for visualization of the bacterial distribution on soil surfaces described in a previous
135 study (36).
136
137 Initial tests with *P. putida* KT2440 GFP and full agar plates pressed onto the ceramic disc of the
138 PSM showed a clear discrepancy between the bacterial spatial distribution observed on the
139 ceramic disc with epifluorescence microscopy before pressing and that captured on the agar plate.
140 It was clear that pressing the agar plate onto the surface of the ceramic disc disturbed the
141 bacterial distribution, so that the high density of cells at the inoculation point were often spread
142 over a much larger area. To avoid this error, we developed a series of concentric annular
143 hollowed-out agar plates, which were pressed sequentially, starting from the edge of the ceramic
144 disc and leaving the center undisturbed until a full plate was used to capture the total community
145 that had developed on the PSM disc (Fig. 1 and S1).
146
147 To test the method, we inoculated a mixture of the motile strain *P. putida* KT2440 GFP and its non-
148 flagellated mutant *P. putida* K2440 dsRed *fliM*$^-$ which had previously been used for motility studies
149 on the PSM (18, 35). This pure culture experiment demonstrated the ability of the method to
150 clearly contrast the dispersal potential of these strains (Fig. 1 and Fig. 2). The non-motile strain
151 generally stayed near the inoculation point. For the motile strain, the fastest dispersal was seen at
152 -0.5 kPa with 4 out of 6 replicates reaching the edge of the pressed plate furthest from the
153 inoculation point, i.e. the 25 - 41.3 mm section, after 40 hours incubation (Fig. 2). Dispersal at -1.2
154 kPa was not significantly different from that at -0.5 kPa, after 24 h ($p = 0.229$) or 40h ($p = 0.857$),

155 and no dispersal was registered at -3.1 kPa. This was consistent with the threshold for flagellar
156 motility of -2.0 kPa previously reported for *P. putida* KT2440 (18).
157
158 To test the ability of the method for capturing other types of motility than flagellum powered
159 swimming we inoculated the gliding bacteria *Flavobacterium johnsoniae* strain CJ1827 (37) and
160 the non-motile mutant *F. johnsoniae* strain 2122 Δ*gldK* (38) on separate PSMs incubated at -0.5
161 kPa. After 48h incubation the non-motile mutant (n=2) stayed near the inoculation point while the
162 gliding bacteria (n=3) were recovered in the 11.5-15 mm section and, in one case, at the edge of
163 the pressed plate, 25-41.3 mm section.
164
165 **Dispersal potential of environmental communities.**
166 Applying the novel method on extracted soil and lake bacterial communities confirmed that
167 dispersal rate declined as conditions became drier (Fig. 3). However, surprisingly, for both
168 community types, dispersal was detected even under the lowest hydration condition tested (-3.1
169 kPa and one sample at -4.2 kPa, not shown), previously proven too dry for *P. putida* KT2440
170 dispersal (Fig. 2). For the soil community, the slowest dispersal was detected at –3.1 kPa with 2
171 out of 3 replicates dispersed to the 11.5-15mm section at 24 h, though all reached the most
172 distant section of the plate (25 - 41.3 mm section) after 48 h (Fig. 3). To record the magnitude of
173 the colonization of the ceramic plate sections a coverage score was introduced for the
174 environmental samples, where the extent of colony coverage of the agar plates was roughly
175 assigned into four categories. This scoring scoring indicated that even though soil bacteria reached
176 the most distant sections of the plates after 48 h, the colonization was less at -3.1 kPa (1-25% to
177 26-50% coverage) than at -1.2 kPa and -0.5 kPa (51-76% to 76-100% coverage).

Accepted Manuscript Posted Online

178 The lake bacterial community study was mainly included for comparison purposes, as we assumed
179 that this community would have experienced a weaker selection for dispersal ability on dry
180 surfaces, and to demonstrate the versatility of the method. It was based on fewer replicates which
181 limits interpretation, but revealed a similar picture with bacteria reaching the edge of the plate
182 after 48 h for both dry (-3.1 kPa) and wet (-0.5 kPa) conditions though the extent of colonization
183 was less for the dry samples (Fig. 3). Direct comparisons of the soil and lake data should be done
184 with caution because the CFU counts suggested that more cultivable cells were inoculated for the
185 lake than for the soil samples (34 x 10^3 vs 2-8 10^3 CFUs per inoculum, respectively). However, for
186 both soil and lake communities it remains clear that we registered much faster dispersal at both -
187 0.5 kPa and -3.1 kPa (Fig. 3) compared to *P. putida* KT2440 (Fig. 1).
188

189 **Diversity of dispersers.**

190 DNA was extracted from the Nycodenz soil extracts and the lake filtrate used for inoculations,
191 from agar plates reflecting the total community present on the ceramic disc (Full Plate), and from
192 the community that developed upon inoculation of the environmental cell extracts onto a
193 'standard' 25% R2A solid medium plate with 20 g agar l^{-1}, which provides conditions that are not
194 conducive to motility (39) (the No Motility Reference Plate, shortened as 'Reference Plate'). All
195 samples were sequenced using Illumina sequencing targeting the V3-V4 regions of the 16S rRNA
196 gene. A total of 3.8 million sequences were kept after filtering for further analysis.
197 Comparisons between the communities in the inoculum (Nycodenz extractions and the Lake
198 filtrate) and the cultivable communities dispersed or not, confirm the expected cultivation bias
199 (Fig S7-8). However, the cultivable community represented on the Full plates and Reference plates
200 retained a high diversity with representatives of 261 unique genera for soil, and 143 for lake. In

Downloaded from http://aem.asm.org/ on January 30, 2018 by TECH KNOWLEDGE CTR OF DENMARK

Applied and Environmental Microbiology
AEM
Applied and Environmental Microbiology

Accepted Manuscript Posted Online

201 addition, 4172 and 665 amplicon sequence variants (ASVs (40)) in soil and lake samples were not
202 identifiable at the genus level. Moreover, the dominating genera in the cultivated soil
203 communities, (*Pseudomonas, Flavobacterium* and *Paenibacillus*) were also among the abundant
204 taxa of the Nycodenz extractions (Fig S7) and lake water filtrate (*Aeromonas Flavobacterium* and
205 *Exiguobacterium*) (Fig S8), respectively.
206
207 For each PSM we collected the DNA of the fastest dispersers i.e. that of the colonies of the pressed
208 agar plate the furthest from the point of inoculation that presented growth. As the method did not
209 allow for selective recovery of the cells unable to disperse we compared these 'dispersed'
210 communities to the total community present on the Full Plate and the Reference Plate.
211 Sequencing results from the soil community showed a dominance of *Pseudomonas* in the
212 dispersed communities benefitting from increasingly dry conditions, and achieving almost total
213 dominance at the driest conditions (-3.1 kPa and -4.2 kPa: 99.4 - 98.3% after 48 h) (Fig. 4). Under
214 wet conditions (0.0 kPa and -0.5 kPa) the dispersed bacterial community consisted, besides
215 *Pseudomonas,* mainly of *Paenibacillus, Rahnella, Lysinibacillus* and, after 48 h (-0.5kPa), also of
216 *Flavobacterium* and *Janthinobacterium.* At moderate dryness (-1.2 kPa), *Bacillus* was almost equal
217 in abundance to *Pseudomonas* (47.2% and 50.4% respectively) at 24 h but were reduced over time
218 to 3.7% at 48 h in favor of *Pseudomonas* (50.8%), *Paenibacillus* (19.1%) and to some extent
219 *Janthinobacterium* (11.7%).
220
221 For the lake community, *Aeromonas* was the most abundant genus in all samples and almost
222 completely dominated the dispersed community under dry conditions (91.9% after 24 h and 95.6%
223 after 48 h, -3.1 kPa) (Fig. 5). Under wet conditions *Aeromonas* dispersed and colonized fast (79.1%,

Applied and Environmental Microbiology

AEM

Applied and Environmental Microbiology

224 after 24 h) but appeared to experience increased competition from *Exiguobacterium* over time
225 (43.3% and 37.5% respectively after 48 h).
226
227 The bacterial diversity, calculated using the Shannon Diversity index (Fig. 6 A, B and S3 A, B),
228 revealed that diversity was significantly affected by the matric potential in the 24 h soil samples
229 ($p< 0.001$, ANOVA based on comparison of the differences between Full Plates and dispersed
230 communities). Both the dry (-3.1 kPa) and moderately dry (-1.2 kPa) conditions were significantly
231 different from the wet (-0.5 kPa) and very wet (0.0 kPa) conditions ($p<0.05$ for all pairwise
232 comparisons). The two dry (-3.1 and -1.2 kPa) and two wet (0.0 and -0.5 kPa) soil communities did
233 not significantly differ from each other (Fig S3 B). At 48 h, the differences between the Shannon
234 Diversity indices at the four matric conditions were not significant ($p=0.121$) in spite of a clear
235 trend for decreasing diversity with drier conditions (Fig. 6 B). The difference in diversity between
236 the dispersed community and that recovered on the Full plate could only be rigorously tested at
237 48 h, due to the significant effect of matric potential at 24 h, but showed that the dispersed soil
238 community had a significantly lower diversity ($p=0.001$) (Fig. 6 B).
239 The lake data also indicated a trend for lower diversity in the dispersed community compared
240 to the Full Plate at both 24 h and 48 h (Fig. 6 A and S3 A). As expected, the Shannon diversity
241 values of the Nycodenz extract and the Lake filtrate were much higher than for the samples
242 collected after cultivation on the agar plates (5.57 ± 1.45 S.D ($n=4$) and 3.82 ($n=1$), respectively)
243 clearly indicating cultivation bias.
244 The phylogenetic diversity calculated using Faith's Phylogenetic Diversity index (Fig. 6 C, D and
245 S3 C, D) revealed a consistently narrow phylogenetic diversity of the fastest dispersers at all tested

Downloaded from http://aem.asm.org/ on January 30, 2018 by TECH KNOWLEDGE CTR OF DENMARK

Accepted Manuscript Posted Online

246 matric potentials, compared to the total community of the Full Plate and the motility restricted
247 Reference Plate for both the soil and lake community.
248

249 A closer look at the phylogenetic distribution of the two dominant genera *Pseudomonas* and
250 *Aeromonas* in soil and lake water, respectively, showed that the dispersed communities at 48 h
251 consisted of multiple and diverse amplicon sequence variants (ASVs) (Fig. S4, Table S1 and Fig. S5,
252 Table S2). Notably, a search of the literature uncovered that all the type strains with the closest
253 sequence similarity to our ASVs possess the ability for active motility mainly by using flagella,
254 except for one for which motility is unknown (table S1 and S2). Neither for the soil community nor
255 for the lake water community was there a clear separation of ASVs between matric conditions
256 visible in the phylogenetic trees (Fig. S4 and S5).
257

258 A comparison of the *Pseudomonas* present in the total community of the Full Plate and the
259 dispersed soil community at 48 h shows that only 11 out of 44 ASVs were solely present in the
260 total community, and thus did not disperse from the center of the ceramic disc (Fig S6). This
261 supports the general notion of *Pseudomonads* as efficient dispersers. Furthermore, 9 out of 44
262 ASVs were solely detected in the dispersed community. This is most likely because they were
263 below detection limit in the total community, as strains present in the dispersed community must
264 also be present in the total community. Other evidence of large enrichments in the dispersed
265 community can be found in the heatmap (Fig. 4), where, in addition to *Pseudomonas,*
266 *Paenibacillus* (at matric potential below -3.1) and *Bacillus* (at -1.2 kPa) also notably increased their
267 abundance in the dispersed community compared to the total community of the Full Plate and the
268 motility restricted Reference Plate. These results illustrate that there can be a large fitness gain

269 associated with dispersal for a motile strain i.e. going from being below detection limit to
270 potentially very high relative abundance far from the inoculation point. By moving ahead of the
271 pack, such strains benefit from decreased competition for nutrients and maximize their growth.
272

273 Discussion

274 *Performance and limitations of the method*

275 In this study, we developed a method for assessing dispersal of natural bacterial communities
276 under controlled hydration conditions. We achieved this by expanding on the Porous Surface
277 Model already well established for single strain motility studies (18, 35, 39), and using agar plates
278 to get an imprint of the colonization on the surface of the ceramic disc. The method proved
279 effective in separating the dispersal of a motile flagellated *P. putida* strain from a non-motile
280 mutant, which stayed near the inoculation point in the center of the ceramic disc on the agar plate
281 imprints (Fig. 1 and 2). It was also able to capture the effect of lowered matric potential, which
282 resulted in a reduced dispersal rate of the motile strain and a cessation of all movement at -3.1
283 kPa, in agreement with previous studies (18, 34). In addition, the method was able to detect
284 dispersal of the gliding bacterium *F. johnsoniae*, indicating the potential for detection of other
285 types of motility than swimming.
286

287 The possibilities for precise control of hydration conditions are one of the key points that separate
288 this method from the few previous studies on community motility (27–29). Calculations coupled
289 with recent measurements of the liquid film thickness on the surface of the ceramic disc in the
290 PSM model (18, 34, 35) provides us with a unique platform to study the behavior of microbial
291 communities on surfaces as they are affected in their microhabitats by water film thickness. While

Accepted Manuscript Posted Online

292 we only tested the effect of fixed hydration conditions in this study, exploring dynamic conditions
293 such as dry-wet cycles would be straightforward. Indeed, recent studies with a synthetic soil
294 community on the PSM demonstrated a clear effect of such cycles on competition and co-
295 existence (41).
296
297 We recognize that the results from using this method are biased by cultivation and are only valid
298 for the fraction of bacteria able to grow under the selected growth conditions. However, we did
299 find a high diversity of genera among the cultured community and that the most dominant genera
300 e.g. *Pseudomonas* and *Aeromonas* were prominent parts of the original inocula. This indicates
301 that, in spite of the existence of some cultivation bias, our method do provide information of
302 relevance to the original communities.
303
304 In addition, nutrient supplementation is often necessary to detect dispersal (28) and one of the
305 strengths of this setup is that it does allow for easy isolation of strains of interest as we essentially
306 already have them on agar plates. This has led to a culture collection of soil isolates able to
307 disperse at -0.5 and -3.1 kPa for use in future studies (data not shown). A possible venue to
308 decrease cultivation bias is to optimize the medium. We currently use a medium with a relatively
309 low substrate concentration (25% R2A and R2B) to avoid selection of only fast growing bacteria,
310 but this could be further improved by e.g. using a soil extract medium (42). Results are also likely
311 affected by the extraction methods used to obtain microbial inocula from the environment,
312 because extraction, and especially Nycodenz extraction (43, 44), affects the composition of the
313 inoculum. However, this is not a limit to the method itself. The method would also be applicable
314 when using intact environmental samples (for example, soil aggregates) placed in the center of the

315 ceramic disc. Finally, while there are benefits of using the agar plate sampling method (low
316 detection limit for cultivable bacteria), a possible improvement would be to recover the dispersed
317 community for DNA extraction directly from the surface of the PSM. The recovery rate and
318 detection limit would need to be evaluated carefully.
319
320 *Dispersal of environmental communities under low hydration conditions*
321 When we applied the method to soil and lake water communities, the results extended previous
322 pure culture studies in confirming that dispersal rates decline as conditions become drier.
323 However, surprisingly, for both communities, relatively rapid dispersal was detected even under
324 the lowest hydration conditions (-3.1 kPa). After 48 h, members of both communities had reached
325 the maximum possible distance of 25-41.3 mm (Fig. 3). It is unlikely that the detection of cells
326 several cm away from the inoculation point could have been caused by simple colonial growth (i.e.
327 cell division and shoving) because colony expansion by growth only is very slow (e.g. diameter
328 expansion rate of 17 µm h^{-1} for a P putida KT2440 at -3.6 kPa) (35). Therefore, this dispersal is
329 likely facilitated by motility. This strong dispersal potential under low hydration conditions was
330 particularly surprising for the lake water community because the selective value of such traits in
331 the original habitat is not obvious.
332
333 A possible explanation for the rapid dispersal at conditions previously thought to be too dry could
334 be a difference in cell size between the model strains and the bacteria in the environmental
335 samples. As discussed in Dechesne *et al*. (18) the effective thickness of the liquid-film on the
336 surface of the ceramic disc is the limiting factor for flagellar motility. Pure culture studies on the
337 PSM using the motile strains *Pseudomonas protegens* CHA0 and *Pseudomonas putida* KT2440

Accepted Manuscript Posted Online

338 report a threshold for swimming and dispersal at -2.0 kPa (18, 34, 35). At -2.0 kPa the predicted
339 effective liquid film thickness on the surface of the ceramic is less than 1.5 µm and decreases to
340 approximately 0.4 µm at -3.6 kPa, close to the shorter dimension of *P. putida* KT2440 rods
341 (measured by others as 0.74 µm (rod shaped) (45) and as 0.6 µm by us under nutrient rich
342 conditions). Hence, motility becomes strongly limited in liquid films thinner than the cell diameter,
343 due to exposing the cell surface to liquid-air interfaces, capillary pressure and pinning forces (18,
344 35). As many bacteria from soil and aquatic environments are small, with diameters less than 0.4
345 µm and some even passing through 0.2 µm filters (44, 46–48), it is possible for some of them to be
346 able to actively disperse in the thinnest liquid films tested in this study. It should be noted,
347 however, that as bacterial cell size can vary with the conditions, e.g. Pseudomonads have been
348 known to change both size and shape as a response to starvation or other chemical stressors (45,
349 49), the size of the bacteria used in this study should be measured under the actual imposed
350 conditions to confirm this theory.
351
352 *Diversity of efficient dispersers*
353 Our results show that diversity decreased in the dispersed communities compared to the total
354 community in the soil and lake samples. This indicates that, within natural communities, there is a
355 less diverse sub community of bacteria with the potential for dispersal, which will most likely have
356 important consequences for community composition, competition and microbial succession. The
357 study by Wolf *et al.* (28), which is most comparable to ours, identified the most abundant
358 dispersers in their soil community as members of the genera *Enterobacteriaceae*, *Pseudomonas*,
359 *Massilia* and *Undibacterium*, with *Enterobacteriaceae* as the most dominant. Here, we also find
360 both *Pseudomonas* and *Enterobacteriaceae* within the 20 most abundant ASVs in the dispersed

Applied and Environmental Microbiology
AEM
Applied and Environmental Microbiology

361 soil community and *Pseudomonas* is the most dominant disperser. We also find *Paenibacillus* and
362 *Cupriavidus*, that Wolf *et al*. (28) detected in low abundance, but along with *Enterobacteriaceae,*
363 they are only present in our study at relatively wet conditions, with matric potentials of -1.2 kPa or
364 lower. *Undibacterium* was not present in either the initial community or in the dispersed, and
365 *Massilia* was only detected in low numbers on one Reference Plate and in one of the Nycodenz
366 extractions. The differences in the abundance and composition of communities between the two
367 studies are most likely caused by a combination of various factors such as different initial
368 communities in the inoculum, medium selection, and variation in hydration conditions.
369 Nonetheless, it remains clear that *Pseudomonads* play a key role in the two soil communities as
370 early colonizers of unoccupied habitats and possibly gaining a further advantage at relatively low
371 hydration conditions where they dominate the community.
372
373 *Potential modes of dispersal*
374 Under dry conditions *Pseudomonas* and *Aeromonas* dominated the dispersed soil and lake
375 communities (Fig. 4 and 5). Many members of these two genera produce biosurfactants which
376 have been shown to facilitate dispersal on surfaces (50–53) such as leaves, an ability which has
377 been hypothesized to increase fitness for *Pseudomonas* (54, 55). We speculate that biosurfactants
378 also play a role in increasing the connectedness in the liquid film on surfaces. An important factor
379 in our model system is the residual roughness of the ceramic surface, although polished, it can
380 result in the fragmentation of the aqueous habitat as matric potential decreases along with the
381 liquid film thickness, and the topography of the surface, as a result, becomes more apparent.
382 Tecon *et al*. reports that a rapid decrease in connectedness of the aqueous habitat was found at -
383 2.0 to -5.0 kPa which influenced the motility of their tested flagellated bacteria (34). Hence,

Downloaded from http://aem.asm.org/ on January 30, 2018 by TECH KNOWLEDGE CTR OF DENMARK

Accepted Manuscript Posted Online

384 biosurfactant production could be a strategy to overcome dispersal limitation under dry conditions
385 for the two genera observed in our study. In addition members of the orders *Exiguobacterales*
386 (*Exiguobacterium*) and *Bacillales* (*Bacillus and Paenibacillus*), which are frequent in the dispersed
387 lake and soil community at wet conditions (Fig. 4 and 5) have also been found to produce
388 biosurfactants giving rise to speculation that the benefit of surfactant production for increased
389 dispersal ability might not only be limited to dry conditions (53). While we did not look for
390 biosurfactant production in this study, it would be straightforward to screen the obtained isolates
391 for biosurfactant production in the future (56).
392
393 Alternative modes of surface motility apart from flagella powered swimming might play an
394 increased role as conditions become dryer (7). Therefore, one of the strengths of the PSM for
395 complex community studies is that it is not limited to investigate bacteria with swimming ability,
396 as in the previous work by Grossart *et al.* (29) and Dennis *et al.* (27), but also enables studies of
397 other modes such as sliding, gliding, biosurfactant aided movement, fungal highways (23), or even
398 expansion by filamentous growth (32). The PSM could thus be instrumental to establish which of
399 these modes of motility are relevant on rough unsaturated surfaces.
400 The pure culture experiment with *F. johnsoniae* CJ1827 confirmed that gliding is possible, and can
401 provide a detectable dispersal advantage, on the rough surface of the PSM. In the soil community
402 experiments, *Flavobacterium* was detected in low abundance in the dispersed communities at -0.5
403 to -4.2 kPa (Fig. 4). Many members of this genus have been found to possess gliding motility (12,
404 57, 58), while flagellar motility in the family *Flavobacteriaceae* is almost unheard of (59), and
405 recent isolates of the order *Flavobacteriales* from leaf surfaces have also been reported as
406 biosurfactant producers (53). While the role of chemotaxis was not directly measured, it is

Accepted Manuscript Posted Online

407 possible that chemotactic organisms are enriched at the rim of the ceramic plate where the
408 substrate concentration is highest thanks to the low cell density. As many pseudomonads are
409 known to possess chemosensory systems (60), this might contribute to their prevalence in the
410 dispersed communities.

411

412 In theory, not all the strains we observe in our dispersed community have to possess the ability for
413 active motility themselves, they might be non- motile strains hitching a ride with their flagellated
414 or gliding companions (21). The co-dispersal of multiple species unveils a much more complex
415 picture of interactions that could be addressed by future studies employing the current PSM
416 model system. A possible next step could be to test the isolates obtained in this study to establish
417 which are able to autonomously disperse, versus those that rely on others.

418

419 **Conclusion:**

420 A novel method to study motility at the community level was developed and tested on a soil and a
421 lake microbial community. The results obtained suggest that within the motile fraction of a
422 bacterial community only a minority of the bacteria is able to disperse under relatively low
423 hydration conditions, previously thought too dry for flagellar motility. During dry periods, these
424 highly efficient dispersers will gain a significant advantage with their ability to colonize new
425 habitats ahead of the rest of the community. This highlights the need for increased focus on
426 complex communities, rather than pure culture studies for the prediction of actual dispersal ability
427 on solid surfaces such as soil.

430 **Bacterial Strains.**

431 The bacterial strain *Pseudomonas putida* KT2440 GFP, a tagged-derivative of a motile bacterium
432 initially isolated from rhizosphere soil (61) was used as a motile model strain for flagellar motility
433 and a nonflagellated mutant *P. putida* K2440 dsRed *fliM*$^-$ previously created (18) was used as a
434 non-motile model strain.

435 The bacterial strain *Flavobacterium johnsoniae* CJ1827 (37), was used as a model strain for gliding
436 motility, and a non-motile mutant *F. johnsoniae* 2122 Δ*gldK* (38) was used as a non-motile model
437 strain. All strains were routinely maintained on agar plates. *P. putida* strains on R2 agar (R2A,
438 Fluka; Sigma-Aldrich, St. Louis, USA) and *F. johnsoniae* strains on CYE agar (62) medium at 25°C.

439

440 **Visualizing dispersal of non-fluorescent bacteria from environmental samples on the PSM.**

441 The porous surface model (PSM) has previously been described and used for observing motility
442 and growth of fluorescent strains after their inoculation at the center of a ceramic disc (diameter =
443 41.3 mm, thickness = 7.1 mm, maximum pore size <1.5 µm, 1 bar bubbling pressure; Soilmoisture,
444 Santa Barbara, USA) simulating a soil surface, under controlled hydration conditions (35).
445 Imposing suction on the disc controls the thickness of the liquid film on the ceramic surface.

446

447 In this study, we have expanded the use of the PSM for environmental communities. As non-
448 fluorescent cells are not detectable on the surface of the ceramic disc by standard microscopy, we
449 trapped the bacteria from the PSM by pressing small agar plates on top of the ceramic disc. This
450 allows visualizing the colonization on the ceramic disc by observing the growth on the
451 corresponding agar plates (Fig. S1).

452

Accepted Manuscript Posted Online

453 The agar plates were obtained by pouring 6.3 ml 25% R2A with 20 g agar l^{-1} into the lid of a small
454 plastic petri dish (Star™Dish diameter, 40 mm; height, 12.5 mm; Phoenix Biomedical Products,
455 Mississauga, Canada) filling it to the brim. To further flatten the surface of the agar, the sterile lid
456 of a standard petri dish (diameter 90 mm; height, 14.2 mm; VWR International, Søborg, Denmark)
457 was pressed on top of the small agar plate before it had completely solidified. After drying the
458 small agar plate was transferred into a big petri dish for storage. The PSM reservoirs were filled
459 with 200-250 ml 25% R2B (Alpha Biosciences, Maryland, USA) and autoclaved before use.
460
461 Preliminary tests with fluorescent strains revealed that pressing of agar plates on the ceramic discs
462 provided a distorted image of the bacterial spatial pattern because cells are inevitably displaced
463 along the contact plane. Therefore, we detected bacterial colonization in concentric annular
464 sections of the PSM surface. By preparing agar plates with holes of diameters ranging from 11.5
465 mm, 15 mm, 20 mm and 25 mm (Fig. S1) we could estimate dispersal by sequentially pressing
466 these plates on the PSM starting with that with the biggest hole and finishing with a full plate (Full
467 Plate).
468 The holes were punched in the agar plates with a custom-made tool consisting of a teflon handle,
469 for safe handling during flame sterilization, fitted to brass tubes of varying diameters (length: 12.5
470 cm; diameters: 11.5, 15, 20, 25 mm) (Fig. S2). A printed template was placed under the agar plate
471 to help center the holes. All plates were kept for a minimum of 48 h at room temperature before
472 use on the PSM to test for contamination.
473
474 **Proof of concept with motile and non-motile pure cultures.**

475 We tested the ability of the method for distinguishing the dispersal patterns of *P. Putida* KT2440
476 GFP and *P. putida* K2440 dsRed *fliM*⁻. The bacteria, cultivated on R2A plates, were suspended in
477 0.9% NaCl solution and adjusted by optical density measurements at 600 nm to obtain a cell
478 density of ca. 2000 cells μl^{-1}, as confirmed by plate counts. Before inoculation the PSMs were
479 elevated to -4.2 kPa (the length of the hanging water column is 40 cm and equals a suction of -4.2
480 kPa) for 20 minutes to drain excess fluid from the ceramic surface. The two bacterial suspensions
481 were mixed in equal ratio and 0.5 µl was inoculated in the center of the ceramic disc, where it was
482 rapidly absorbed. The discs were then brought to matric potentials (suction) of -0.5, -1.2 or -3.1
483 kPa (-5, -12 and -30 cm of water suction) and incubated at room temperature for 14, 24 or 40
484 hours before sampling by pressing the suite of agar plates onto the surface. Plates were incubated
485 at 25°C for a 48 h growth period before being stored in the fridge at 4°C until observation by
486 microscopy.
487
488 To test the applicability of the method for other types of motility, we tested the gliding bacterium
489 *Flavobacterium johnsoniae* strain CJ1827 (37), and a non-motile mutant *F. johnsoniae* 2122 Δ*gldK*
490 (38) on separate PSMs. Bacteria were streaked from CYE agar and grown in overnight cultures at
491 25°C in motility medium (MM) (63) and adjusted by optical density measurements at 600 nm to
492 obtain a cell density of ca. 63000 cells μl^{-1}, as confirmed by plate counts, before inoculation of 1 µl
493 in the center of the ceramic disc. The PSMs were kept at -0.5 kPa for 48h of incubation at room
494 temperature, using 25% R2B medium in the PSM reservoirs. The 25% R2A pressed plates were
495 kept at 25°C for a 48 h period before growth was recorded.

498 *P. putida* KT2440 GFP and *P. putida* KT2440 dsRed *fliM*⁻ spatial patterns on the PSM and on agar
499 plates were determined with a Leica MZ16 FA epifluorescence stereomicroscope equipped for GFP
500 and DsRed detection and fitted with a charge-coupled device (CCD) camera. Each plate was scored
501 for the presence or absence of each strain. For documentation purpose, the entire surface of
502 selected plates was imaged by sequentially capturing several fields of view, using a motorized
503 stage piloted by Image Pro Plus (version 7.1; Media Cybernetics, Silver Spring, MD, USA) and then
504 assembling a tiled image using the same software. The GFP and DsRed images of each plate were
505 captured separately and then combined into one image.
506
507 To document the presence of colonies on the plates independently of fluorescence, the plates
508 were subsequently imaged using the camera of a GelDocXR (Bio-Rad), operated in 'epiwhite'
509 mode.
510
511 **Dispersal potential of environmental communities.**
512 A soil sample was collected from the plow layer (5-15 cm depth) of a Danish agricultural field,
513 included in the Danish Pesticide Risk Assessment Program (PLAP) (64) in March 2016 (Fårdrup,
514 Sjælland). The soil is characterized by clay till and further details can be found at
515 http://pesticidvarsling.dk/. The soil was stored at 4°C. For each experiment 25 g sieved (2 mm) soil
516 was taken by composite sampling, i.e. as small subsamples taken from the original soil sample and
517 then mixed. The soil bacteria were extracted using Nycodenz density gradient centrifugation as in
518 (65), except for the final cell density determination, which was performed directly using a Thoma
519 counting chamber. Cell density was adjusted to $0.5 – 1 \times 10^6$ cells μl^{-1} in 0.9% NaCl solution and 10
520 µl inoculated as 1 µl drops in the center of the ceramic discs. This inoculum corresponded to ca.

Accepted Manuscript Posted Online

521 2000 to 8000 CFUs on R2A plates. All plates used for the environmental communities were
522 amended with 100 mg l^{-1} Delvocid to inhibit fungal growth (Natamycin, DSM food specialties,
523 Delft, The Netherlands).
524 Lake water was sampled from the urban lake Sortedamssøen (Copenhagen), in September 2016.
525 Four litre were collected from the surface water approximately 1.5 m from the shore. The water
526 sample was filtrated first through a 2 µm glass fiber prefilter (Merck Millipore; Tullagreen, Ireland)
527 and then through 0.2 µm polycarbonate filters (GVS Filter Technology; Morecambe, United
528 Kingdom) on a filtration manifold (DHI Lab Products; Hørsholm, Denmark). The filters were
529 transferred into a 15 ml falcon tube with 2.5 ml 0.9% NaCl solution and vortexed for 45 seconds.
530 The filters were removed, and the cell density was adjusted by Thoma count to 2×10^6 cells μl^{-1}. 20
531 µl of the suspension was inoculated as 1 µl drops, yielding 34125 CFUs per inoculum based on
532 drop plate counts on R2A plates. Both the lake and soil inoculum were kept at 4°C overnight
533 before inoculation on the ceramic discs. After inoculation, the discs were brought to matric
534 potentials of -0.5 and -3.1 kPa and incubated at room temperature for 24 to 48 hours before
535 sampling.
536

537 After sampling by pressing of the agar plate series on the PSMs at appropriate times, plates were
538 incubated for 72 hours at 25°C. In addition to the presence / absence score, used in the pure
539 culture studies, the coverage of bacterial growth on the individual agar plates were roughly
540 estimated by eye using 4 categories; 1-25, 26-50, 51-75 and 76-100% coverage.
541

542 After scoring, for each pressed plate series, the plate with the fastest colonizers (bacteria present
543 the furthest from center) and the Full Plate with the total cultivable community were chosen for

Accepted Manuscript Posted Online

544 amplicon sequencing. In addition to these, for each separate experiment a “Reference Plate” was
545 made, by drop plating 10 µl of the inoculum onto the center of a small 25% R2A plate with 20 g
546 agar l^{-1}. This was meant as a motility-restricted control for the bacteria cultivable on the medium.
547
548 The bacteria were then washed from the agar plates by transferring the agar from the small petri
549 dish into a standard size petri dish with a flamed spatula, adding 2 ml 0.9% NaCl solution for 10
550 minutes and then gently rubbing the surface of the agar with a sterile inoculation loop and
551 collecting the bacterial suspension by pipetting into an Eppendorf tube. The procedure was
552 repeated twice with 1.5 ml 0.9% NaCl and the suspensions collected. The Eppendorf tubes were
553 centrifuged for 5 minutes at 7500 x g before pooling into a single 1 ml sample suspension. The cell
554 suspensions (plate wash) from the pressed plates, the Reference Plates, Nycodenz extracts, lake
555 filtrate and leftover inoculums were all transferred to cryotubes and stored at -80°C.
556
557 **DNA extraction and sequencing.**
558 DNA was extracted using the Powerlyzer Powersoil kit (MoBio; Carlsbad, USA) following the
559 manufacturer’s protocol with a few changes. 500 µl of the thawed plate wash was centrifuged for
560 5 minutes at 10.000 x g. the supernatant was removed and the pellet dissolved by adding 750 µl
561 bead solution and vortexing. The suspensions were transferred to Glass Bead Tubes, 60 µl C1
562 solution was added and samples were placed in a Bead Beater for 5 minutes at 2000 RPM.
563 Hereafter the manufacturer’s protocol was followed. DNA concentrations were measured on
564 Qubit 2.0 (Life Technologies, Invitrogen; Carlsbad, USA) and stored at -80°C until sequencing.

566 The extracted DNA was PCR-amplified using the universal primer set PRK341F (5'-
567 CCTAYGGGRBGCASCAG-3') and PRK806R (5'-GGACTACNNGGGTATCTAAT-3') that amplify the V3-
568 V4 hypervariable regions of the 16S rRNA genes (66). 2 x 300 bp Purified PCR products were
569 sequenced on the Illumina MiSeq platform at the DTU Multi Assay Core Center (Lyngby, DK). All
570 raw 16S rRNA gene amplicons were processed with the DADA2 pipeline (67) with default
571 parameters. The sequences were classified based on the SILVA prokaryotic reference database
572 version 123 (68). A total of 3.8 million sequences passed the filtering steps, representing an
573 average of $5.3*10^4$ sequences per sample.
574
575 Shannon indices were computed in R software (version 3.3.1; R Core Team (2016)) using the
576 “plot_richness” function in the “phyloseq” package (69). Samples were rarefied to even depth
577 (average of 10 iterations) with the “rarefy_even_depth” function in the “phyloseq” package before
578 calculating Faith’s Diversity with the “pd.query” function of the “PhyloMeasures” package (70).
579 Heatmaps were plotted using the “amp_heatmap” function of the “ampvis” package (71), while
580 “ggplot2” (72) and “ggtree” (73) were used for plots and phylogenetic trees, respectively.
581 Type strains were identified using EZBioCloud (www.ezbiocloud.net) (74), and the closest match
582 along with sequences for common *Pseudomonads* and *Aeromonads* were added to the trees for
583 reference. For construction of phylogenetic trees with type strains, sequences were aligned with
584 ClustalW in MEGA7 with the following parameters: Pairwise Alignment: Gap open: 1, extension:
585 6.66, Multiple Alignment: Gap open: 15, extension: 6.66. Sequences were trimmed to even length.
586 Tree was constructed with the “UPGMA” function in package "phangorn" (75).

822 **FIG 2 Dispersal dynamics of motile and non-motile strains as affected by the matric potential.**

823 The progressive dispersal of the motile strain *P. putida* KT2440 GFP was captured by our method,
824 as well as the inability of the non-motile *P. putida* KT2440 *fliM*$^-$ DsRed to disperse away from
825 center of the ceramic disc. Both motile (green) and non-motile (red) strains were tested at three
826 matric potentials (kPa). For the non-motile, only -0.5 kPa is depicted as the other values were
827 similar, with bacteria solely present at the center. The distances shown are ranges, e.g. colonies
828 have been observed on the agar ring at a distance between 11.5 to 15 mm from center. Numbers
829 of replicate dispersal experiments vary from 2 to 5.
