46 **ABSTRACT**

47 We reported the results of an isotopic study aimed at evaluating the medium to long-term effects of
48 different water qualities and deficit irrigation strategies on the ecophysiology of grapefruit in a 7-
49 year-old plantation in SE Spain. For a better understanding of the interaction between nitrogen and
50 salts from reclaimed water, RW, an experiment using natural abundance (δ) of ^{15}N was conducted.
51 This study showed that in grapefruit crop irrigated with RW leaf $\delta^{15}\text{N}$ value increased. We
52 concluded that: (i) causal links exist between leaf $\delta^{15}\text{N}$ isotope and salt stress: positive correlation
53 between values of this isotope and leaf salt content was showed; (ii) excess of nitrates provided by
54 the reclaimed irrigation water were lost in the ecosystem through leaching, denitrification, etc.,
55 enriching the medium with $\delta^{15}\text{N}$ and increasing $\delta^{15}\text{N}$ values in plants. Therefore, the results of this
56 study highlight the key role that salt content from RW can play in N uptake by plants and, hence,
57 isotopic discrimination of leaf N. Consequently, it has been demonstrated the usefulness of isotopic
58 discrimination measure to predict crop sustainability in the medium to long term when using water
59 sources of different quality combined with deficit irrigation strategies.

68 INTRODUCTION

69 Increasing agricultural productivity in a sustainable way, conserving water and preventing soil
70 pollution by nitrates, are currently the main challenges in agricultural research at the ecosystem level.
71 It is well known that water is the most limiting factor for crop production, especially in areas where
72 agriculture relies heavily on irrigation. Therefore it is necessary to evaluate alternative water
73 sources for our irrigation systems. In this regard, reclaimed water, RW, reuse has been integrated
74 into water resources management; it is considered as an integral part of the environmental pollution
75 control and water management strategy. The volume of treated used for irrigation of crops in Spain
76 RW is increasing due to the progressive implementation of the European Waste Water Directive
77 (91/271/EEC). Moreover, frequent water-shortage periods are even forcing farmers to combine RW
78 with deficit irrigation strategies in order to reduce water use in agriculture, such as regulated-deficit
79 irrigation (RDI), based on the application of lower amounts of irrigation water than those needed by
80 the crop to compensate for evapotranspiration losses (Rana et al., 2005). Murcia, as a semi-arid
81 Mediterranean agronomic region, uses 100 hm³ of RW per year, however 93% of this water has an
82 electrical conductivity, EC, above 2 dS·m⁻¹ and 37% has EC values above 3 dS·m⁻¹ (ESAMUR,
83 2013). Salinity is among the most significant environmental factors responsible for substantial
84 losses in agricultural production worldwide, and it is one of the serious problems confronting the
85 long-term feasibility of agriculture in production systems irrigated with RW in these semiarid
86 regions (Ravindran et al., 2007). This is a critical problem, especially in Citrus, since they are one
87 of the most globally important horticultural crops considered salt sensitive (Al-Yassin, 2005).
88 Studies have shown that citrus are strongly affected by chloride and sodium (Grattan *et al.*, 2013)
89 which can be toxic to the plant. On the other hand, RW irrigation is generally considered beneficial
90 for the crop, as a result of its macronutrients (N, K, P), and in helping to reduce the requirements for
91 commercial fertilizer, making important savings. Therefore, RW can efficiently substitute for
92 potable water for irrigation and simultaneously save nitrates, according to Ferreira da Fonseca et al.
93 (2007), but requires careful management of N to obtain an optimal level of N use efficiency.
94 Relatively little is known about the effects of saline RW irrigation on N cycling in agroecosystems.
95 In this regard, stable isotope methods have emerged as one of the more powerful tools for
96 advancing understanding of relationships between plants and their environment. The stable isotope
97 composition of bulk leaf material is mostly determined by the environmental conditions prevailing
98 during leaf formation. Leaf nitrogen isotope enrichment, $\delta^{15}\text{N}$, is determined by the isotope ratio of
99 the external N source and physiological mechanisms within the plant (Evans, 2001), as $^{15}\text{N}/^{14}\text{N}$
100 fractionations during N assimilation, N transport within plants and N loss from the plant. An
101 improved understanding of major factors controlling leaf $\delta^{15}\text{N}$ can advance our knowledge of plant
102 N acquisition and allocation in grapefruit crops. Some studies have evaluated the effect of water and

103 salt stress and/or nitrogen inputs on soil/plant nitrogen isotope composition in field crops (Khelil et
104 al., 2013ab) or pine seedlings (Marañon-Jiménez et al., 2013). However, because of the cost and
105 time required to research on the leaf $\delta^{15}\text{N}$ value in woody crops irrigated over extended periods (i.e.
106 multiple years) are scarce.

107 Our experiment is the first to evaluate the sustainability after five years of combined use of saline
108 RW with RDI in grapefruit trees crop under field conditions by isotopic measurements in order to
109 elucidate the relationships between salinity and ^{15}N natural abundance. The purpose here is to
110 assess the utility of $\delta^{15}\text{N}$ as a physiological integrator and indicator of N use efficiency in grapefruit
111 tree crops irrigated with RW combined with regulated deficit, after 5 years. Specifically, the aims
112 are to (1) measure the variations in leaf $\delta^{15}\text{N}$ in relation to different water source and irrigation
113 strategies (2) correlate these measurements with phytotoxic ion accumulation; and (3) assess the
114 potential usefulness of $\delta^{15}\text{N}$ as an indicator of sustainability in the medium to long term.

115 **MATERIALS AND METHODS**

116 Twenty leaves per tree were sampled through the growth season in 2012, DOY from 72 to 345, in
117 the early morning and transported in refrigerated plastic bags to determine the leaf area using an
118 area meter (LI-3100 Leaf Area Meter, Li-cor, EEUU). Nitrogen total content ($\text{g}\cdot 100\text{g}^{-1}$) was
119 measured too (Flash EA 112 Series, England and Leco TruSpec, Saint Joseph, USA) and this value
120 relative to the total leaf area ($N_{\text{area}}, \text{gN}\cdot\text{m}^{-2}$) were reported. The concentration of sodium and boron
121 were determined by Inductively Coupled Plasma (ICP- ICAP 6500 DUO Thermo, England).
122 Chloride ion was analyzed by ion chromatography with a Chromatograph Metrohm (Switzerland)
123 after using a standard leaf to distilled-water ratio of 1:2.5 (w:w).

124 Two grapefruit leaves from ten selected trees per treatment were collected on day of year (DOY)
125 145, 234 and 345 for nitrogen and stable isotope determinations. Leaf $\delta^{15}\text{N}$ analysis was conducted
126 at the University of California (Davis, EE.UU.) Stable Isotope Facility using a continuous flow,
127 isotope ratio mass spectrometer (CF-IRMS, Europa Scientific, Crewe, UK)
128 (<http://stableisotopefacility.ucdavis.edu/>). The measurements of stable nitrogen isotope ratios is
129 expressed in thousandths (‰) following classical delta notation (δ), where $\delta^{15}\text{N} = [(\text{R}_{\text{sample}} -$
130 $\text{R}_{\text{reference}})/\text{R}_{\text{reference}}] \cdot 1000$, where $\text{R} = ^{15}\text{N}/^{14}\text{N}$. $\delta^{15}\text{N}$ data are reported using differential notation,
131 relative to an internationally accepted standard. The standard was atmospheric N_2 (‰). Replicate
132 analysis of 10 plant matter samples for treatment and season showed that the precision for $\delta^{15}\text{N}$
133 measurements was $\leq 0.18\text{‰}$.

134

135 **Statistical design and analysis**

136 Statistical analysis was performed as a weighted analysis of variance (ANOVA; statistical software
137 IBM SPSS Statistics v. 21 for Windows. Chicago, USA). Tukey's HSD test ($P < 0.05$) was used for
138 mean separation.

139 **EXPERIMENTAL**

140 **Experimental conditions and plant material**

141 The experiment was conducted at a commercial citrus orchard, located in the northeast of the
142 Region of Murcia in Campotéjar, 7 km north of Molina de Segura (38°07'18"N, 1°13'15"W) in
143 2012. The experimental plot of 0.5 ha was cultivated with 7 year-old 'Star Ruby' grapefruit trees
144 (*Citrus paradisi* Macf) grafted on Macrophylla rootstock [*Citrus Macrophylla*] planted at 6 x 4
145 metres. The irrigation was scheduled on the basis of daily evapotranspiration of the crop "ETc"
146 accumulated during the previous week. ETc values were estimated as reference evapotranspiration
147 (ETo), calculated with the Penman-Monteith methodology and a monthly local crop factor (Allen *et*
148 *al.*, 1998). All trees received the same amount of fertilizers which were applied through the drip
149 irrigation system: 263 kg N, 105 kg P₂O₅ and 155 kg K₂O ha⁻¹.year⁻¹. A total of 192 trees were used
150 in this study.

151

152 The experimental design of each irrigation treatment was 4 standard experimental plots and
153 distributed following a completely randomized design. Each replica was made up of 12 trees,
154 organized in 3 adjacent rows. Central trees of the middle row were used for 1 measurements and the
155 rest were guard trees.

156

157 **Irrigation treatments and water quality**

158 The irrigation head was equipped and supplied with two water sources. The first was pumped from
159 the Tagus-Segura canal, transfer water (TW) and the second water source was pumped from the
160 North of "Molina de Segura" tertiary wastewater treatment plant (WWTP), reclaimed water (RW),
161 characterized by generating a highly saline effluent and higher nutrient levels. The water quality
162 was different between each source of irrigation water (Table 1). Reclaimed irrigation water showed
163 the highest values in salinity, with EC –an indicator of the salt content- values close to 3 dS·m⁻¹,
164 while transfer irrigation water had an average electrical conductivity near unity (1 dS·m⁻¹). The high
165 level of salinity observed in the RW treatment was mainly due to the high concentration of Cl⁻
166 (>600 mg·L⁻¹) and Na (>500 mg·L⁻¹). Moreover, in the reclaimed irrigation water there was also a
167 higher concentration of N (NO₃⁻), P and K than in the transfer irrigation water. No differences in the

168 concentration of heavy metals were found between the different irrigation water sources (data not
169 shown).

170 Two irrigation treatments were established for each water source. In the first treatment, irrigation
171 was applied throughout the growing season according to water requirements (100% ETC), full
172 irrigation, FI, treatment. The second treatment was regulated deficit irrigation (RDI) irrigated
173 similarly to the FI treatment, except during the second stage of fruit growth when it received $\approx 50\%$
174 the water amount applied to the FI treatment. The amount of water applied to full irrigation
175 treatments was $6066 \text{ m}^3 \cdot \text{ha}^{-1}$, while the water applied in RDI treatments was $4980 \text{ m}^3 \cdot \text{ha}^{-1}$.

176

177 **Table 1. Average value of chemical parameters of irrigation water in each water source:**
178 **reclaimed water (RW) and Tajo-Segura transfer water (TW).**

| Water sources | | |
|--|--------------|-------------|
| | RW | TW |
| pH | 7.49±0.02 | 8.79±0.41 |
| EC (dS·m⁻¹) | 3.95±0.04 | 0.97±0.00 |
| NO⁻³ (mg·L⁻¹) | 16.45±9.91 | 2.52±0.77 |
| PO₃⁻⁴ (mg·L⁻¹) | 2.26±0.20 | <1.0 |

186

187 **RESULTS AND DISCUSSION**

188 The analysis of leaf $\delta^{15}\text{N}$ was measured on DOY 145 (24/05/2012), 234 (22/08/2012) and 345
189 (11/12/2012). Because of the integrative response of plant isotopic composition to multiple
190 ecophysiological constraints through time, leaf $\delta^{15}\text{N}$ can be used to evaluate environmental
191 conditions prevailing during leaf formation and the form (source) of N most used by plants
192 (Querejeta et al., 2008). The growth season was divided into 3 phenological periods: Stage I (DOY
193 72-145), Stage II (DOY 152-234) and Stage III (DOY 247-345).

194 **Seasonal change in $\delta^{15}\text{N}$ values**

195 In the first analysis (DOY 145), the $\delta^{15}\text{N}$ values of the treatment TW-FI ranged from 1.81 to 1.96
196 ‰, with an average of 1.91 ± 0.02 ‰. The $\delta^{15}\text{N}$ values of the treatment RW-FI were more enriched,
197 ranging from 3.05 to 3.47 ‰ and an average of 3.23 ± 0.05 ‰. Therefore, trees irrigated with RW
198 resulted in a significant increase of 69.11% in the natural abundance of the isotope ^{15}N . The second
199 analysis (DOY 234-RDI period) showed the same behavior: the treatments irrigated with TW were
200 less enriched, with corresponding values of 1.21 ± 0.14 and 1.16 ± 0.13 ‰, for TW-FI and TW-RDI,
201 respectively, and the treatment irrigated with RW reflected an increase of ^{15}N isotope, 2.68 ± 0.06
202 and 2.19 ± 0.13 ‰ for RW-FI and RW-RDI, respectively, so in this Stage II of rapid fruit growth the
203 increase between TW-FI and RW-FI was 121.94%. As expected, the isotopic composition of leaf
204 nitrogen of the third analysis (DOY 346) exhibited the same trend: 1.46 ± 0.067 , 1.10 ± 0.16 ,
205 2.94 ± 0.12 and 2.60 ± 0.18 ‰ for TW-FI, TW-RDI, RW-FI and RW-RDI, respectively, with an
206 increase of the abundance of ^{15}N of 101.23% in RW-FI treatment, compared to TW-FI. However,
207 neither average leaf nitrogen total concentration nor the area-based leaf nitrogen content measured
208 on the same leaves was statistically significant between treatments in any of the three analysis
209 evaluated (Figure 1B and 1C). Nitrate uptake depends on internal factors related to N demand of the
210 plant, rather than on nitrate availability in the soil volume (Cerezo et al., 2007). In this regard,
211 greater N rates from RW did not improve total N plant uptake, in the three dates analyzed,
212 according to recent work by Khelil et al. (2013b). Moreover, area-based leaf nitrogen content, N_{area} ,
213 had a tendency to increase with the growth season, the values measured in the first analysis (DOY
214 145) being significantly lower than the values of the other two analyses, mainly because all
215 treatments reached their maximum leaf area at this stage, in accordance with the results reported by
216 Albrigo et al. (2005).

217 On the one hand, the most likely explanation for the pattern in leaf ^{15}N abundance of trees irrigated
218 with TW might be that: for plants growing under moderate nitrate-N concentration, there is
219 negligible fractionation between ^{15}N and ^{14}N during the root uptake of nitrate and its incorporation

220 into plant tissues (Shearer and Kohl, 1986). Under natural conditions (i.e., normal substrate nitrate
221 concentrations) plants do not discriminate between ^{15}N and ^{14}N in the uptake and assimilation of
222 nitrate (Mariotti et al. 1982).

223 On the other hand, the increase of the abundance of leaf ^{15}N in RW treatments could be argued, a
224 *priori*, by the close relation between the availability of inorganic nitrogen in soil and leaf ^{15}N
225 values. A general pattern is that the discrimination increases with external NO_3^- concentration
226 (Evan, 2001). I.e., the plant becomes more ^{15}N enriched as the availability of source NO_3^- increases
227 (Robinson, 2001). In our case, this may be because RW has a higher concentration of nitrates, as
228 cited in Table 1, and these treatments with a surplus of N inputs over outputs (excess N) might
229 either be stored in soils or lost to the environment by leaching, denitrification, etc. (Bedard-Haughn
230 et al., 2003; Craine et al., 2009; Dawson et al., 2002; Marañon-Jimenez et al., 2013; Steven et al.,
231 2005; Watzka et al., 2006; Xu et al., 2003). All these N transformations in any ecosystem lead to N
232 isotope fractionation and as the lighter ^{14}N isotope reacts more rapidly than the heavier ^{15}N , the
233 residual N-source (soil) becomes enriched in ^{15}N . The close relationship between soil and plant ^{15}N
234 observed by several authors confirms that the higher the concentration of ^{15}N in the plant, the more
235 inefficient the system (Kriszan et al., 2009). Moreover, increased denitrification in the saline soil,
236 possibly related to drainage (Sutherland et al., 1993), would result in enrichment with $\delta^{15}\text{N}$ in soil
237 and plant. In summary, the increase in $\delta^{15}\text{N}$ value is a powerful indicator of long-term inefficient N
238 usage and past N management in the terrestrial environment (Destain et al., 2010) and higher
239 efficient N could be achieved with low N applications rates if the crop is irrigated with RW
240 containing nitrogen.

241 Seasonal trends of leaf $\delta^{15}\text{N}$ for the four treatments tested are reported in Figure 1A. As shown, the
242 natural abundance of $\delta^{15}\text{N}$ increased significantly for all trees in Stage I, regardless of the treatment,
243 coinciding with the highest values of leaf salts content (data not shown). By contrast, the lowest ^{15}N
244 values for the four treatments were registered in Stage II, also coinciding with the lowest average
245 values of leaf salts (data not shown) in the fruit growth. TW-FI treatment reduced $\delta^{15}\text{N}$ levels by
246 36% (from 1.91‰ in Stage I to 1.21‰ in Stage II) and RW-FI treatment declined 19% (from
247 3.32‰ in Stage I to 2.60‰ in Stage II).

248 Differential translocation of nitrogen isotopes within the tree is a second alternative explanation for
249 temporal variation in leaf ^{15}N abundance, besides the variation in leaf salts content. Studies of
250 nutrient translocation in trees showed that nitrogen stored in woody tissues was a major source of
251 leaf nitrogen in the spring (Luxmoore et al. 1981, Martínez-Alcántara et al., 2012). At the plant
252 level the $\delta^{15}\text{N}$ abundance is affected, not only by the water source, but also by physiological
253 transformation within the plant. Reallocation of N during growth should result in products with

254 lower $\delta^{15}\text{N}$ than the original source (Evans, 2001). So during sprouting of new leaves, the plant
255 releases a high amount of N recycled from old leaves and woody tissues to young leaves. We might
256 expect that, compared with the older leaf tissues, the more physiologically active tissues (new
257 leaves which are the destinations of the recycled N) have lower $\delta^{15}\text{N}$. This explains why we
258 observed a general decrease in the abundance of leaf $\delta^{15}\text{N}$ in all treatments in Stage II: because $\delta^{15}\text{N}$
259 enrichment on DOY 234 was measured in mature leaves which sprouted new in spring.
260 Accordingly, TW-FI treatment showed a higher percentage of decrease in leaf $\delta^{15}\text{N}$ value from
261 Stage I to Stage II due to a greater mobilization of reserves, as these trees were not subjected to salt
262 stress.

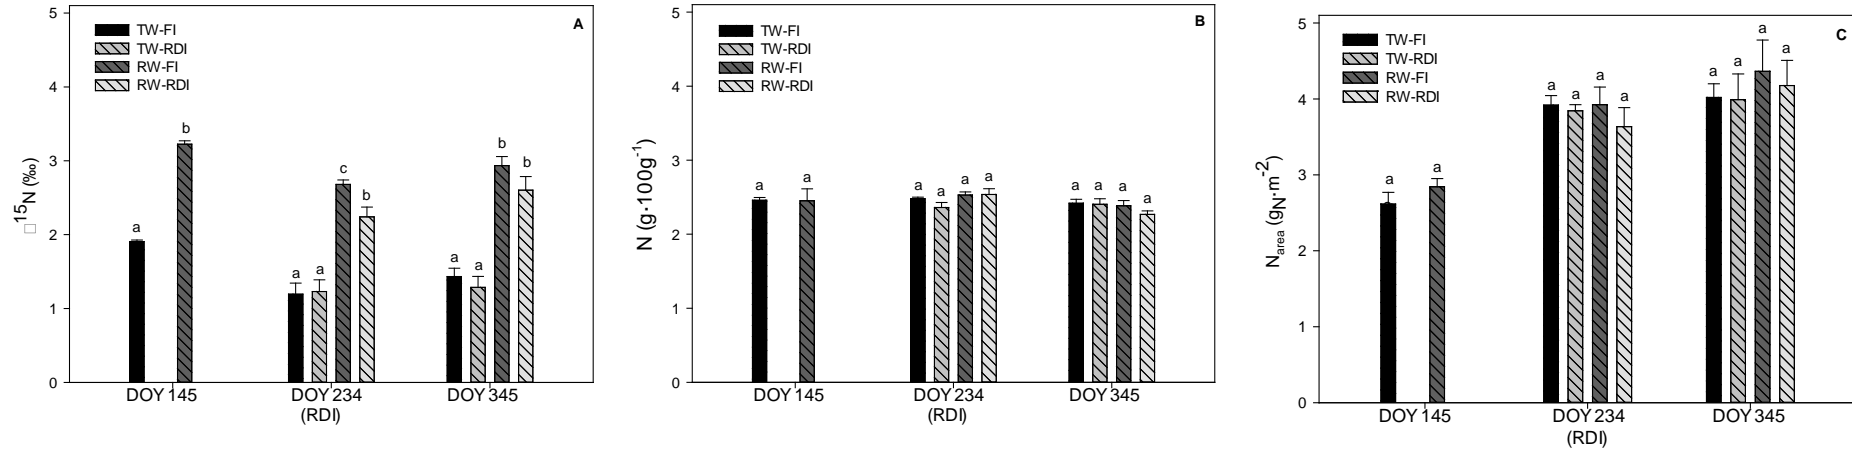

263 **Effect of salinity on leaf $\delta^{15}\text{N}$ values**

264 Leaf $\delta^{15}\text{N}$ was positively correlated with leaf salt level. On the one hand, the value of $\delta^{15}\text{N}$
265 increased with increase of Cl^- ion (Figure 2A). Considering the linear regression obtained, the
266 increase in leaf Cl^- content of 0.3 to 0.8 $\text{g}\cdot 100\text{g}^{-1}$ would lead to an increase of 5.37 times in the
267 natural abundance of $\delta^{15}\text{N}$. On the other hand, the presence of sodium in leaf samples also enhanced
268 isotopic fractionation (Figure 2B). Increasing Na content of 0.02 to 0.25 $\text{g}\cdot 100\text{g}^{-1}$ in leaf tissue
269 would cause the leaf $\delta^{15}\text{N}$ value multiply by 3.71, according to linear regression of Figure 2B. The
270 slope that correlated sodium with $\delta^{15}\text{N}$ was greater than the slope that correlated chlorine ion with
271 $\delta^{15}\text{N}$ (Figure 2A and 2B). Otherwise, RW-FI treatment showed a significant increase respect to
272 RW-RDI during Stage II. This was probably caused by the significant increase of leaf sodium
273 content in RW-FI (Stage II: 0.108 and 0.070 $\text{g}\cdot 100\text{g}^{-1}$ for RW-FI and RW-RDI, respectively). Our
274 study showed that the salinity pattern found in leaves, and therefore in soil, was strongly present in
275 the $\delta^{15}\text{N}$ of the leaf.

309 **CONCLUSIONS**

310 To assess the sustainability in the medium to long term in grapefruit crops, which were
311 irrigated with RW, combined with regulated deficit irrigation, both nutritional and
312 structural traits measurements at leaf level and isotopic measurements were used. Our
313 study showed that in a grapefruit crop irrigated with RW the leaf $\delta^{15}\text{N}$ value increased,
314 most notably in RW-FI. Accordingly, we hypothesize that (i) the positive correlation
315 between leaf $\delta^{15}\text{N}$ content and leaf salt content suggested that causal links exist between
316 $\delta^{15}\text{N}$ and salt stress; (ii) excess of nitrates provided by the reclaimed irrigation water
317 were lost in the ecosystem through leaching, denitrification, etc., enriching the medium
318 with $\delta^{15}\text{N}$ and increasing $\delta^{15}\text{N}$ value in plants. Therefore, the usefulness of isotopic
319 discrimination measure as an indicator of sustainability in the medium to long term in
320 grapefruit irrigated with saline reclaimed water it has been demonstrated.
