Abstract (100-200 word limit)

This work demonstrates the application of a 3D culture system, which is known as **C**ells-**i**n-**G**els-**i**n-**P**aper or CiGiP, in evaluating the response of lung cancer cells to ionizing radiation. This system has four attributes: (i) multiple layers of paper, containing cell-embedded hydrogels, are assembled into a stack to form a thick (~800 μm) tissue-like construct, (ii) the metabolism of the cells, coupled with the boundary conditions imposed by an impermeable holder, generate a gradient of oxygen and nutrients that decreases monotonically in the stack, (iii) the construct has no peripheral components (e.g., pumps, tubing), that fits easily in an irradiator, and (iv) the construct can be disassembled into individual layers, allowing for the quantification of cellular phenotypes based on their position within the stack. With increased distance from the source of oxygenated media, cells show increased levels of hypoxia-inducible factor, decreased proliferation, and reduced sensitivity to ionizing radiation. The multi-layer culture setup for CiGiP also distinguished differences in the radiosensitivity of three isogenic variants of A549 cancer cells, which have known differences in their metastatic behavior *in vivo*. The CiGiP system can, therefore, capture aspects of radiosensitivity of populations of cancer cells related to mass-transport phenomenon inaccessible in traditional culture systems.

1. Introduction

In the United States and many developed countries, the overall 5-year survival rate of a patient with lung cancer is estimated to be between 15 to 20 % [1, 2]. One-third of lung cancer patients are diagnosed at an advanced stage, and radiation therapy remains a preferred strategy for targeting tumor cells because these cells are known to possess compromised DNA repair machinery, and often proliferate at higher rates than normal cells [3-5]. The mechanism by which cells die from radiation therapy is believed to result from damage to DNA; ionizing radiation can damage DNA directly by inducing single- or double-strand breaks, or indirectly by generating free radicals that subsequently react with DNA [6-15]. While the ultimate goal of radiation therapy is cell death, cells can respond to ionizing radiation in three ways: (i) repairing the damage directly; (ii) undergoing cell cycle-arrest, which can lead to irreversible arrest (called senescence); or (iii) inducing programmed cell death (apoptosis) [9, 16, 17].

Oxygen plays a significant role in radiation therapy and is believed to act as a sensitizer for malignant cells to radiation. In contrast, hypoxic cells are often associated with poor outcomes and tumor recurrence [18-22]. To support the metabolic needs of cells for oxygen (O_2), cells should be no more than $150 - 200$ μm away from a capillary [23-25]. Beyond this distance, cells receive inadequate concentrations of oxygen and other molecules (e.g., glucose, autocrine factors) [26]. Subpopulations of cells with varying phenotypes arise in the gradients of molecules that form within the tumor. Well-oxygenated cells, which are closest to a well-perfused blood vessel, undergo aerobic respiration. Poorly-oxygenated cells, which are further from the blood vessels, cope with

the decreased oxygen tensions by switching from aerobic to anaerobic metabolism. This metabolic switch is mediated by hypoxia-inducible factor (HIF) [27-31], transcription factors which regulate the expression of genes related to cancer cell survival such as glycolysis, angiogenesis, and invasion/metastasis [27, 32-34]. Cells that adjust to these hypoxic conditions in a tumor have also been associated with the ability to resist both chemotherapy and radiotherapy [19, 22, 34-37]. Elucidating the mechanisms by which cancer cells survive after radiation therapy is key to discovering novel therapies to improve outcomes and prevent tumor recurrence for patients undergoing these treatments.

Current *in vitro* models in radiobiology evaluate cellular response based on changes in either metabolism or proliferation following exposure to radiation. These models are either cells grown in 2D as a monolayer, or in 3D as spheroids or embedded in hydrogel slabs. While 2D cultures are easy to establish experimentally, they fail to mimic many aspects of a tissue because the cells lack the structural features of a tissue: the 3D contacts formed between adjacent cells; 3D contacts between cells and the extracellular matrix; and 3D structural features that limit the mass transport of molecules (e.g., oxygen, glucose, lactate, and carbon dioxide) within the culture environment [38, 39]. These factors are crucial to the response of cells to chemo- and radio-therapy [40]. Spheroids provide a more realistic 3D microenvironment for cells than monolayer cultures do because: cells within the spheroids are able to participate in cell-to-cell interactions, and spheroids can form a diffusion-limited environment in which cells receive different concentrations of oxygen, other nutrients, or drugs as a function of their location. Due to these properties, models of diffusion in solid tumors are often based on

studies with spheroids [41-44]. The analysis of spheroids, however, can be challenging because: (i) dissociation of the intact spheroid into a suspension of single cells prevents spatial analysis of the heterogeneity in the spheroid, (ii) histology requires fixation of cells, thus preventing further culture of these cells, and (iii) the heterogeneity in the size of the spheroids can affect the reproducibility of the assay (i.e., drug and radiation assays).

To address the issues in 3D cultures for radiation biology, we adapted **Cells-in Gels-in-P**aper, or CiGiP, [45-47] to evaluate the response of cells to increasing doses of ionizing radiation. CiGiP is a 3D cell culture system consisting of a stack of layers of paper, which are patterned to contain hydrophilic zones surrounded with hydrophobic borders. Cells suspended in a hydrogel are pipetted into these hydrophilic zones, and can be cultured in the paper-based scaffolds for prolonged periods of time. CiGiP provides a culture environment that mimics some of the features of tumor tissues including (i) cell-cell and cell-ECM interactions, and (ii) 3D structure that influences the transport of molecules (e.g. oxygen, glucose, proteins and other waste products); these aspects are crucial to the viability of cells [45, 47, 48]. We used sheets of a paper-plastic construct with a thickness of ~130 μm (Fig. 1A) to support the cell-laden gels. The sheets were stacked to form thick (~800 μm), tissue-like constructs, which were placed in an acrylic holder. The geometry of the holder allowed us to control access of fresh medium (e.g., oxygen, glucose, other nutrients) to the stack, thus generating monotonically decreasing gradients—from top to bottom of the stack—not only of these nutrients, but also of the factors being secreted by the cells (e.g., carbon dioxide, lactate, cytokines). The format of

the CiGiP system we used in this study forms an environment that mimics two features of a poorly vascularized tumor *in vivo*: (i) Cells at the top of the stack are proximal to the region of the holder containing a series of holes, which provide access to the source of fresh medium; these cells experience an environment similar to cells in a tumor that are near a blood vessel (i.e., in a normoxic environment). (ii) Cells at the bottom of the stack do not have access to fresh medium; these cells experience an environment similar to cells in a region of a tumor that is far from a blood vessel (i.e., in a hypoxic environment). Isolation of the cells from the different regions of this tumor model do not require histological sectioning–layers can be de-stacked at the end of an experiment simply by peeling apart the layers of paper; this ability allows us to evaluate a variety of phenotypes of the cells as a function of the distance from the source of medium (in ~130–µm increments, based on the thickness of each sheet in the stack), and hence the distance-dependent gradients (e.g., oxygen, nutrients, growth factors, waste products) formed in the stack. In this work, we used multi-layer 3D culture to demonstrate that the radiosensitivity of cells is driven by proliferation rate.

2. Materials and Methods

2. 1. Materials and Reagents

Polvinyl sheets with a thickness of ~130 µm were obtained from Warp Bros. (Chicago, IL). Whatman 105 lens paper with a thickness of ~ 40 µm was purchased from GE Healthcare Biosciences (Pittsburgh, PA). Poly(methyl methacrylate) (PMMA) were purchased from McMaster-Carr (Princeton, NJ) and machined to prepare the custom-built

holders used in this work. We purchased the A549 cells from American Type and Culture Collection (Manasas, VA). Supplies for cell culture and cell labeling such as Dulbecco's Modified Eagle Medium (DMEM), penicillin-streptomycin, TrypLE™ Express, and Click-iT® EdU were purchased mostly from Life Technologies (Grand Island, NY). Fetal bovine serum (FBS) was purchased from HyClone (Logan, Utah), Matrigel (growth factor-reduced) was purchased from Corning (Tewksbury, MA), and RIPA buffer was purchased from Teknova (Hollister, CA). For immunoblotting, primary antibodies were purchased from Cell Signaling Technologies (Danvers, MA) and R&D Systems (Minneapolis, MN); secondary antibodies and Odyssey® blocking buffer were purchased from LI-COR Biosciences (Lincoln, Nebraska).

2.2. Fabrication of PVC-lens paper composite sheets

We used a Graphtec Craft ROBO Pro craft cutter (Irvine, CA) to cut the design in the sheets of polyvinyl chloride (PVC); the pattern containing perforations (~ 3 mm in diameter) was designed in Illustrator C4 (Adobe) and is available upon request. We used a heat press to melt and sandwich the patterned sheet of polyvinyl chloride (PVC) between two sheets of Whatman 105 lens paper (Fig. 1A). We pressed the sheets together at 215 °C in three to four cycles of 10-15 seconds to form a single composite sheet (See Fig. S-1). The thickness of the single-layer composite sheet is ~130 um. We routinely patterned the composites to contain ten 3-mm holes, which are referred to as the "zones" of the composite. The composites were placed in a glass petri dish and autoclaved. The

autoclaved composites were air-dried in a laminar flow hood, exposed to UV light for 1 hour, and then stored in a sealed sterile container.

2. 3. Cell culture conditions and seeding of cells into the composite sheets

We cultured all cell lines in vented tissue culture flasks in DMEM with 5% FBS and 1% Penicillin-Streptomycin and then passaged them every 4-6 days until use. Unless stated otherwise, the cultures were maintained in 5% CO_2 at 37°C. For each experiment, we detached the cells from the flasks by treatment with TrypLE™ Express (5mins at 37°C), washed them in media, and then pelleted them by centrifugation at 1500 rpm. We prepared a suspension of cells with cold Matrigel (4°C) at a concentration of 2,000 cells/ µL, unless stated otherwise. The suspension was kept on ice to avoid the gelling of Matrigel. We spotted 1 µL of the suspension into each zone of the composite with a micropipette and then incubated the composite into a 6-well plate containing warm (37°C) media. The cold suspension wicks into the composite, fills up the zone, and then forms a gel upon warming (37°C) in media. To ensure that the Matrigel gelled completely, and that the cells recovered from being in a cold temperature, we incubated the sheets with zones containing cell-embedded gels for at least 12 hours before conducting further experiments such as stacking or exposure to radiation.

2.4. Fabrication of the PMMA holder and stacking of cell-containing composite sheets

The PMMA holders comprised of a perforated top piece with holes that correspond to the position and diameters of the zones of the composite and a solid bottom

base, were custom machined (Figure S-1). Both pieces of the holders were also equipped

with threaded holes to fit screws, which not only guide the alignment of the individual

sheets of the composite, but also ensure the sheets are held in place after stacking. The

holders were placed in a glass petri dish and autoclaved. The holders were dried in a

laminar flow hood and kept in a sealed container until use.

Using the PMMA holder, we stacked the six sheets of the composite to prepare a

multi-layer 3D culture. We then incubated these multi-layer cultures in petri dishes

containing (37 °C) warm media. To ensure that the medium covered the top of the multi-

layer culture completely, we used a tip of the micropipette to remove any air bubbles,

which formed on top of the holders during stacking. Unless stated otherwise, we

incubated the multi-layer cultures for at least four days before irradiation to ensure a

gradient in oxygen and nutrients formed within the stack.

2.5. Irradiation

The samples were exposed to ionizing radiation using a GammaCell 40 Extractor

Cesium-137 irradiator, which emits radiation at the rate of $1Gy \cdot min^{-1}$ (Best Theratonics,

Ontario, Canada). The irradiated samples were incubated for an additional 6 to 7 days

before measurement of metabolic activity, senescence, and proliferation rates.

2.6. CellTiter-Glo® (CTG) Assay

Multi-layer cultures were de-stacked by disassembling the holder and separating the

individual sheets with tweezers. Each sheet was washed in 1X PBS (5 min, room

temperature), lysed in 1mL RIPA buffer (10 min, at 4°C) on an orbital shaker (at ~160

rpm), and then diluted the lysate (1:10 by volume) with 1X PBS. We transferred the

diluted cell lysate (100 µL/well) into the wells of a black 96-well plate with a clear

bottom. We prepared the CTG reagent by following the manufacturer's protocol. We

added CTG reagent (100 µL/well) into the wells containing the cellular lysates and

incubated them for 20 minutes, and measured the luminescence of the samples using a

Perkin Elmer Wallac Luminometer (Waltham, MA), or a BMG Labtech PHERAstar FS

microplate reader (Ortenberg, Germany). For each scaffold, we took eight measurements

(i.e., n = 8 wells) for CTG assay, calculated the average luminescence, and used this

average value in calculating for the % metabolic activity.

2.7. Senescence Assay

We recovered A549-GFP cells from the composite sheets by incubating the

samples in warm (37°C) Accumax for 30-45 minutes. Accumax degrades the Matrigel,

and releases the cells from the paper into the Accumax solution. The cells were pelleted

by centrifugation (~1500 rpm), and resuspended in culture medium (10,000 A549-GFP

cells/mL). We dispensed the resuspended cells into the wells of a 96-well plate (100 µL/

well) and cultured them overnight. We stained the senescent cells using Millipore

Cellular Senescence Assay Kit (Cat. KA002). Following the manufacturer's suggested

protocol, we aspirated the media out of the wells, washed the wells in 1X PBS (5 min),

incubated the cells in the provided fixative solution (diluted to 1X, 15 min), washed the

wells with 1X PBS (5 min), and incubated the cells in senescence-associated β-

galactosidase staining solution in a CO_2-free incubator (24 hours at 37°C). We aspirated the staining solution and then washed the wells in 1X PBS (5 mins × 3). We collected images of the samples using a bright field microscope and counted all the senescent cells, which stained blue. We also collected images of the cells using a fluorescence microscope and counted the total number of cells, which expressed GFP.

2.8. Proliferation Assay

We used Click-iT® EdU kit to label A549-GFP cells undergoing proliferation. In brief, we incubated the composite sheets in culture medium containing 10 µM EdU solution (24 hours at 37°C and 5% CO_2). The EdU-labeled samples were then fixed with 4% paraformaldehyde for 20 minutes, washed with 3% (v/v) BSA in 1X PBS (5 mins × 3), incubated in 0.5% (v/v) Triton X-100 (20 mins), washed with 3% (v/v) BSA in 1X PBS (5 mins × 3), and incubated in Click-iT® reaction cocktail for 30 minutes. The Click-iT® reaction cocktail, which contained Alexa Fluor® 594-conjugated azide, 4 mM copper (II) sulfate was prepared based on manufacturer's suggested protocol. The samples were washed once with 3% BSA in 1X PBS (5 min) and kept in 1X PBS (4°C). The composite sheets containing labeled cells were scanned with a Typhoon Gel Scanner. EdU was scanned using LPG filter, 532 nm (excitation) / 615 nm (emission), PMT value of 400 V, and resolution of 50 µm; GFP was scanned using 590 nm (excitation)/615(emission), PMT value of 400 V, and resolution of 50 µm; GFP was scanned using BPB1 filter, 473 nm (excitation) / 519 nm (emission), PMT value of 300 V, and resolution of 50 µm.

2.9. Western Blot

Multi-layer cultures were de-stacked by disassembling the holder and separating the sheets with tweezers. Each sheet was washed in 1X PBS (5 min, room temperature) and then lysed in 500 μL RIPA buffer (30 min, at 4°C) on an orbital shaker (at ~160 rpm). We quantified the total protein content for each lysate using (bicichoninic acid) BCA Assay, following manufacturer's protocol. For each sample, we prepared the protein solution containing approximately 0.5 μg/μL protein, 1X NuPAGE® sample reducing buffer, and 1X NuPAGE® LDS sample buffer in 1X PBS. We heated the protein solutions at 100°C for 10 mins and centrifuged them at 10,000 rpm (10 min at °C). We loaded 20 μL of the protein solution per lane in a NuPAGE® 4-12% Bis-Tris Gel and ran the gels with 1X NuPAGE® MOPS SDS Running Buffer. The proteins were transferred electrophoretically from the gel to a Bio-Rad Trans-Blot® Turbo™ 0.2μm PVDF transfer membrane using a Bio-Rad Trans-Blot® Turbo™ transfer system. We blocked the membranes with an Odyssey blocking buffer for 1h, incubated them in the primary antibody solution containing anti-HIF-1α (diluted 1:1000), anti-CAIX (diluted to 1:200) anti-GAPDH (diluted 1:1000) in blocking buffer (overnight at 4°C) on a slow rocking platform. We washed the membranes containing the labeled bands with TBST (5 min × 3) and incubated them in the secondary antibody solution containing IR Dye 680-conjugated donkey anti-rabbit IgG (diluted 1:10,000) in blocking buffer (1 hour at 20°C). We imaged the membranes using Odyssey CLX (LI-COR Biosciences) and analyzed them using Odyssey 2.1 Software. See Table S-3 for the description of the antibodies in detail.

2.10. Immunoassay for Quantification of Levels in Cells

We seeded A549, A549-HGF, or A549-HGF-M cells into black-walled 96-well plates with clear bottom at 2,000 cells/ well, and cultured overnight. We assayed the HGF levels using a Quantikine® ELISA from R&D Systems which utilized a sandwich immunoassay method, and followed the protocol recommended by the manufacturer. The HGF microplate (i.e., a well plate pre-coated with monoclonal antibodies specific to human HGF), assay diluent, wash buffer, HGF conjugate (polyclonal antibody specific to HGF conjugated to horseradish peroxidase), substrate solution (solution of horseradish peroxidase and chromogen tetramethylbenzdine) and stop buffer (2N sulfuric acid) were all included in the kit. In brief, we transferred 50 µL of the media into the microplates (HGF microplate) containing 150 µL assay diluent, incubated the media in the microplate for two hours, washed the microplate with wash buffer four times, added the HGF conjugate into the HGF microplate for two hours, washed the microplates four times, incubated in substrate solution for 30 minutes, then added the stop solution. If the culture medium contained HGF, the color of the solution in the microplate changes from blue to yellow. The absorbance of the solutions was measured using Spectramax at 450 nm. The absorbance read at 450 nm was corrected by subtracting the absorbance at 540 nm to account for the optical imperfections of the well plate. The HGF concentration was calculated from the best-fit line obtained from a standard curve.

3. Results

3.1 Design of Paper-Based Composite to Support 3D Culture

Previously described scaffolds in the **C**ells-**i**n-**G**els-**i**n-**P**aper (CiGiP) [46, 49-51] and **C**ells-**i**n-**G**els-**i**n-**M**esh (CiGiM) [48] culture systems used sheets of paper (or mesh) that were patterned to contain an array of hydrophilic regions separated by hydrophobic borders. In this work, we used a scaffold that requires fewer steps to fabricate than the paraffin film-patterned mesh sheet, but has a hydrophobic barrier that prevents the lateral diffusion of oxygen more efficiently than wax-printed paper [46, 48]. We fabricated a composite material by sandwiching a ~130 μm-thick sheet of polyvinyl chloride (PVC), perforated with an array of holes (3 mm in diameter), between two sheets of Whatman 105 lens paper (Fig. 1A). We chose sheets of lens paper because it is thin (~ 40 μm in thickness) and contains a large void volume (~70 %). Using a heated press (~215°C), we melted the PVC plastic into the paper layers to form a single composite sheet. The perforated spaces in the PVC formed cylindrical regions (referred to as "zones") in which we seeded the cells. We routinely patterned the composites to contain ten zones; these zones allowed for replicates in a single experiment, and provided a convenient means of aligning the cell-embedded gels during the stacking process. We sterilized the composite sheets using an autoclave.

3.2. Modulation of Oxygen Availability in Cells Supported on Composite Sheets

Gradients of nutrients (e.g., oxygen, glucose), waste products (e.g., CO_2, lactate), and secreted factors form monotonic gradients in the individual layers and throughout the stacked structure. These gradients are controlled by three parameters: (i) the rates in

which cells in each layer consume the available nutrients and produce waste products; (ii) the number of layers in the stack determines the characteristic thickness over which the transport of molecules will occur; and (iii) the rate of diffusion of molecules into the sheets (from medium, or from adjacent layers) by diffusive mass transport [52]. In a single-layer composite sheet (Fig. 1A) cells receive adequate amounts of oxygen and nutrients because molecules can diffuse efficiently from the bulk medium into the zones of the composite from both sides of the layer. This configuration, which we refer to as "single-layer culture" (Fig. 1A), is comparable to the region of the tumor near a functional blood vessel and contains well-oxygenated cells. In a stack of composite sheets containing cell-embedded gels, a custom-built acrylic holder keeps the sheets in conformal contact. The holder consists of two main parts: (i) a solid bottom plate, which blocks the mass transport of soluble factors at the bottom of the stack; and (ii) the top plate, which was machined with an array of holes corresponding to the zones in the composite. The top plate provides access of the oxygenated media to the top of the stack. In this work, we prepared multi-layer stacks of six composite sheets, each containing cell-embedded gels. For convenience, we refer to these layers as L1, L2, L3, L4, L5, and L6, where L1 is the topmost layer, and is in contact with the oxygenated media. We refer to cultures in this multiple layer configuration as "multi-layer cultures" (Fig 1B).

3.3. Sensitivity to Radiation Decreases with Increasing Cellular Densities

To determine if the density of cells in single-layer cultures affects their response to radiation, we prepared single-layer cultures of A549 cells with varying cellular

densities, exposed them to ionizing radiation, and measured the reduction in metabolic activities of the samples as a result of irradiation. We seeded each zone by spotting the suspensions of cells in Matrigel with a micropipette onto the top sheet of lens paper and allowing the suspension to wick into the entire scaffold; zones contained concentrations of A549 cells ranging from 2,000 cells/zone to 80,000 cells/zone. We cultured the cells overnight and irradiated these samples with doses ranging from 0 to 16 Gray in a cesium-137 irradiator. One Gray (Gy) is a measure of absorbed dose of radiation in the international system (SI) of units, and is defined as the amount of energy absorbed by a kilogram of matter in $J\ kg^{-1}$; for an irradiator delivering a dosage of $1\ Gy \cdot min^{-1}$, we exposed samples for either 2 or 16 mins to receive dosages of 2 Gy or 16 Gy, respectively. We measured the metabolic activity of the cells six days post-irradiation using the CellTiter-Glo® (CTG) assay, which quantifies the level of ATP present in cells [53]. The sensitivity of cells to radiation (Eq 1 and 2) decreased with increasing seeding density of cells (Fig. 2A). We compared the metabolic activities of an irradiated sample and a non-irradiated sample; the zones in both samples were seeded at the same densities. Six days post-irradiation, the metabolic activity of samples seeded at 2,000 cells/zone decreased by up to 81% (values ranged from 78% to 85% for n = 3 scaffolds) when irradiated with 16 Gy. The metabolic activity of samples seeded at a density of 80,000 cells/zone irradiated with the same dose decreased by less than 29% (values ranged from 26% to 35% for n = 3 scaffolds). These results suggest cells seeded at higher densities are more resistant to radiation and single-layer cultures can accommodate high seeding densities.

3.4. Increases in Cellular Density Decrease Cellular Proliferation

Exposure to ionizing radiation can damage DNA [3, 6, 7, 54, 55], and the continued replication of unrepaired and defective DNA can result in cellular death [55]. We hypothesized that the reduced sensitivity of cells to radiation for increasing seeding densities correlated with the rate in which these cells proliferate. To test this hypothesis, we seeded A549 cells at a density of 2,000 cells/zone or 100,000 cells/zone in the single-layer composite sheets, and cultured the layers for seven days. We then incubated the samples in media containing 5-ethynyl-2´-deoxyuridine (EdU), a thymidine analog that intercalates into the DNA of cells undergoing replication [56], to label proliferating cells. We then fixed and visualized the EdU–labeled cells with Alexa Fluor® 488-conjugated azide [56]. Confocal fluorescence micrographs (Fig. 2B) revealed a higher fraction of proliferating cells in single-layer cultures seeded at low density than those seeded at high densities. This result is consistent with the hypothesis that radiation-induced damage to cells can be enhanced by increasing the population of cells undergoing proliferation.

3.5. Radiation-Resistant Cells in Oxygen-Rich Environments are Mostly Non-Proliferating and Senescent.

There are at least two possible explanations for the metabolically active cells that remain after irradiation with as much as 16 Gy: (i) the surviving cells were senescent at the time of irradiation, or became senescent after irradiation [57], or (ii) the surviving cells retain properties of "cancer stem cells" that allow them to repair DNA damage during irradiation [58-61]. To characterize cells appearing to survive high doses of radiation in well-oxygenated (i.e., single-layer) cultures, we cultured A549-GFP in single-layer composites (seeded at 2,000 cells/zone) overnight, irradiated them with doses ranging from 0 to 16 Gy, and then incubated the irradiated cells with either (i) EdU, or (ii) X-Gal (5-bromo-chloro-3-indolyl-β-D-galactopyranoside), a chromogenic substrate for β-galactosidase, a marker of senescent cells.

3.5.1 Most of the surviving cells do not proliferate

To approximate the ratio of the number of proliferating cells to the total number of cells that survived irradiation, we compared the fluorescence intensities of EdU-labeled cells (proliferating A549 cells) and GFP (surviving A549 cells). The graph in Fig. 2C shows this ratio decreased with higher dosages of radiation. This result indicates that the surviving cells in the cultures exposed to at least 8 Gy were non-proliferating, or that they have lost their ability to proliferate.

3.5.2. Most of the surviving cells are senescent

To determine if the surviving cells were senescent, we incubated the cells in X-Gal and counted the cells which stained blue. The X-Gal substrate is hydrolyzed by β –

galactosidase, a senescence-associated enzyme, to generate a by-product that readily dimerizes to form a blue precipitate [62]. Counting blue-colored cells in the single-layer scaffolds can be difficult with bright-field microscopy [45, 48] because the cellulose fibers of the paper layers scatter light. To count the number of senescent cells more accurately, we recovered the cells from the paper by enzymatically degrading the Matrigel with Accumax, resuspending the cells in media, and dispensing the suspension of cells into 96-well plates (1,000 cells/zone). We then cultured the recovered cells for 48 hours before staining with X-Gal. Fluorescence and bright-field images (Fig. 2D) showed two indications that a fraction of cells were senescent [62, 63]. (i) The fraction of X-gal positive cells increased with increasing dosage of radiation. The graph in Fig. 2D indicates that the number of senescent cells (i.e., % XGal positive cells) increased with increasing radiation dosage; the average fraction of senescent cells increased from 8 % (values ranged from 5 % to 18 % for n = 3 scaffolds) in non-irradiated cultures to 82 % (values ranged from 72 % to 83 % for n = 3 scaffolds) in cultures irradiated at 16 Gy. (ii) The size of the cells increased with radiation dosage, also indicating a senescent phenotype (Fig. 2D) [62, 63]. The majority of cells that survived radiation dosages of at least 8 Gy, therefore, were senescent. Although this result does not preclude the presence of a subpopulation of cancer stem cells, the existence of this subpopulation was not experimentally validated.

3.6. The Availability of Oxygen and Nutrients Influence Radiation Sensitivity in Multi-layer Cultures

To determine if cells cultured in layers of the multi-layer stack have different sensitivities to irradiation, we assembled in parallel two sets of 3D cell culture in stacks —one set of irradiated stacks (i.e., treated stacks), and one set of non-irradiated stacks (i.e, control stacks), irradiated the stacks, and measured the reduction in the metabolic activities of each layer of the stacks as a result of irradiation. We prepared each stack by seeding 2,000 A549 cells/zone in the composite sheets, culturing the sheets overnight as single layers, and then assembling multi-layer stacks composed of six layers. We cultured the stacks for four days (Fig. 3A) before exposing the treated stacks with 8 Gy to ensure a gradient of oxygen formed in the stacks. Each stack was cultured for an additional seven days post-irradiation before they were de-stacked and analyzed using CTG assay (Fig 3B). Unless stated otherwise, radiation experiments for all multi-layer cultures were carried out as described above.

We evaluated the radiation response of cells in the stacks by comparing the metabolic activity of each layer from the irradiated stack with its corresponding layer from the non-irradiated stack (e.g., we compared the number of metabolically-active cells from L1 of the irradiated stack with the number of metabolically-active cells from L1 of the non-irradiated stack). The reduction in metabolic activity in layers that responded to radiation was calculated using Equations 2 and 3.

We found that the metabolic activity of cells in layers closest to the source of oxygen and media was reduced the most after irradiation while layers at the bottom of the

stack did not decrease (Fig. 3B). The metabolic activity of the cells in L1 and L2 decreased by 48% (values ranged from 35 % to 59 % for n = 6 scaffolds). The metabolic activity in L3 decreased by 37% (values ranged from 17 % to 52% for n = 3 scaffolds). No significant decrease was observed in L4 and L5. The responsiveness of the cells in L6 to irradiation is unclear because the mean is smaller than about twice the standard error (i.e., $1.96 \times$ standard error) for L6 of the non-irradiated stack (Table S-1a)[64]. These results are consistent with the response observed in solid tumors *in vivo*: cells in close proximity to blood vessels (i.e., < 200 μm) respond to radiation, and cells residing beyond this distance, which is believed to be a hypoxic environment, are likely insensitive to irradiation [32, 65-67].

We hypothesize the insensitivity of these cells to radiation is due to decreased proliferation caused by the deprivation of oxygen: cells in the uppermost layers consumed most of the oxygen diffusing into the stack, and consequently, deprived cells in the lower layers of the stack of the oxygen required to support proliferation. To verify this hypothesis, we labeled the proliferating cells with EdU in the non-irradiated multi-layer culture of A549-GFP cells after 11 days of culture. Confocal images of the stained layers showed qualitatively a similar observation; the proliferation of cells is highest in L1 and is lowest in L6 (Fig 3C).

3.7. Hypoxia Markers Expressed in Cells Increases with the Distance of Cells from the Source of Oxygenated Media

Our irradiation data for the multi-layer stacks showed that the sensitivity of cells to ionizing radiation decreased with increasing distance from the source of the oxygenated medium. To verify the cells were experiencing different oxygen tensions, we measured the expression of two markers for hypoxia in each of the six layers of the multi-layer 3D culture: (i) hydroxy-HIF-1α, the predominant form of HIF-1α in cells when oxygenated (upon de-stacking) [68], and (ii) carbonic anhydrase 9 (CAIX), a HIF-1 inducible protein [69-71]. We stacked six sheets of lens paper-PVC composite containing overnight cultures of A549 (seeded at 2,000 A549 cells/zone) in an acrylic holder, cultured the stack for 4 days, disassembled the stacks into separate layers, and analyzed lysates for expression of hydroxy-HIF-1α and CAIX. To account for differences in total protein content in each lysate, we used glyceraldehyde 3-phosphate dehydrogenase (GAPDH) as a control to normalize the signal of hydroxy-HIF-1α and CAIX to the total protein content. Table S-3 lists the brand and specificity of primary antibodies, and the secondary antibody used for immunoblotting. Images of the membrane from the Western blot showed an increase in the intensity of hydroxy-HIF-1α and CAIX band from L1 to L6 (Fig. 4A). The ratio of the intensities of the bands of hydroxy-HIF-1α to GAPDH also increased from L1 to L6 (Fig. 4B). These results support our assumptions about multi-layer 3D cultures when nutrients, oxygen specifically, can only diffuse from one side of the cultures: The cells receive decreasing levels of oxygen, resulting in lower rates of proliferation than the cells receiving adequate oxygen, and therefore show resistance to ionizing radiation (Figs. 3A-C).

3.8. Multi-layer Cultures Provide a System that can Distinguish Differences in Radiation Response of Cell Lines that Secrete Different Levels of Hepatocyte Growth Factor

We compared the radiation sensitivity of three isogenic cell lines, the parental A549 cell line and two variants expressing different levels of hepatocyte growth factor (HGF): A549 cells that overexpress HGF (A549-HGF), and a sub-clone of A549-HGF cells that was collected from a metastatic tumor in the lung of a xenografted mouse (A549-HGF-M). The parental A549 cells is known to be less metastatic *in vivo* than the other two A549 variants [49]. Using sandwich-based ELISA, we found that the A549 parental cell line did not secrete a detectable level of HGF, while both A549-HGF and A549-HGF-M secreted significant levels of HGF (Table 1). HGF is known to increase cellular migration and proliferation [72, 73]. When cultured in a monolayer (Fig. 5A) or when cultured in a single-layer composite sheet (Fig. 5B), the three lines of A549 cells responded similarly to increasing dosages of radiation.

We prepared two sets of stacks for each cell line; one set was irradiated, and another set was not irradiated. We compared the metabolic activity of each layer of the stack seven days post-irradiation. Response to radiation is indicated by the reduction in the viability in the layer of the irradiated stack from its corresponding layer of the non-irradiated stack. When cultured in the multi-layer stacks, cells that released the most HGF responded the least to irradiation (Fig. 5C): (i) A549-HGF-M cells, independent of their location in the stack, have no clear response to radiation (Tables S-2e,f); (ii) A549-HGF have an observable response in L1 (a distance of ~150 μm from the source of fresh

media) with 18 % in reduction in metabolic activity (ranging from 13 % to 30 % for n =3 scaffolds) (Tables S-2c,d) ; and (iii) wild-type A549 cells have a clear response in L1 through L3 (a distance of ~400 μm away from the source of fresh media) (Tables S-2a,b). We hypothesized that the different HGF levels in the three cell lines attributed to the observed differences in radiosensitivity by affecting the proliferation or migration rate of the cells.

To better understand the effects of migration and proliferation during culture, we analyzed the irradiated multi-layer stacks of A549-HGF-M at shorter time-points. The metabolic activity of cells in the upper layers showed an observable decrease in viability, two days and four days post-irradiation (Fig. 6A); and by day six post-irradiation, the number of viable cells in each layer of the stack matches that of a stack that was not irradiated. These results support our hypothesis that after irradiation, cells can repopulate by proliferating rapidly, and/or migrating from the lower layers of the stack to the upper layers of the stack; both events might account for the apparent unresponsiveness of A549-HGF-M cells to radiation seven days after irradiation.

To decouple the contribution of migration from proliferation in multi-layer cultures of A549-HGF-M cells, we separated the layers with sheets of polycarbonate filters with 0.20 μm diameter pores; these pores prevented the migration of cells to adjacent layers during culture, but allowed diffusion of molecules (e.g., oxygen and glucose) into the stack. The graph in Fig. 6B indicates that blocking migration does not enhance the sensitivity of cells to radiation, and thus suggests that the unresponsiveness

we observed in long-term cultures of A549-HGF-M cells was due to proliferation, and not migration.

These results, therefore, demonstrate that multi-layer cultures can serve as an *in vitro* system for studying biological processes such as radiation response, while taking into account factors that are native to tumor biology such as limitations of mass transport and migration of cells.

4. Discussion

The paper-based cell culture system we describe in this work offers many advantages over the monolayer or spheroid cultures currently used in radiation studies because: (i) millimeter-thick cultures can be generated by simply stacking the single-layer composite sheets; (ii) cells in the different layers of the culture can receive a gradient in nutrients, waste products, and drugs by restricting the diffusion of media from one side of the stack; (iii) each sheet in the stack can contain different types of cells and/or gels; (iv) the multi-layer stack can be sectioned easily by peeling the layers apart and does not require histology equipment; (v) the separated sheets can be analyzed optically or through the use of enzymatic assays; and (vi) the sheets can be patterned using the fabrication method described above to create multi-zone patterns that can be adapted for high-throughput assays [46, 48, 51].

Using this system, we were able to demonstrate *in vitro*, that decreasing levels of oxygen can reduce the proliferation of non-small cell lung cancer cells, and consequently, reduce the sensitivity of these cells to ionizing radiation. Increases in the expression of

hypoxia-inducible factor and CAIX with increasing distance from the source of oxygen

and media can also be observed in this system; a trend also observed in tumors *in vivo*.

Since HIF-1α in re-oxygenated tumors only has a half-life of less than one minute [74],

and cells within the stacks get re-oxygenated upon de-stacking, we expect that most of

the HIF-1α expressed in cells, even at the lower regions were hydroxylated [68]. It is

therefore not surprising that the expression of hydroxy-HIF-1α is lowest in L1, and

highest in L6, as HIF-1α is targeted for degradation following hydroxylation and

ubiquitination [27-30]. These results are in agreement with the widely held view that

gradients of oxygen present in a tumor directly affect the sensitivity of the cells to

radiation, but emphasize that the presence of these oxygen gradients are as, if not more,

influential post-treatment than during treatment.

The current disadvantage of the system is that any kind of analysis requires the

system to be disassembled, and consequently the gradients in the stack to be destroyed, if

multiple measurements are taken over time. Incorporating sensors into the layers, for

example, printing electrodes to measure oxygen concentration or pH, can be an approach

to monitor cellular activities in the different layers without disassembling the stack, and

hence keeping the fidelity of the molecular gradients formed in the stack. Integrating a

sensing system to the 3D culture system that could quantify oxygen concentration within

the stack will enable direct assessment of the influence of oxygen levels on cellular

phenotype.

We believe this approach can be further used to evaluate the response of different

tumors under different oxygen tensions to radiation, while taking into account differences

in the rates of proliferation and migration of the cells within the population. The dynamics would be particularly interesting when studying the heterogeneous populations of cells found in the tumor environment (e.g., cancer stem cells and stromal cells). For example, we have used paper-based 3D culture to model an orthogonal system—cardiac ischemia, and study the interactions that arise between cardiomyocytes and cardiac fibroblasts [47]. The study of the interaction between tumor cells with stromal cells, co-cultured in this multi-layer culture system, is among our group's current work. We believe this system also has the potential to be used as an *in vitro* assay for evaluating drugs that target hypoxic cells, or to evaluate the resistance of cells to radiation over long periods (i.e., weeks) post-treatment.

5. Conclusion

This work describes a paper-based 3D culture system that can distinguish the sensitivity of cells to ionizing radiation, within gradients of small molecules of oxygen, nutrients, and autocrine factors, using a single setup. These gradients are also present in tumors *in vivo*, and recapitulating these factors *in vitro*, may more accurately predict tumor response to therapeutic treatments than conventional 2D and 3D culture systems.

Using this system, we were able to demonstrate *in vitro* that cellular proliferation, and sensitivity to radiation decrease with monotonically-decreasing gradients of oxygen and nutrients. This system therefore provides a unique ability to evaluate and distinguish the response of different cellular populations—rather than measure one collective cellular response—to radiation treatment. The simplicity of the CiGiP system, with minimal

required equipment, will enable users from a broad-range of disciplines to adopt this technology in their own radiation studies.

The radiation response, represented by the reduction in the metabolic activity of cells, was measured using the luminescence-based CellTiter-Glo® (CTG) assay. Data represent the ratio of the luminescence between irradiated to non-irradiated samples for n = 3 scaffolds. The luminescence value for each scaffold is an average of eight measurements (see supporting information for details of CTG assay) **(B)** Confocal fluorescence images of A549 cells stained with Click-iT® EdU Alexa Fluor® 488. Both images were taken at the same magnification. **(C)** Confocal fluorescence images of A549 cells stained with Click-iT® EdU Alexa Fluor® 594. The scale bar for all the images are found on the sample irradiated at 16 Gy—the top scale bar is for images at low magnification, while the bottom one is for images at high magnification. Graph showing the ratio of proliferating cells with surviving A549-GFP cells. The intensities of Alexa Fluor® 594 (proliferating A549-GFP cells) and GFP (surviving A549-GFP cells) were measured using a Typhoon scanner. Error bars represent the standard deviation for n = 10 zones. **(D)** Fluorescence (top) and bright field (bottom) images of A549-GFP cells labeled for senescence-associated β-galactosidase activity. All images were taken at the same magnification. Graph showing the percentage of senescent cells (stained with blue) with the total number of A549-GFP cells. Data points represent the % X-Gal for n = 3 wells.
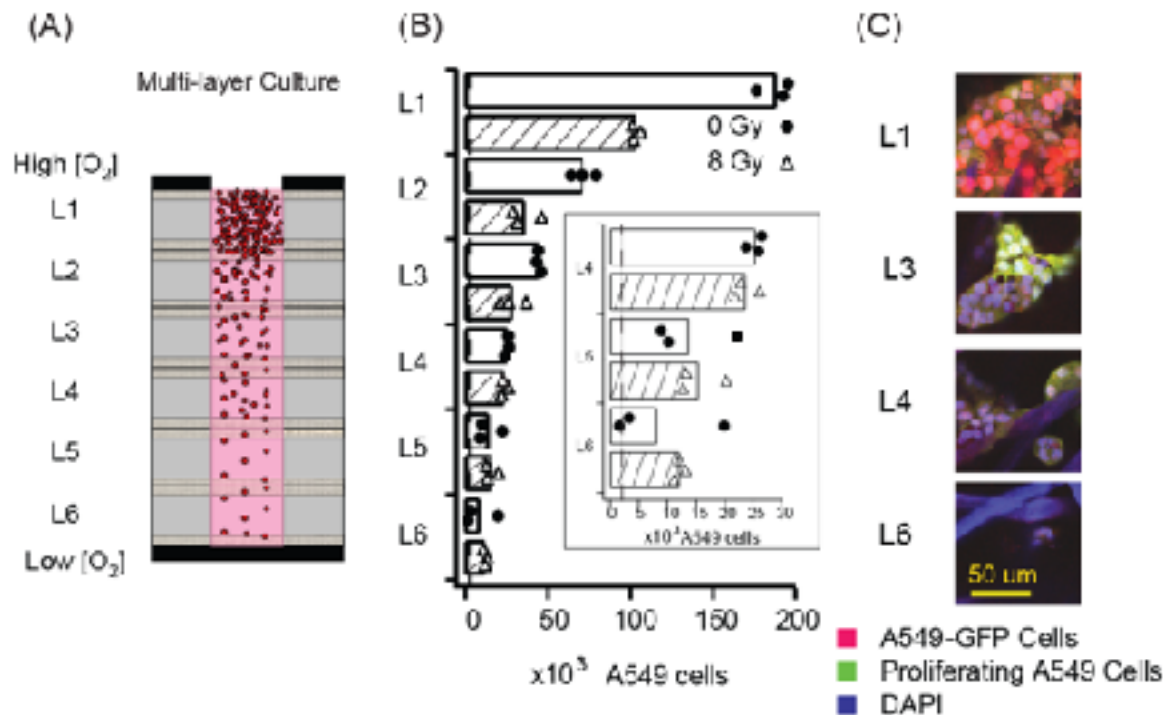

Figure 3. Radiation Response of Cells in Multi-layer Cultures of A549 Cells (A) Scheme representing a column of cells in a zone of the multilayer stack. Blocking the bottom of the stack with a plate impermeable to gases and small molecules limits the diffusion of molecules to the top of the stack. **(B)** Graph summarizing the number of metabolically-active cells in multi-layer culture of A549 cells from L1 to L6. Circular and triangular markers represent values obtained for each stack; bars represent the average for 3 stacks. The luminescence value for each scaffold is an average of eight measurements (see supporting information for details of CTG assay). (Inset) Enlarged graph for the viability of multi-layer cultures from L4 to L6. The broken lines indicate the seeding density of cells (2,000 cells/zone) in each layer. **(C)** Confocal fluorescence images of A549 cells in a non-irradiated, multi-layer culture showing decrease in the density of cells, and decrease in the incorporation of the proliferation stain, EdU (Click-iT® EdU Alexa Fluor® 594), as cells get depleted of oxygen (i.e., from L1 to L6).
Figure 4. Hydroxy-HIF1-α and CAIX Expression of A549 Cells in Multi-layer Cultures Using Western Blot (A) Images of blots of A549 lysates carried out for hydroxy-HIF-1α, CAIX and GAPDH (loading control). Lysates were collected from multi-layer cultures that were cultured for four days and then disassembled into separate layers. CAIX is a dimeric protein, and is the reason for the two bands in the Western Blot. **(B)** Graph summarizing the ratio of HIF and CAIX intensities to the normalization factor (the normalization factor was calculated from the ratio of the intensity of the band from GAPDH of each layer, to the intensity of the highest GAPDH among all the layers).
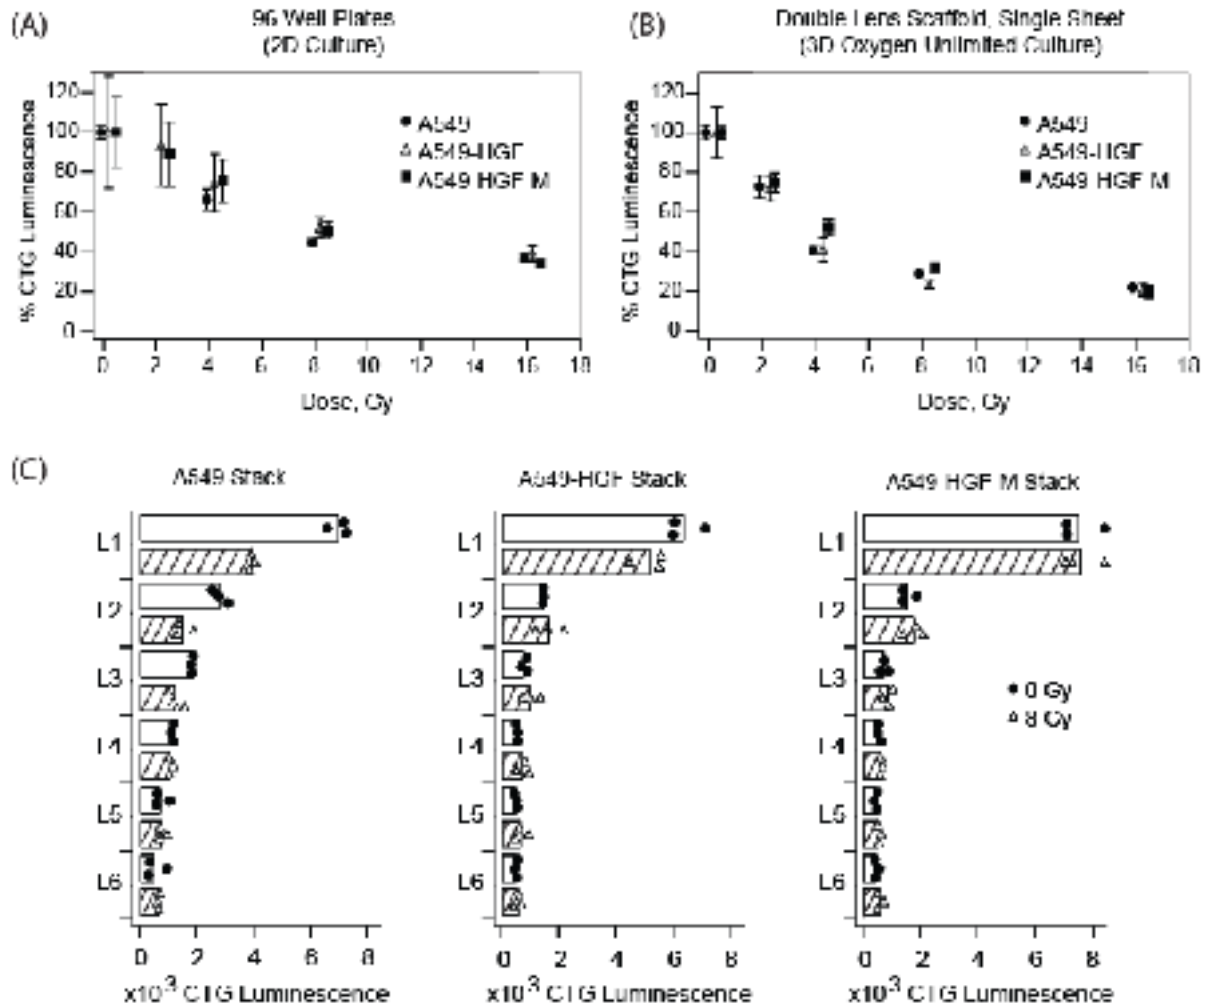

Figure 5. Radiation response for Lung Carcinoma Lines in Different Culture Systems.
Viability curves of A549, A549-HGF and A549-HGF-M in **(A)** 2D and **(B)** single-layer cultures.
Error bars represent the standard deviation for n = 6 wells (96-well plates), and n = 3 sheets
(PVC-lens paper composite). **(C)** Graphs summarizing the viability of A549, A549-HGF and
A549-HGF-M in multi-layer cultures. Circular and triangular markers represent values obtained
for each stack; bars represent the average for n = 3 stacks.

Figure 6. Radiation response of A549-HGF-M in Multi-layer Culture (A) Viability of multi-layer cultures of A549-HGF-M measured at different time points. **(B)** Viability of multi-layer cultures of A549-HGF-M with polycarbonate filters (pore diameter = 0.20 μm to block migration). (Inset) Enlarged graph for the viability of multi-layer cultures of A549-HGF-M from L2 to L6. Circular and triangular markers represent values obtained for each stack; bars represent the average for n = 3 stacks.

Table 1. HGF Levels Released from Overnight Cultures of A549 and A549-derived Lines

Cell Line	pg HGF / mL
A549	None Detected
A549-HGF	257 ± 36
A549-HGF-M	608 ± 71
