<b>Abstract:</b>	<p>The Antarctic-South American bank-forming moss <i>Chorisodontium aciphyllum</i> is known for having the oldest sub-fossils of any extant plant in Antarctica as well as extreme survival abilities, making it a candidate species for possible long-term survival in Antarctica. Applying phylogeographic and population genetic methods using the plastid markers <i>trnL-F</i> and <i>rps4</i> and the nuclear Internal Transcribed Spacer (ITS) we investigated the genetic diversity within <i>C. aciphyllum</i> throughout its range. Low genetic variation was found in all loci, both between and within Antarctic and southern South American populations, suggesting a relatively recent (likely within the last million years) colonization of this moss to the Antarctic, as well as a likely severe bottleneck during Pleistocene glaciations in southern South America. We also performed a simple atmospheric transfer modeling approach to study potential colonization rates of small (microscopic/microbial) or spore-dispersed organisms (such as many mosses and lichens). These suggested that the northern Antarctic Peninsula shows potentially regular connectivity from southern South America, with air masses transferring, particularly southbound, between the two regions. We found elevated genetic variation of <i>C. aciphyllum</i> in Elephant Island, also the location of the oldest known moss banks (&gt;5500 years), suggesting this location to be a genetic hotspot for this species in the Antarctic.</p>	
<b>Response to Reviewers:</b>	<p>Dear Editor,</p> <p>Thank you for your decision. We've addressed the remaining minor issues accordingly:</p> <p>1) Please add accession numbers in Table 1. These are added in the files called: "Biersma et al_PolBiol_2_Marked"</p>	

Manuscript\_clean\_version.docx" and "Biersma et al\_PolBiol\_2\_Marked Manuscript.docx". Both of these were uploaded on 10 Nov 2017. For simplicity, we've only included the clean version "Biersma et al\_PolBiol\_2\_Marked Manuscript\_clean\_version.docx" in the final submission today (as the addition of the accession numbers was the only change to the manuscript), but the marked changes can be viewed in the file "Biersma et al\_PolBiol\_2\_Marked Manuscript.docx" which was previously uploaded.

2) Figures 2 and 5: Please add labels of some major geographic features to the maps. We've now added geographic labels to the figures.

Please let us know if there are any other issues or comments.

Please send all future correspondence (proofs and other comments) to Peter Convey (pcon@bas.ac.uk), as I will be on Antarctic fieldwork with no to very limited internet for 2.5 months from the start of December. Peter will be the corresponding author until this time, although I would like to remain the corresponding author on the final publication.

Thank you,

Best wishes,  
Elisabeth M. Biersma

23

24 **Abstract**

25

26 The Antarctic-South American bank-forming moss *Chorisodontium aciphyllum* is known for having

27 the oldest sub-fossils of any extant plant in Antarctica as well as extreme survival abilities, making it a

28 candidate species for possible long-term survival in Antarctica. Applying phylogeographic and

29 population genetic methods using the plastid markers *trnL-F* and *rps4* and the nuclear Internal

30 Transcribed Spacer (*ITS*) we investigated the genetic diversity within *C. aciphyllum* throughout its

31 range. Low genetic variation was found in all loci, both between and within Antarctic and southern  
32 South American populations, suggesting a relatively recent (likely within the last million years)  
33 colonization of this moss to the Antarctic, as well as a likely severe bottleneck during Pleistocene  
34 glaciations in southern South America. We also performed a simple atmospheric transfer modeling  
35 approach to study potential colonization rates of small (microscopic/microbial) or spore-dispersed  
36 organisms (such as many mosses and lichens). These suggested that the northern Antarctic Peninsula  
37 shows potentially regular connectivity from southern South America, with air masses transferring,  
38 particularly southbound, between the two regions. We found elevated genetic variation of *C.*  
39 *aciphyllum* in Elephant Island, also the location of the oldest known moss banks (>5500 years),  
40 suggesting this location to be a genetic hotspot for this species in the Antarctic.

42 Keywords: bryophyte – LGM – Last Glacial Maximum – peat moss – sub-Antarctic – wind

43

44

45 **Introduction**

46

47 The timing of origin of the contemporary Antarctic biota and understanding the connectivity of  
48 populations between southern South America and the Antarctic Peninsula have increasingly become  
49 central questions in Antarctic biogeographic studies (e.g. Allegrucci et al. 2006, 2012; Convey et al.  
50 2008, 2009b; Fraser et al. 2012). Ice-sheet modeling studies and glaciological reconstructions suggest  
51 the entire Antarctic continent, and in particular the low altitude and generally coastal areas occupied by  
52 the better developed terrestrial ecosystems present today, to have been almost fully covered by thick  
53 ice-sheets during the Last Glacial Maximum (LGM; ~18-20 ky BP), as well as previous Miocene and  
54 Pleistocene glaciations, implying that most contemporary terrestrial life could only have colonised  
55 Antarctica since the LGM. Conversely, recent molecular phylogeographic and classical biogeographic  
56 studies have overturned this long-held paradigm, strongly supporting a long-term persistence of  
57 Antarctica's extant terrestrial biota, including many faunal as well as microbial groups, with estimated  
58 persistence ranging from hundreds of thousands to multi-million year timescales (e.g Chong et al.  
59 2015; Convey et al. 2008, 2009a; Convey and Stevens 2007; De Wever et al. 2009; Fraser et al. 2014;  
60 Iakovenko et al. 2015; McGaughan et al. 2010; Pisa et al. 2014; Stevens et al. 2006; Vyverman et al.  
61 2010).

62 The origin of the Antarctic bryophytes, the dominant macroscopic flora on the continent, is less well  
63 understood. As with the other groups, Antarctic bryophytes have been widely thought to be recent  
64 arrivals in the Antarctic, a hypothesis that is consistent with several lines of evidence: their i) low  
65 endemism (see discussion in Convey et al. 2008), ii) low species richness, iii) perceived potentially  
66 high dispersal ability through spore and other propagule production, and iv) distribution patterns, with  
67 most species restricted to the relatively mild maritime Antarctic, and very few restricted to the much  
68 harsher continental Antarctic (Ochyra et al. 2008). However, a recent population genetic study on the  
69 cosmopolitan moss *Bryum argenteum* Hedw. suggested a long-term persistence of this moss in the  
70 Antarctic (Peninsula and continent), identifying at least three separate colonisation events on very  
71 conservatively estimated multi-million-year timescales (~4.4, ~1.4 and ~0.6 Mya; Pisa et al. 2014; see  
72 also Hills et al. 2010). This first direct indication of long-term persistence implies that, perhaps, more  
73 extant Antarctic bryophytes have similarly had a long-term (pre-LGM) presence within Antarctica.  
74 High genetic variation amongst Antarctic populations of *Polytrichum juniperinum* Hedw. (Biersma et

75 al. 2017) suggests this common Antarctic moss may also have had a long-term *in situ* persistence in the  
76 maritime Antarctic, although this requires further investigation.

77 The oldest subfossils of any extant Antarctic moss species are of the bank-forming moss  
78 *Chorisodontium aciphyllum* (Hook. f. & Wils.) Broth. This moss is therefore a suitable candidate  
79 species to examine for evidence of long-term persistence in the Antarctic. *Chorisodontium aciphyllum*  
80 is a common moss in the sub- and maritime Antarctic (Antarctic Peninsula and Scotia Arc  
81 archipelagos). Its overall distribution includes southern South America (also including the Juan  
82 Fernandez Islands), the Falkland Islands, the Scotia Arc, the Antarctic Peninsula and associated  
83 islands, Tristan da Cunha, Amsterdam Island and the Kerguelen archipelago (Hyvönen, 1991; Ochyra  
84 et al. 2008, and references therein). New Zealand was previously also thought to be part of its range  
85 (Bartlett & Frahm, 1983), however a later consultation found the plant here to have been misidentified  
86 (Department of Conservation of New Zealand, 2013, see reference list for website link). The plant is  
87 thought to be sterile in the maritime Antarctic, but is known to locally produce sporophytes on sub-  
88 Antarctic South Georgia (Ochyra et al. 2008), and further north in southern South America (Hyvönen,  
89 1991, Ochyra et al. 2008).

90 *C. aciphyllum* forms banks often up to 1-2 m in depth, with the deepest banks known reaching a depth  
91 of almost 3 m on Elephant Island in the South Shetland Islands (Björck et al. 1991; Collins 1976a,  
92 1976b; Fenton 1980, 1982a; Fenton and Smith 1982; Smith 1972, 1979, 1996; Fig. 1). The bases of 1.5  
93 m deep peat banks at Signy Island (South Orkney Islands) and Elephant Island (South Shetland  
94 Islands), have been radiocarbon dated at ~5000 and 5500 years old, respectively (Björck et al. 1991;  
95 Fenton and Smith 1982), and deeper cores may potentially be older.

96 In maritime Antarctic moss banks, the active layer depth is typically 30-50 cm, with depths below that  
97 being frozen in permafrost. The moss in these banks is therefore extremely well preserved physically or  
98 morphologically, and regrowth studies from a core obtained on Signy Island (South Orkney Islands)  
99 have revealed that old moss shoots deep within the peat banks are still viable and able to regrow after  
100 experimental thawing and supplying with water and light (Roads et al. 2014). New shoots of *C.*  
101 *aciphyllum* grew directly from existing gametophyte shoots (and not spores, which are not produced by  
102 this moss in the maritime Antarctic) at 110 cm depth in the core examined, a depth radio-carbon dated  
103 to 1533–1697 yrs BP, revealing the longest survival and viability of any bryophyte (or indeed  
104 multicellular eukaryotic organism) known. These observations suggest that mosses such as *C.*

105 *aciphyllum* have the potential to survive at least through shorter periods of ice extension, for instance  
106 the Little Ice Age (1550–1850 BC), such as are inferred in various studies of glacial extent over time  
107 and through palaeoclimate proxies in the Antarctic (Guglielmin et al. 2015; Hodgson and Convey  
108 2005). Whether they have the capability to persist similarly through entire glacial cycles appears a  
109 considerably greater challenge, but is at present unknown.

110 These characteristics make *C. aciphyllum* a particularly interesting species to examine for clues of a  
111 possible long-term (hundreds of thousands to multi-million year timescales) Antarctic origin. Applying  
112 several widely-used genetic markers and Bayesian inference approaches, in this study we investigated  
113 the genetic variation between and within populations of *C. aciphyllum* throughout the full extent of its  
114 natural distribution in southern South America and Antarctica. Additionally, in order to further assess  
115 the connectivity of spore-dispersed organisms between South America and Antarctica we used  
116 atmospheric wind modeling techniques to study the relative frequency and direction of atmospheric  
117 transfer events between the regions. These analyses will increase our general understanding of the  
118 likely age of spore-dispersed organisms within Antarctica.

119

## 120 **Materials and methods**

121

### 122 *Sampling and molecular methods*

123 Material was sampled throughout the natural range of *C. aciphyllum* from 25 herbarium and 77 fresh  
124 (sub-)samples (the latter included spatially separated subsamples taken from eight different locations  
125 on four different islands, as described below; see Table 1 and Fig. 2). Most of the fresh (frozen)  
126 samples of *C. aciphyllum* included in this study were collected recently from locations in the South  
127 Shetland Islands (Ardley Island and Elephant Island) and Anvers Island west of the Antarctic Peninsula  
128 (Norsel Point), as described in Royles et al. (2016). From these we sampled multiple shoots to  
129 investigate within-population variation. These samples were spatially separated by approximately 50-  
130 300 m intervals (numbered 1-3), and from each sample several sub-samples were taken at a finer-scale  
131 interval of approximately 5 cm (letters A-E). Several shoots were taken per sub-sample. All herbarium  
132 samples originated from the British Antarctic Survey (BAS) Herbarium (herbarium code AAS). We  
133 also included several closely related species, taxonomically assigned to different *Chorisodontium*  
134 species: *C. magellanicum* (Card.) Bartr., *C. lanigerum* (Müll. Hal.) Broth., *C. spegazzini* (C. Müll.), *C.*

135 *dicranellatum* (C. Müll.) Broth., *C. sphagneticola* Roiv., *C. mittenii* (C. Müll.) Broth. and *C. setaceum*  
136 (Bartr.) Bartr.

137 DNA was extracted using the DNeasy Plant Mini Kit (Qiagen GmbH, Hilden, Germany), with use of  
138 mortar and pestle and liquid nitrogen, following the manufacturer's instructions, and using one  
139 gametophyte shoot per sample. We amplified three commonly used markers for phylogenetic inference  
140 at the genus to population level (Stech and Quandt 2010): the nuclear Internal Transcribed Spacer (*ITS*)  
141 and the plastid markers *trnL-F* and *rps4*. Amplification was performed using the Taq PCR Core Kit  
142 (Qiagen GmbH, Hilden, Germany) with addition of Bovine Serum Albumin (BSA), checking the  
143 results using agarose gel electrophoresis. *ITS* was amplified using primer combinations ITS1 and ITS4  
144 (White et al. 1990) or ITS-A (Blattner 1999) and 25R (Stech 1999). Plastid markers *trnL-F* and *rps4*  
145 were amplified using primer combinations *trnLF-c* and *trnLF-f* (Taberlet et al. 1991) and *trnS* (Souza-  
146 Chies et al. 1997) and *rps 5'* (Nadot et al. 1994), respectively. An annealing temperature of 60°C was  
147 used for all amplifications, except for *rps4*, which ranged between 55-60°C. Forward and reverse  
148 sequencing was performed by LGC Genomics (Berlin, Germany), using the same primers as mentioned  
149 above.

150

#### 151 *Molecular analyses*

152 All sequences were manually examined, with forward and reverse sequences assembled by Codoncode  
153 Aligner v.5.0.2 (CodonCode Corp., Dedham, MA). We included several Genbank sequences of all  
154 three regions derived from the same original specimens as outgroups in all alignments: *Dicranoloma*  
155 *cylindrothecium* (Mitt.) Sakurai. and *D. robustum* (Hook.f. & Wils.) Paris. (see Table 1). Additionally,  
156 as the above mentioned *rps4* outgroup sequences were only partial, we included several other  
157 *Dicranoloma* sequences in the *rps4* alignment (*D. billardieri* (Brid.) Paris., *D. blumii* (Nees) Paris., and  
158 *D. eucamptodontoides* (Broth. & Geh.) Paris.), as well as extra *Chorisodontium* sequences (*C. mittenii*,  
159 and *C. setaceum*). In the *trnL-F* alignment, we added additional outgroup sequences (*D.*  
160 *cylindrothecium* and *D. robustum*, respectively) and two *Chorisodontium* sequences (*C. mittenii* and *C.*  
161 *setaceum*, respectively). Loci were aligned per locus using the Geneious aligner within Geneious 9.0.4  
162 (Biomatters, LTD, Auckland, NZ). Short, partially incomplete sections at the ends of each alignment  
163 were excluded. The numbers of variable and parsimony informative sites were calculated per locus in  
164 MEGA7 (Kumar et al. 2016) using ingroup sequences with *Chorisodontium* species only.

165 Bayesian analyses using MrBayes 3.2 (Ronquist et al. 2012) were performed on each locus separately.  
166 Nucleotide substitution models were selected according to the SPR tree topology search operation and  
167 AICc calculations as implemented by jModeltest-2.1.7 (Darriba et al. 2012) for each individual marker,  
168 resulting in the TIM2, TPM1uf and TPM3uf (n=6, rates=equal for all) for *rps4*, *trnL-F* and *ITS*,  
169 respectively. For the MrBayes analysis indels in *ITS* were coded in SeqState v1.0. (Simmons and  
170 Ochoterena 2000) using the simple indel coding. MrBayes runs of all markers were continued for  
171 1000000 generations, sampling every 1000, ensuring all parameters exceeded effective sample sizes  
172 (ESS) >200 and split frequencies reached values >0.01 using Tracer v.1.6 (Rambaut et al. 2014), and  
173 discarding the first 25% as burn-in. Maximum clade credibility trees with mean node heights were  
174 visualised using Figtree v1.4.2 (<http://tree.bio.ed.ac.uk/software/figtree/>).

175 We examined phylogeographic structure within ingroup specimens with TCS networks produced for  
176 each locus using the program Popart (Leigh and Bryant 2015), using default settings.

177

#### 178 *Aerial modeling*

179 The potential relative frequency of atmospheric dispersal events between different locations was  
180 evaluated using a method of following trajectories of air-mass movements from reconstructions of past  
181 atmospheric winds. Simplifying assumptions were made that (i) particles are blown by the wind  
182 without any independent movement (e.g. fall-out) and that (ii) there are no thresholds on survival in  
183 terms of environmental conditions such as temperature or humidity. For a given location of interest  
184 three-dimensional forward trajectories were calculated at daily intervals over a 10 y period from 1979.  
185 In other words, for every day, starting at a specified location, a calculation was conducted which  
186 estimates the path that a particle released at that location at midnight would follow if it were blown by  
187 the wind over the following two days. For the purpose of this study we used two different starting  
188 locations in the area of interest: one from southern South America (55°S, 67.5°W) and one in the South  
189 Shetland Islands (62.5°S, 57.5°W) in the maritime Antarctic.

190 The atmospheric winds were taken from a reconstruction of past winds available from the European  
191 Centre for Medium-Range Weather Forecasts (ECMWF). The specific version used was ERA - 40  
192 (Uppala et al. 2005) and the post-1979 period was chosen, which is known to be more reliable due to  
193 the introduction of widespread data from satellites in late 1978 (Marshall 2003). The three-dimensional  
194 air mass trajectories were calculated from ERA-40 data using a service provided by the British

195 Atmospheric Data Centre (BADC) (available at <http://badc.nerc.ac.uk/community/trajectory/>). Density  
196 maps from these trajectories show the proportion (in %) of trajectories from a given location that pass  
197 within a 200 km radius of each grid point on the map.

198

## 199 **Results**

200

### 201 *Molecular analyses*

202 Sequence lengths within *rps4*, *trnL-F* and *ITS* alignments ranged between 649-650 bp, 454-462 bp and  
203 744-777 bp (including outgroups), respectively. Variation between *Chorisodontium* species was low in  
204 all markers (including only *Chorisodontium* sequences: 2, 3 and 9 variable sites, and 2, 2 and 3  
205 parsimony informative sites in *rps4*, *trnL-F* and *ITS*, respectively). The Bayesian analyses resulted in  
206 well-supported phylogenetic trees, with most ingroup (all *Chorisodontium* specimens) nodes receiving  
207 posterior probability (PP) values >0.95, and all had a minimum PP of 0.70 (Fig. 3a-c). Haplotype  
208 networks of each locus are shown next to each phylogenetic tree in Fig. 3.

209 Both phylogenetic and haplotype analyses revealed that in the loci *trnL-F* and *ITS* (Figs 3b and c,  
210 respectively) *Chorisodontium* species other than *C. aciphyllum* were resolved together with *C.*  
211 *aciphyllum* specimens, suggesting that either very little variation exists in these markers for these taxa,  
212 or that the specimens were initially misidentified. In the *trnL-F* phylogenetic tree specimens of the two  
213 neotropical species *C. mittenii* (AF435311) and *C. setaceum* (AF435312; this species is a likely  
214 synonym of *C. wallisii* (D Müll); Frahm 1989) were identical to *C. aciphyllum*. Similarly, in the *ITS*  
215 phylogeny specimens identified as the southern South American *C. spegazzini* (Chile 00523) and *C.*  
216 *dicranellatum* (Chile 00509 and 00511) were resolved together with *C. aciphyllum* specimens.  
217 Alternatively, in both *trnL-F* and *ITS* phylogenies (Figs. 3b and c, respectively) some specimens  
218 identified as *C. aciphyllum* (Chile 00504, 11472A, 02015) were resolved as sister-species or together  
219 with other *Chorisodontium* species, again suggesting these specimens were initially misidentified and  
220 represent different *Chorisodontium* species.

221 All phylogenetic trees revealed a large polytomy of *C. aciphyllum* specimens, with very little (*rps4* and  
222 *ITS*; Fig. 3a and c, respectively) or no (*trnL-F*; Figs. 3b) genetic variation amongst them. This  
223 polytomy included specimens from all populations and the entire geographic range of *C. aciphyllum*,  
224 and therefore revealed very little or no genetic variation within the species.

225 The *ITS* marker (Fig. 3c) revealed within-population variation in specimens derived from Elephant  
226 Island (South Shetland Islands): sample replicates (defined by the numbers between brackets behind  
227 samples in Fig. 3a-c) revealed variation between specimens sampled from the same 5 cm diameter  
228 plots in locations “1C”, “1D”, “2A” and “3B”. The variation between South Shetland Island samples  
229 included two nucleotide additions, situated in both *ITS1* and *ITS2* (for positions of the nucleotide  
230 additions in an alignment of Elephant Island samples see Fig. 4). The two added nucleotides were only  
231 found in Elephant Island samples, and were not present in any other locations of *C. aciphyllum*.

232

### 233 *Aerial modeling studies*

234 Two 95%-probability distribution figures were produced that show the relative connectivity between  
235 southern South America and the northern maritime Antarctic (Figs. 5a, b). These revealed that, given  
236 the assumptions (see methods), small particles transported *via* regional air masses can clearly cover  
237 long distances within a 24 h period. The figures also revealed a strong asymmetry in directional  
238 probability, revealing that aerial transfer from southern South America to the northern maritime  
239 Antarctic (Fig. 5a) is more likely than *vice versa* (Fig. 5b). Both dispersal density plots show the clear  
240 influence of the westerly winds prevailing in the region, and that west-to-east transport is much more  
241 likely than east-to-west.

242

### 243 **Discussion**

244

245 Within *C. aciphyllum*, all loci revealed little or no genetic variation between specimens sampled from  
246 geographically separate locations throughout the species’ natural distribution in southern South  
247 America and the Antarctic and/or sub-Antarctic. This suggests the species has been distributed across  
248 its current geographic range relatively recently. From dating analyses of peat cores the species is  
249 known to have been in the Antarctic for a minimum of ~5.5 ky, the age of the oldest fossil evidence of  
250 *C. aciphyllum* in the Antarctic (Björck et al. 1991; Fenton and Smith 1982). We can therefore dismiss  
251 human dispersal as a source of the first arrival of the species in the Antarctic. Exactly how long the  
252 species has been present in the Antarctic is uncertain as, because of extremely low levels of variation,  
253 molecular dating analyses of the different populations in *C. aciphyllum* were not informative (data not  
254 shown). However, theoretically, from a predefined *ITS* substitution rate of  $1.35 \times 10^{-3}$  subst. site<sup>-1</sup> my<sup>-1</sup>,

255 originally derived from angiosperms (Les et al. 2003, and references therein) we would expect one  
256 substitution to have happened every 982,415 years in a 754 bp long *ITS* sequence (the *ITS* sequence  
257 length of *C. aciphyllum* haplotype IV, Fig 3c; 0.00135 subst. site<sup>-1</sup> my<sup>-1</sup> results in 1.0179 subst. 754  
258 sites<sup>-1</sup> my<sup>-1</sup>, which is one mutation every 982,414.78 years). This simplistically suggests populations in  
259 South America and the Antarctic have likely been separated no longer than one million years, and a  
260 minimum of ~5.5 ky, the age of the oldest dated *C. aciphyllum* peat core in the Antarctic (see above).  
261 However, we acknowledge the rate used in this rough estimation does not take into account a rate  
262 standard deviation (which is not available), and that this rate might be different in bryophytes  
263 compared to angiosperms, and may also vary within bryophytes. From the genetic variation in this  
264 study it is not possible to assess the direction of spread, but it is perhaps more plausible that the species  
265 has spread from South America to the maritime Antarctic and/or sub-Antarctic, as the extant  
266 distributions of sister-species of *C. aciphyllum* only include South America. The 95%-probability  
267 distribution figures from the aerial modeling studies (Fig. 5) also suggest local wind patterns are more  
268 likely to transfer particles from southern South America to the northern maritime Antarctic than *vice*  
269 *versa*. Long-distance migration of moss particles *via* migratory birds may also have been a possibility  
270 for dispersal (and in either direction) (Lewis et al. 2014; Viana et al. 2016), although further research  
271 efforts are still needed to validate this mode of transfer in mosses.

272 Even though using three markers that are often variable at species and population level (particularly  
273 *ITS*; Stech and Quandt 2010), there was no genetic variation within South American populations of *C.*  
274 *aciphyllum*, whereas the opposite would be expected of an ‘ancestral’ population. Further sampling  
275 might provide clarification on the genetic variation of *C. aciphyllum* in South American populations  
276 (many of the Chilean specimens used in this study identified as *C. aciphyllum* in herbarium records  
277 turned out to be misidentified and represent *C. sphagneticola*; see below). It is likely that these  
278 southern South American populations experienced a strong bottleneck throughout the LGM and  
279 possibly other Pleistocene glacial maxima, when the region was extensively glaciated (Hulton et al.  
280 2002). Molecular studies on a wide range of terrestrial biota strongly suggest the existence of local  
281 refugia in Patagonia throughout the LGM and previous glaciations, rather than recolonisation from  
282 northern regions (Sersic et al. 2011, and references therein). This scenario matches the still restricted  
283 distribution of *C. aciphyllum*, essentially limited to the far southern latitudes within South America.

284 Despite the potential in *C. aciphyllum* for regeneration from viable shoots preserved in permafrost

285 (Roads et al. 2014), and therefore a possible survival strategy for long-term persistence in the Antarctic  
286 *in situ*, this study reveals very little genetic variation exists between South American and Antarctic  
287 populations. This suggests the species has not been present in the Antarctic on a multi-million year  
288 timescale, unlike for example the suggested Antarctic presence of *Bryum argenteum* (Pisa et al. 2014;  
289 Hills et al. 2010). If the oldest known bank of *C. aciphyllum* in the Antarctic (~5500 yrs old, on  
290 Elephant I., South Shetland Is.; Björck et al. 1991) represents the approximate arrival date of this  
291 species in the Antarctic, such a recent arrival would likely not have generated a strong detectable  
292 genetic differentiation, a finding consistent with the genetic signals in our study. The moss banks on  
293 Signy Island on the South Orkney Islands are also estimated to have begun to accumulate  
294 approximately 5.59-5.49 kya (Fenton 1982b; Smith 1990), suggesting this was one of the earliest  
295 periods with suitable conditions for post-glacial colonization. A similar implication of recent (post-  
296 LGM) arrival of an Antarctic moss was reported by Kato et al. (2013), studying the moss *Leptobryum*  
297 *wilsonii* (Mitt.) Broth., a species found growing uniquely in lakes of the Sôya Coast region in East  
298 Antarctica. Using the same makers as applied here (*rps4*, *trnL-F* and *ITS*) very low genetic variation  
299 (one base substitution and three to four indels) was detected between samples of *L. wilsonii* from East  
300 Antarctica and Chile, locations separated by a considerably greater distance than those separating  
301 *Chorisodontium* populations in the current study. Both Kato et al. (2013) and the current study provide  
302 examples of species whose genetic diversity is consistent with the widespread but generally untested  
303 assumption that Antarctic moss species may be post-LGM arrivals (e.g. Convey et al. 2008; Ochyra et  
304 al. 2008; Peat et al. 2007). However, other features of the biology of both *C. aciphyllum* and *L.*  
305 *wilsonii*, in particular that neither produce sporophytes in the Antarctic and/or sub-Antarctic (Ochyra et  
306 al. 2008) where both rely solely on asexual reproduction, might (due to a lack of genetic variation  
307 associated with asexual reproduction) considerably slow their rates of evolution and hence  
308 underestimate the timing of their arrival in the continent. It should be noted, however, that we also  
309 observe little genetic variation within southern South American populations of *C. aciphyllum* (see Fig.  
310 3), as well as southern South American versus maritime Antarctic populations, despite the occurrence  
311 of sexual reproduction in the former population.

312 We found evidence of local genetic variation in *C. aciphyllum* within several locations on Elephant  
313 Island (Figs. 3 and 4). Although this genetic variation was only small (two nucleotide additions in *ITS*),  
314 it revealed more variation in *ITS* between samples from Elephant Island than between samples from

315 much more geographically divergent locations in South America and the Antarctic. This increase in  
316 genetic variation may suggest that Elephant Island, which is also the most northern island in the South  
317 Shetland Islands, might possibly have had sufficiently mild environmental conditions to have enabled  
318 sexual reproduction in the past. Elephant Island is also the location with the deepest banks of *C.*  
319 *aciphyllum* in the Antarctic, suggesting this is the oldest Antarctic location where the moss has been  
320 present. It is possible that Elephant Island represents a genetic ‘hot spot’ relative to other Antarctic  
321 locations and, if so, this may apply to other plant and animal species that occur here. The finding of  
322 genetic variation within Elephant Island also highlights the importance of sampling multiple shoots per  
323 moss clump/patch to capture the full genetic variation present in a location, a factor overlooked if  
324 sampling single shoots alone.

325 In both *trnL-F* and *ITS* phylogenies (see Figs. 3b, c), several Chilean specimens identified as *C.*  
326 *aciphyllum* (11472A, 02015 and 00504) were genetically similar to *C. sphagneticola*, likely due to a  
327 misidentification of these specimens. Likewise, several specimens identified as other *Chorisodontium*  
328 species were genetically identical to *C. aciphyllum*. The *ITS* region (Fig. 3c) of *C. dicranellatum* was  
329 genetically identical to *C. aciphyllum*. Similarly, the *trnL-F* spacer (Fig. 3b) of both specimens of the  
330 Neotropical *C. mittenii* and *C. setaceum* (i.e. *C. wallisii*; Frahm 1989) were genetically identical to *C.*  
331 *aciphyllum*. Frahm (1989) and Hyvönen (1991) distinguish *C. wallisii* and *C. dicranellatum* as different  
332 species, and therefore the similarity between these species in our study is likely due to misidentification  
333 of the specific material examined. This is exemplified by the *rps4* sequences of *C. setaceum* (i.e. *C.*  
334 *wallisii*) and *C. mittenii*, which do differ from *C. aciphyllum* (Fig. 3a), while *rps4* is often less  
335 divergent between species than *ITS* and *trnL-F* (Stech and Quandt 2010). Other specimens identified as  
336 different *Chorisodontium* species revealing genetic variation relative to the *C. aciphyllum* polytomy  
337 were *C. sphagneticola* (*trnL-F* and *ITS*), *C. magellanicum* and *C. lanigerum* (*ITS*), and *C. spgazzini*  
338 (00523) (different in the *trnL-F*; no genetic variation in *ITS*), suggesting these specimens indeed  
339 represent different species. However, although Hyvönen (1991) identifies *C. sphagneticola* as synonym  
340 of *C. aciphyllum*, we find this is likely not the case. We highlight here that, while this genus has  
341 received attention from systematic morphological studies (Frahm 1989; Hyvönen 1991), future  
342 taxonomic work on the phylogeny of this genus requires both morphological and phylogenetic  
343 approaches.

344

345 **Acknowledgements**

346 We thank Helen Peat at the AAS herbarium (British Antarctic Survey; BAS) for access to herbarium  
347 specimens, Dr. Jessica Royles for providing fresh samples, Instituto Antartico Chileno (INACH) for  
348 logistic support, and Laura Gerrish (BAS) for preparing Fig. 2. Thanks to James Fenton for the  
349 photographs in Fig. 1. This research was funded by a Natural Environment Research Council (NERC)  
350 PhD studentship (ref. NE/K50094X/1) to E.M.B. and supported by NERC core funding to the BAS  
351 Biodiversity, Evolution and Adaptation Team. This study also contributes to the Scientific Committee  
352 on Antarctic Research 'State of the Antarctic Ecosystem' programme. The authors declare no conflict  
353 of interest.

498 Islands. For scale, the yellow post on the left is one meter long. Photographs: James Fenton

499

500 **Fig. 2** Map showing locations of samples of *Chorisodontium aciphyllum* (dark grey) and other  
501 *Chorisodontium* species (*C. magellanicum*, *C. lanigerum*, *C. spegazzini*, *C. dicranellatum* and *C.*  
502 *sphagneticola*; light grey), as used in this study. Specimens from *C. mittenii* and *C. setaceum* are not  
503 shown as collection coordinates are unknown or fall outside the map (see Table 1)

504

505 **Fig. 3** Bayesian phylogenetic trees and haplotype networks constructed with (a) plastid loci *rps4* and  
506 (b) *trnL-F*, and (c) nuclear marker *ITS* for *Chorisodontium aciphyllum*. Posterior probabilities are  
507 shown next to the relevant branches. Scale bars below the trees represent the mean number of  
508 nucleotide substitutions per site. Taxon colours refer to the different locations and/or different  
509 *Chorisodontium* species (see legend and map). Outgroup specimens in the trees are indicated in black.  
510 Numbers in brackets behind some taxa from the South Shetland Islands and the Antarctic Peninsula  
511 represent the number of replicates with identical haplotypes. In the *ITS* phylogeny (c) sample names  
512 with a and b represent different haplotypes within Elephant Island samples. Haplotype network circle  
513 sizes correspond to the number of specimens per haplotype (see legend). Different haplotypes are  
514 indicated with roman numerals (I-V). Branches represent mutations between haplotypes, with  
515 mutations shown as black lines and indel information with double lines (see legend)

516

517 **Fig. 4** Partial alignment of *ITS* showing the within-population variation in *Chorisodontium aciphyllum*  
518 populations on Elephant Island. The two variable sites between samples are situated in the *ITS1* (left;  
519 alignment position 144\*) and in *ITS2* (right; alignment position 475\*). Nucleotide differences are  
520 marked with number 1 and 2 below the alignment. Sample names with a and b represent samples  
521 without and with the extra nucleotide sites, respectively. \*= relative position in alignment of Elephant  
522 Island specimens only

523

524 **Fig. 5** Dispersal density spatial maps expressed as the percentage of times that an air mass from a given  
525 initial location passes within a radius of 200 km, re-created from daily air mass movements within a 24  
526 h period. (a) and (b) represent starting locations (shown as \*) from southern South America and the  
527 northern maritime Antarctic, respectively  
528  
529

**Table 1.** *Chorisodontium* specimens used in this study including herbarium details, collection coordinates (in decimal degrees) and accession numbers. Specimens include *C. aciphyllum* as well as several specimens from other *Chorisodontium* species (if species name is not mentioned the specimen is identified as *C. aciphyllum*). SSI= South Shetland Islands, AP= Antarctic Peninsula. Numbers in brackets behind some taxa from the South Shetland Islands and the Antarctic Peninsula represent the number of replicates of a particular location (within ~5 cm) with identical haplotypes. In case of identical sequences in all replicates of one location (e.g. SSI, Ardley I. 1A (4)) only one sequence is uploaded to Genbank. UC = University of Cambridge
