Abstract

A recently published analytical technique to detect chloride ions in ceramic vessels that were used to produce salt is replicated (Horiuchi et al. 2011). The method involves releasing bound chloride ions permanently retained by the vessel via a chemical exchange reaction with ammonium fluoride, following the removal of all unbound salt with water. The chloride concentration is measured in solution and used to quantify the amount of salt that was bound to the ceramic matrix. Our data suggest that this method is not a viable way to consistently discriminate salt-making pottery, as the detected chloride may not be derived from salt production activities, but from the ceramic material of the pot itself. We employ experimental vessels in which salt-making was simulated, in addition to analyzing excavated sherds from two Chinese and one North American site known to have been involved in salt production. The method proposed by Horiuchi et al. is not able to distinguish salt-making and non-salt-making vessels from one another.

9 **1. Introduction**

10
11 There is currently no low-cost method to unambiguously identify salt pro-
12 duction pottery. The technique proposed by Horiuchi et al. (2011) promised
13 to allow for the inexpensive chemical detection of salt within salt-making
14 vessels, and would have had great potential to impact work on the archaeol-
15 ogy of salt production worldwide. This study replicated this method using
16 experimental pots and sherds from archaeological sites different from those
17 of the original experiments.
18

19
20 One of us (RKF) was involved in the investigation of a specialized salt
21 production site named Zhongba along the Yangzi River in the Three Gorges
22 region of China (Flad 2011). Various aspects of the salt production taking
23 place at the site were investigated, including an attempt to chemically verify
24 that certain vessels were primarily used in the process of salt making (Flad et
25 al. 2005). However, studies employing scanning electron microscopy (SEM)
26 to examine concentrations of sodium (Na^+) and chloride (Cl^-) through cross-
27 sections of pottery have proven equivocal and unreliable. Furthermore, it is
28 an expensive technique and requires highly skilled analysis.
29
30
31

32
33 (Insert Figure 1)
34

35 Horiuchi and colleagues proposed a method to retrieve water-insoluble
36 chloride ions trapped within pottery matrices through the use of a relatively
37 inexpensive chloride probe. They created ceramics that were similar to vessel
38 types in antiquity, used them to make salt, and subsequently washed them
39 with distilled water to mimic the removal of chloride by natural percolation
40 after use. Their analysis showed that an ammonium fluoride solution was
41 able to extract the trapped chloride ions from this experimental sample,
42 via an anion exchange reaction (Fig. 1). They then tested the approach
43 using excavated ceramics from several Japanese sites, and showed that the
44 concentration of the trapped chloride ions was higher, in all cases, in ceramics
45 thought to have been used for salt production relative to those that were not.
46

47 We replicated the experiment of Horiuchi et al. (2011) in a straightfor-
48 ward manner, using a variety of different material. We simulated salt making
49 in experimental vessels, and employed archaeological samples both associated
50 and unassociated with salt production. We analyzed sherds from Zhongba,
51 from the recently excavated site of Shuangwangcheng in Shandong Province,
52 China (Li et al. 2009), and from Kimmswick, Missouri, a prehistoric saline
53

8
9 site curated in the Peabody Museum of Archaeology and Ethnology at Har-
10 vard. We hoped to verify this method and thus further extend previous re-
11 search on salt production at these sites and, in the case of Zhongba, expand
12 on the limited but provocative chemical work done previously by compar-
13 ing ceramics thought to have been used for salt making to those that were
14 thought to be used for other purposes.
15
16

17 18 **2. Experimental**

19 *2.1. Materials*

20
21
22 Four sets of material were analyzed in this study in order to evaluate the
23 claims made by Horiuchi and associates (2011) that chloride ions exchange
24 with anions in pottery during the process of salt pan formation and can be
25 thus chemically released and detected. These include experimental vessels in
26 which salt making was simulated, sherds from two sites in China and one in
27 North America where salt production activities have been identified. A total
28 of forty-two samples were analyzed, twenty-eight of which are known, based
29 on context and typology, to have been used in salt production, seven that are
30 known to have not been used in salt production, and seven of unconfirmed
31 function.
32
33

34
35 Three terra cotta vessels were donated by the Harvard Ceramics Program.
36 Two experimental pots were filled with a brine solution made up of tap
37 water saturated with salt and heated on a stove. Salt pan was left behind as
38 the water evaporated, simulating the salt extraction process from sea water.
39 One pot (E2) went through a single cycle of being filled with salt water and
40 reduced down to a solid salt pan. Additional brine was continuously added
41 to the other pot (E1) until the bottom cracked and the vessel was no longer
42 able to carry water. The entire exterior of the pot was caked in salt, which
43 travels through a porous ceramic body during evaporation. Samples from the
44 rim (E1R, E2R), body (E1M, E2M), and base (E1B, E2B) were separately
45 analyzed for the two experimental vessels used to make salt pan. A third
46 experimental pot (E3) was never put into contact with salt and served as a
47 control.
48
49

50
51 The second group of sampled material included sixteen sherds from the
52 site of Shuangwangcheng in Shandong Province, China (SI Fig. C.1; Cao
53 1996; Cui 2011; Li et al. 2003, 2009; Peng 2012; Shandong and Shandong
54 2012; Shandong et al. 2010a, 2010b). Eleven of these (S1-11) are known to
55 have been used to produce salt and include both rim and body sherds, orange
56
57

1
2
3
4
5
6
7
8
9 and grey ceramic materials, and lightly to heavily rope-corded exterior surface textures (SI Table A.1). Two sherds from Shuangwangcheng (S12, S14) are known to have not been used to produce salt while the three remaining sherds (S13, S15-16) were most likely unassociated with salt production.

10
11
12
13
14 The third group of ceramics was made up of ten sherds from the site of Zhongba in the Three Gorges Region of China (SI Fig. C.2; Chen 2008; Flad 2007, 2011; Sichuan and Chongqing n.d.; Sun 2003), eight of which are portions of vessels known to have been involved in salt production, including the rims of storage vats and conical cups (Z1-6, Z9-10). One conical cup was potentially used to hold salt (Z7), while another rim sherd was definitely not involved in salt production (Z8).

15
16
17
18
19
20
21
22
23 The fourth set of sherds came from the Mississippian site of Kimmswick, Missouri, and was provided for this study by the Peabody Museum of Archaeology and Ethnology at Harvard University (SI Fig. C.3; Bushnell 1907, 1908). A total of nine sherds included three used in salt production (K7-9), three that were not (K1, K5-6), and three that were found near a salt spring but were not necessarily associated with salt production (K2-4; SI Table A.1).

46
47
48
49
50
51
52 The first step of the Horiuchi method requires all unbound, water-soluble chloride to be completely removed from each sample. All visible dirt was washed off of the sherds by hand in a sink. Next, each sherd was sonicated in a beaker of distilled water, to mimic post-depositional removal of soluble chloride through the surface. Using a rock cutting saw, 6-10g pieces of each sherd were removed; in the case of the smallest sherds (S6, S16), the entire sample was used. In the case of the Mississippian ceramics from Kimmswick, samples were removed before any dirt was cleaned off, in order to preserve the original soil on the sherds so that they may be returned to the Peabody museum as unaltered as possible. The removed pieces were then rinsed off and sonicated in distilled water. Once thoroughly washed, each sample was cut into small cubes and left in a desiccating vacuum chamber overnight to completely dry. These were then powdered in either a rock crusher or a shatterbox.

53

59
60
61
62
63
64
65 Three 1.00g portions of powdered sherds were placed in three separate 50mL centrifuge tubes (every measurement was taken in triplicate, and the data points are reported here as averages plus or minus one standard deviation). Once the powdered sherds were measured into centrifuge tubes, 10mL

1
2
3
4
5
6
7
8
9 of distilled water was added via pipet. These were next sonicated for 10 min-
10 utes, then centrifuged at 300rpm for five minutes. The clear supernatant was
11 poured into a new centrifuge tube containing 1mL of ionic strength adjustor
12 (ISA). The chloride concentration of this solution was measured with a Sym-
13 pHony Chloride Ion Selective Combination Electrode (VWR International),
14 calibrated using standard solutions of 10, 100, and 1000ppm Cl^- .
15

16
17 An additional 10mL of distilled water was added to the centrifuge tube
18 containing the pellet of powdered sherds, and the procedure was repeated
19 through a total of one to four additional cycles of sonication, centrifugation,
20 and measurement until the chloride concentration dropped below the limit
21 of detection ($<\text{LOD}$; 1.8ppm) of the probe (Fig. 4a; Extractions 1-5). To
22 confirm the necessity of using distilled, or de-ionized (DI) water, the chloride
23 concentration of tap water and distilled water were measured and found to
24 be 200ppm and below the limit of detection, respectively.
25
26

27 28 *2.3. Extraction of Bound Chloride*

29
30 Once all unbound chloride was removed from the powdered sherds via
31 repeated washings with distilled water, a second round of extractions with
32 ammonium fluoride (NH_4F) was carried out in order to release the bound
33 chloride permanently installed in the ceramic matrix. A stock solution of
34 0.25M NH_4F (98+% purity, Sigma Aldrich) in distilled water was prepared.
35 The chloride concentration of this solution was confirmed to be below the
36 limit of detection of the probe. The same cycle of sonication, centrifugation,
37 and measurement was repeated, this time with the 0.25M NH_4F solution
38 instead of distilled water, until either the chloride concentration dropped
39 below the limit of detection of the probe, or eight cycles were completed
40 (Fig. 4; Extractions 6-13).
41

42
43 Horiuchi et al. (2011) tested aqueous ammonium fluoride solutions of
44 0.028, 0.056, and 0.28M, and determined 0.28M to be the most suitable
45 concentration. In this study, we accordingly employed a solution of 0.25M
46 NH_4F , approximately equal to their concentration yet more mathematically
47 round.
48
49

50 51 *2.4. Scanning Electron Microscopy*

52
53 Scanning electron microscopy with energy-dispersive X-ray spectroscopy
54 (SEM-EDS) analyses were carried out on cross-sections of samples that were
55 thoroughly washed and sonicated with de-ionized water. The sectioned
56 sherds were examined with a Tescan Vega III scanning electron microscope
57
58

5
6
7
8
9 equipped with a Bruker X-Flash 5030 energy dispersive spectrometer. The
10 backscattered SEM images and the EDS spectra and maps were acquired
11 at an accelerator voltage of 20kV and a working distance of 16mm (40kcps
12 and 3% detector dead time for the spectra and 4kcps and 15% dead time for
13 the maps). All EDS spectra and maps were collected from areas measuring
14 1.5mm x 1.5mm.

23
24

25 **3. Results and Discussion**

26
27 The first stage in the analysis was the removal of any unbound chloride.
28 This is necessary for two potential reasons: (a) salt may have been introduced
29 into the ceramic matrix postdepositionally, and is therefore unrelated to the
30 function of the vessel and must be removed, or (b) salt actually introduced
31 into the ceramic during salt production that remains soluble may be removed
32 during burial in the ground and is thus an inconsistent and unreliable marker.
33 Consequently, only the bound chloride extracted by the exchange reaction
34 with fluoride would potentially be able to display meaningful trends.
35

36
37 After all of the unbound chloride was removed by repeated washings with
38 water and the measured concentration of chloride falls below the limit of
39 detection of the probe, ammonium fluoride was employed in subsequent cycles
40 (Fig. 4). Fluoride exchanged with chloride permanently bound in the ceramic
41 matrix, releasing it into solution and causing the measured amount of chloride
42 to significantly increase. Thus, we see a spike in chloride concentration once
43 an ammonium fluoride solution is used instead of water (between extractions
44 5 and 6 in Fig. 4a). Horiuchi et al. observed this trend, but only significantly
45 for samples that had been used in salt production. They argue that the total
46 amount of bound chloride extracted by ammonium fluoride (the sum of each
47 individual extraction, given in units of mg Cl⁻ per g pottery) may be used as
48 a marker for salt production. Our data, however, do not show this distinction.
49

50
51 Tabulated results of the total amount of chloride recovered from extractions
52 with water and with ammonium fluoride are given in Table 1. Vessels
53 known to have been used in salt production do not generally release more
54
55
56
57
58

1
2
3
4
5
6
7
8
9 bound chloride than vessels known to have not been used in salt production.
10 This is highlighted in Figures 2 and 3, which show the average amount of
11 chloride extracted from salt and non-salt ceramics at each site.
12

13
14 (Insert Figure 4)
15

16 *3.1. Analysis of Experimental Vessels*

17

18 For the experimental vessels in which salt production was simulated, we
19 see a direct correlation between contact with salt and the concentration of
20 unbound chloride in the ceramic matrix (Table 1; SI Table B.2). The most
21 unbound chloride was extracted and measured in solution from all samples
22 taken from the pot that was used to make salt pan until vessel failure (E1;
23 $\sim 10\text{mg Cl}^-/\text{g}$ pottery). Slightly less salt was recovered from the samples
24 of the pot that was put through only one cycle of salt water evaporation
25 (E2; $6\text{-}7\text{mg Cl}^-/\text{g}$ pottery), though significantly more than the amount of
26 unbound chloride recovered from the control pot (E3; $0.03\text{mg Cl}^-/\text{g}$ pottery).
27 Although these trends correspond well with the function of the pot, chloride
28 that may be removed by dissolution in water (unbound chloride) would not
29 be a reliable marker for salt production for the two reasons that have been
30 described above.
31

32 The total chloride extracted by the solution of ammonium fluoride did not
33 mimic the trend seen above. The amount of bound chloride removed from
34 the pot that was never put into contact with salt (E3) lies within the range
35 of observed values for the amount of chloride extracted from the simulated
36 salt production vessels (Figs. 3, 4b). Our experimental control indicates that
37 bound chloride is not be a dependable proxy for salt making.
38

39 Furthermore, there is a trend for both of the experimental salt produc-
40 tion vessels (E1 and E2) concerning bound chloride extracted from different
41 locations. Samples from the rim (E1R and E1R), body (E1M and E2M),
42 and base (E1B and E2B) were taken from each of the two terra cotta pots.
43 For each vessel, rim sherds produced significantly more bound chloride than
44 body sherds, while the base sherds produced the least. This contrasts with
45 the results of Horiuchi et al. (2011), who reported a higher concentration of
46 salt in body sherds.
47

48 *3.2. Analysis of Shuangwangcheng Ceramics*

49

50 The trends observed in the amount of chloride extracted from the sherds
51 from Shuangwangcheng are even less correlated (Table 1; SI Tables B.3, B.4).
52
53
54
55
56
57

1
2
3
4
5
6
7
8
9 The amount of unbound chloride recovered from washing with water seems
10 unrelated to whether or not the original vessel facilitated salt production,
11 which is to be expected from sherds excavated from the complex saline envi-
12 ronment of the ground. In addition, the total amount of chloride recovered
13 from extractions with ammonium fluoride does not parallel the function of
14 the vessel. Interestingly, one body sample known to have not been used
15 to produce salt (S14; 1.013mg Cl⁻/g pottery; Table 1, Fig.4) produced al-
16 most double the amount of chloride as the known salt-making vessel with the
17 greatest saline content (S6; 0.567mg Cl⁻/g pottery). On average, more salt
18 was extracted from non-salt production pottery (Figs. 2, 3), a trend that
19 can still be seen even if the four rim (S1, S4, S8 and S9) and one base (S12)
20 sherds are excluded from the Shuangwangcheng data set.
21
22
23
24

25 *3.3. Analysis of Zhongba Ceramics*

26
27 This lack of a trend is again observed in the samples from Zhongba (Table
28 1; SI Table B.5). This set of material produced almost no unbound chloride,
29 perhaps indicating some sort of postdepositional environment that drew out
30 the mobile saline content of the sherds. Once again, the sample in this set
31 that released the greatest amount of bound chloride is from a vessel known
32 typologically to not have been used in salt production (Z8). As with the
33 samples from Shuangwangcheng, more salt was extracted on average from
34 the Zhongba sherds not associated with salt production than those that were.
35
36
37

38 *3.4. Analysis of Kimmswick Ceramics*

39
40 The ranges of chloride extracted from salt and non-salt production sherds
41 at Kimmswick, MO overlap as well, regardless of whether rim and body sam-
42 ples are considered separately or together (Table 1; SI Table B.6). Three
43 sherds found near the salt spring, unassociated with salt production activi-
44 ties, yielded the greatest amount of extracted chloride (although the amount
45 of detected unbound chloride was not correlated in this way). It is clear that
46 it would not be possible to classify the unknown sherds based on this method
47 (Fig. 3). The total amount of bound chloride extracted from the samples
48 from Kimmswick were, in all cases, significantly (one order of magnitude)
49 greater than the salt extracted from the experimental and two archaeological
50 Chinese samples (Fig. 2).

58

1
2
3
4
5
6
7
8
9 *3.5. Results from SEM-EDS Analysis*

10 To provide a separate line of evidence, scanning electron microscopy with
11 energy-dispersive X-ray spectroscopy (SEM-EDS) was used to elementally
12 characterize cross-sections of five salt production sherds (S3, S11, Z1, Z2,
13 and Z6) and one non-salt associated sherd (S12). The amount of chlorine
14 detected in the non-salt-production sample S12 (normalized weight percent
15 relative to silicon and aluminum) was within the range of the other sherds.
16 Chlorine was evenly distributed in all samples, with no gradients from inte-
17 rior to exterior of the sherd cross-sections (SI Figs. D4), contrasting with
18 findings previously reported for salt production vessels from Zhongba (Flad
19 et al. 2005). Our results are consistent with the macroscopic observation
20 that salt passed completely through the porous ceramic during evaporation,
21 accumulating on the exterior of the experimental vessel. Backscattered elec-
22 tron images and SEM-EDS elemental maps of sample Z1 (Fig. 5) highlights
23 the extensively heterogeneous nature of these inclusion-rich vessels. Chlorine
24 is not shown in this map due to its even distribution and consistently low
25 concentration, contrasting with the discrete inclusions rich in sodium, silicon,
26 potassium, and iron.
27
28
29
30
31
32

33 (Insert Figure 5)
34

35 *3.6. Comments on Sherd Location*
36

37 Out of the 42 sherds analyzed in this study, 50% are body sherds (21
38 samples), 40% are rim sherds (17 samples) and 10% are base sherds (4 sam-
39 ples). Although most specimens originate from the body of the vessel, a
40 large portion of are rim fragments. These rim sherds were chosen and sup-
41 plied by our Chinese colleagues due to the relative ease by which they may
42 be typologically identified, and confirmed as having been involved in salt
43 production. In our experimental samples, we found that extracted chloride
44 content did depend on salt sherd location, with rim sherds containing the
45 most, and base sherds the least amount of chloride (Table 1; SI Table B.2).
46
47

48 We agree that sampling from the body of a vessel might eliminate extreme
49 values and standardize the data (Horiuchi 2011). However, it is necessary to
50 focus on visually identifiable and diagnostic sherds in order to comment on
51 the viability of this technique. The observed lack of a trend differentiating
52 salt production pottery from non-salt production pottery is detailed in this
53 paper for a mix of body, rim, and base samples. However, these results are
54 consistent for locational subsets of the data, and hold true for an analysis of
55
56
57
58

1
2
3
4
5
6
7
8
9 either just body or just rim sherds. The Horiuchi method may indeed be use-
10 ful to distinguish salt production pottery from body sherds only, but support
11 for such a claim is inhibited by the inability to confirm a significant amount
12 of body sherds as involved in salt production via a typological alternate line
13 of evidence.
14
15

16 17 **4. Conclusions**

18
19 Horiuchi et al. (2011) urge their experiments to be repeated with exam-
20 ples of pottery from other salt production sites made up of different ceramic
21 materials and using different sources of saline water to make salt. This study
22 reports such data from our own experimental specimens: two salt production
23 sites in China and one near a salt spring in Kimmswick, Missouri.
24

25
26 Two rounds of extraction and measurement cycles were carried out in
27 triplicate for each sample of powdered sherds. The first round, employing
28 distilled water as the solvent, dissolved any soluble, or unbound, chloride
29 in the samples, until the concentration of chloride released dropped below
30 the limit of detection of the ion selective electrode. In the second round, a
31 solution of ammonium fluoride was used instead, resulting in an exchange
32 reaction between the fluoride and chloride, releasing chloride bound to the
33 ceramic matrix into solution, where it may be detected (Fig. 1). This caused
34 a noticeable jump in the concentration of chloride compared to the negligible
35 amounts of the last cycle with distilled water (Fig. 4a). Horiuchi et al. see a
36 difference in the total amount of chloride extracted in this second round be-
37 tween salt and non-salt production pottery, thus claiming that their method
38 is a cost-effective way to distinguish between the two.
39
40

41
42 In our experiments, we see that chloride is indeed released upon extrac-
43 tion, but the origin is unlikely to be salt production. The same trend is
44 observed for vessels known to have been involved in salt making and those
45 that are not (Fig. 4). A potential source of bound chloride could be the ma-
46 terial of the pot, either from inclusions or from the ceramic body itself, and
47 not salt production activities. An analogous data set of sodium ion concen-
48 trations might serve to further substantiate these claims. It is interesting to
49 note that the total bound chloride extracted from the Kimmswick sherds, all
50 of which are shell-tempered, is an order of magnitude greater than the other
51 samples. This seems to indicate that inclusions could be a likely source of the
52 bound chlorine. We contend that the Horiuchi method is not a reliable way

(a)

(b)

Figure 4: (a) Chloride recovered per extraction for three salt production sherds. Extractions 1-5 are with DI water, removing unbound chloride. Extractions 6-13 are with 0.25M NH_4F , removing the supposed permanently bound chloride. (b) Chloride recovered per extraction with NH_4F for salt as well as non-salt production pottery samples. Dotted line is the limit of detection. Error bars indicate one standard deviation from the average of three trials.
