Tolerability of a rapid-escalation vinblastine-prednisolone protocol in dogs with mast cell tumours

Small Animal Hospital of The University of Edinburgh, Royal (Dick) School of Veterinary Studies, Easter Bush Campus, Edinburgh, EH25 9RE, UK

Abstract

Optimal chemotherapy protocols for high-risk mast cell tumours (MCTs) are unknown. The purpose of this study was to determine the tolerability and toxicity profile of a rapidly escalating vinblastine and prednisolone protocol (VPP) in which 3.00 mg/m² was administered once 7 days apart: at day 14 and at day 21. Dogs with chemotherapy-naïve MCTs presenting to the Oncology Service of a single institution were prospectively enrolled to receive escalating vinblastine, and haematology and a standardised quality-of-life questionnaire were assessed prior to each dosage. Thirty-four dogs were included: 30 with microscopic disease treated with adequate local therapy and four with macroscopic disease. Of 220 doses of vinblastine administered, 4% were associated with grade 3 and 4 toxicity. A total of 70% of dogs tolerated 3.00 mg/m² given 7 days apart at day 14 and 21, although 29% of dogs developed dose-limiting toxicities and 8% discontinued the protocol due to toxicity. In conclusion, VPP was well-tolerated overall, although prior to further dose intensity optimisation, it is important to determine if dose intensity is linked to outcome in canine MCT to avoid unwarranted toxicity.

Keywords: Oncology, Chemotherapy, Vinblastine, Mast cell tumour.

Introduction

Mast cell tumours (MCTs) represent one of the most common tumours in the dog, accounting for 16–21% of all cutaneous tumours (Bostock 1986). MCTs are heterogeneous in nature with marked variation in biological behaviour (Patnaik *et al.* 1984). Current treatment paradigms suggest that adequate local treatment with surgery or a combination of surgery and definitive intent radiation therapy (RT) is the treatment of choice, although adjuvant systemic treatment is commonly recommended for high-risk MCTs (Blackwood *et al.* 2012). High-risk MCTs are commonly considered to include grade III Patnaik tumours, high grade Kiupel tumours, recurrent MCTs, ≥stage II tumours or tumours arising in specific locations (such as scrotum or mucous membranes)

(Baginski *et al.* 2014; Blackwood *et al.* 2012; Cahalane *et al.* 2006b; Murphy *et al.* 2006; Patnaik *et al.* 1984; Sfiligoi *et al.* 2005; Thamm *et al.* 2006).

Vinblastine is a vinca-alkaloid extracted from the periwinkle plant (*Catharanthus roseus*) (Golden & Langston 1988; Rowinsky 2011; William *et al.* 1975). It is cell cycle specific and binds tubulin to inhibit microtubule formation during mitosis (Golden & Langston 1988; Rowinsky 2011; William *et al.* 1975). The dose-limiting toxicity (DLT) of vinblastine is neutropenia, with a neutrophil nadir occurring approximately 1 week after drug administration (Golden & Langston 1988; Rowinsky 2011; William *et al.* 1975). In veterinary medicine, although efficacy has been demonstrated for various types of neoplasia, it is most often used as adjunctive treatment for canine MCTs (Arnold *et al.* 2011; Bailey *et al.* 2008; Crow 1977; Davies *et al.* 2004; Rassnick *et al.* 2008; Singh *et al.* 1996; Thamm *et al.* 1999, 2006; Trumel *et al.* 2005; Vickery *et al.* 2008). Vinblastine can

Data presented in part at the annual meeting of the European Society of Veterinary Oncology, Krakow, Poland 2015.

be prescribed either as a single agent when local treatment is not an option, or as adjuvant systemic therapy to adequate local control in high-risk canine MCTs (Crow 1977; Davies *et al.* 2004; Rassnick *et al.* 2008; Thamm *et al.* 1999, 2006; Trumel *et al.* 2005; Vickery *et al.* 2008).

Chemotherapy is generally dosed near each drug's maximally tolerated dose in order to optimise tumour cell kill (Frei & Canellos 1980; Madewell & Theilen 1979). Previous work has demonstrated the importance of dose–response relationships and dose intensity, defined as chemotherapy dose per unit time, in improving the outcomes of cancer (Budman *et al.* 1998; Chabner 2011; Frei & Canellos 1980; Kwak *et al.* 1990; Loibl *et al.* 2011; Lyman 2009; Norton 1997; Wudhikarn *et al.* 2015). For tumours considered potentially curable in humans, there is convincing evidence supporting the relevance of delivered dose intensity, and it has been suggested that dose intensity is a quality of care indicator in clinical oncology (Lyman 2009; Norton 1997). In canine lymphoma, dogs which developed grade 3 or 4 neutropenia following chemotherapy demonstrated improved outcomes, raising the possibility that more appropriate individual dosing was administered (Sorrenmo *et al.* 2010; Vaughan *et al.* 2007).

A commonly used and well-tolerated protocol in dogs with high grade or metastatic MCTs, which was initially empirically extrapolated without phase I data in dogs, consists of eight doses of vinblastine at a dosage of 2 mg/m². The first four doses are given weekly, followed by four doses given every other week (Crow 1977; Davies *et al.* 2004; Rassnick *et al.* 2008; Thamm *et al.* 1999, 2006; Trumel *et al.* 2005; Vickery *et al.* 2008). Prednisolone is administered concurrently, as it significantly enhances efficacy compared to vinblastine alone (Stanclift & Gilson 2008). One study evaluating this protocol reported severe adverse effects in only 5% of dogs, suggesting that dogs may tolerate a higher dosage of vinblastine (Thamm *et al.* 1999). In the last decade, several studies have attempted a dosage optimisation for vinblastine in dogs.

In a phase I dose escalation trial of vinblastine, the maximally tolerated dose for vinblastine was 3.50 mg/m² every other week. However, grade 4

toxicity, as graded according to Veterinary Cooperative Oncology Group Common Terminology Criteria for Adverse Effects v 1.1 (VCOG CTCAE), was common (Bailey *et al.* 2008; Veterinary cooperative oncology group, 2011). Notably, of 26 dogs that received vinblastine at 3.50 mg/m² in a subsequent study, 46% developed grade 4 neutropenia and two dogs presented with febrile neutropenia despite the use of prophylactic antibiotics (Rassnick *et al.* 2008). The intended dose intensity of that protocol was 1.94 mg/m²/week; however, dose intensity in the first 4 weeks (1.75 mg/m²/week) was lower than that in the first 4 weeks of the traditional vinblastine protocol using a dosage of 2.00 mg/m² (2 mg/m²/week) (Rassnick *et al.* 2008).

In a separate strategy to increase the dose intensity in canine MCTs, a dose-escalating vinblastine-prednisolone protocol provided a starting dosage of 2.00 mg/m² that escalated in weekly increments to 2.33 mg/m², 2.67 mg/m² and 3.00 mg/m² followed by four doses at 3.00 mg/m² every other week, with an intended dose intensity of 1.83 mg/m²/week (Vickery *et al.* 2008). Of 24 dogs treated, only three dogs (12.5%) required dose reductions during the protocol, and fewer than 10% of vinblastine administrations at 2.67 mg/m² or 3.00 mg/m² were associated with grade 3 or 4 toxicity (Vickery *et al.* 2008).

The current prospective study was undertaken in an attempt to further optimise dose intensity with a rapidly escalating vinblastine protocol (VPP), shown in Table 1, in which vinblastine was escalated from 2.30 mg/m² weekly such that 3.00 mg/m² was given 7 days apart once, at day 14 and day 21, prior to

Table 1. Rapid escalation vinblastine-prednisolone protocol (VPP) involving eight planned doses of vinblastine

continuing a standard every other week administration with a dosage of 3.00 mg/m² for the latter half of the protocol. VPP was designed as an interim step to assess the tolerability of vinblastine given weekly at one point in the protocol prior to instituting weekly vinblastine at 3.00 mg/m². The primary hypothesis was that VPP would be well tolerated in dogs with MCTs with fewer than 20% DLTs as defined by grade 3 gastrointestinal toxicities or grade 4 neutropenias. While arbitrarily chosen, 20% was considered acceptable for continued optimisation of the protocol, and therefore was selected as a defined endpoint. The occurrence of greater than 20% DLTs was deemed unacceptable and would require alteration of the protocol to reduce toxicities. The primary objective of the study was to determine the toxicity profile of VPP.

Materials and methods

Dogs

Chemotherapy-naïve client-owned dogs that were referred to the Oncology Department of the Hospital for Small Animals of the Royal (Dick) School of Veterinary Studies with cytologically or histopathologically confirmed MCTs from February 2013 to July 2015, and with clinical indication for receiving chemotherapy, were eligible to receive VPP. The clinical protocol and data collection were approved by the institutional Veterinary Ethics and Review Committee. Chemotherapy was used as an adjuvant treatment to local therapy in dogs with high-risk MCTs or as a sole or adjuvant therapy for dogs in which adequate local treatment was not feasible or declined. A 'high-risk' MCT was defined as a MCT with at least one of the following negative prognostic factors: high grade (Patnaik or Kiupel), present in a high-risk location (mucosal, preputial or scrotal), recurrence and/or documented locoregional or distant metastases. Dogs with distant metastasis were eligible to be included. Dogs with 'high risk' subcutaneous MCTs could also be included. Although there is not a reliable grading scheme for subcutaneous or mucosal MCTs, Kiupel grading criteria was applied by a pathologist in these tumours in order to provide some measure of

histologic features of malignancy (Kiupel *et al.* 2011). Dogs with completely excised MCTs were defined as those in which ≥ 3 mm radially and at least one fascial plane deep tumour-free margins were obtained. Incomplete excision was defined as < 1 mm of margin histologically. All others were considered narrowly excised (1–3 mm of margin). For dogs with narrowly excised or incompletely excised high-risk MCTs, revision surgery and/or definitive-intent RT with photons or electrons was recommended. All radiation treatments were prescribed by a radiation oncologist board-certified by the American College of Veterinary Radiology (ACVR) and administered by a licensed radiation therapist. Radiation-induced acute toxicity was monitored with routine weekly rechecks until resolution, and graded according to the Veterinary Radiation Therapy Oncology Group acute radiation morbidity scoring scheme (Ladue & Klein 2001). In dogs with microscopic disease, chemotherapy with or without concurrent RT was initiated following recovery from surgery.

All dogs underwent clinical staging prior to starting chemotherapy, consisting of a full physical examination, complete blood count (CBC), serum biochemistry profile, fine needle aspirate of regional lymph nodes if accessible, three-view thoracic radiographs and abdominal ultrasound. In dogs with high-risk MCTs, routine fine needle aspirate of liver and spleen were performed regardless of their ultrasonographic appearance when possible. Ki67 expression was not determined. Exclusion criteria included dogs with a suggestion of significant bone marrow dysfunction (assessed with a CBC), inadequate performance status [Modified Eastern Cooperative Oncology Group (ECOG) constitutional performance score > 1], concurrent diseases requiring immunosuppressive therapy (i.e. severe atopy, immune-mediated disease) other than prednisolone and concurrent systemic anti-neoplastic treatment (Oken *et al.* 1982). Dog and tumour characteristics, including signalment, clinical and histopathologic features, were recorded.

Treatment and toxicity assessment

VPP is described in Table 1. Dogs with macroscopic disease were concurrently treated with gastro-

protectant therapy (a proton pump inhibitor) as well as a systemic histamine blocker.

A complete physical examination was performed and both CBC and standardised quality-of-life questionnaire (Fig. 1) were assessed prior to each dosage of chemotherapy. The decision to perform a CBC at weeks 5, 7, 9, 11 and 13 (1-week post vinblastine) was clinician-dependent and varied among dogs. All toxicities were graded according to VCOG CTCAE v1.1 and the quality-of-life questionnaire aided in ensuring all side effects reported by the owner were documented and graded (Stanclift & Gilson 2008). The following were considered DLTs: grade 4 neutropenia, \geq grade 3 thrombocytopenia, \geq grade 3 gastrointestinal toxicity or any neutropenia that caused a dose delay. Neutrophil and platelet counts were

required to be $\geq 1.5 \times 10^9$ neutrophils/l (1500/ μ L) and $\geq 50 \times 10^9$ platelets/l (50 000/ μ L), respectively, immediately prior to vinblastine administration. Vinblastine dose reductions of 10% were calculated following the occurrence of any DLT. Subsequent to a dose delay associated with neutropenia or thrombocytopenia, a CBC was reassessed 1–3 days after delay. Dose escalation was permitted in the protocol following early dose reduction and was performed in 5% dose increments. Grade 2 gastrointestinal toxicities were managed with supportive care if spontaneous resolution did not occur and/or when clients deemed effects intolerable. Maropitant was used as a first-line medication for vomiting, nausea or decreased appetite, and metronidazole was used as a first-line medication for colitis.

Statistical analysis

Statistical analyses were performed by a statistician (IH) using the R Statistical System (R Core Team, 2015). Initial univariable analysis was performed on the following variables, which were evaluated as possible predictors of toxicity or tolerability of 3.00 mg/m² administered 7 days apart at days 14 and 21: age, weight, sex, neuter status, stage, Patnaik grade, Kiupel grade, margin status, mitotic index (MI) and concurrent RT. Dichotomous variables were evaluated via Fisher's exact test, while the numerical variables were evaluated via Mann–Whitney test. Variables with a univariable $P \leq 0.2$ were entered into a multivariable binary logistic regression model to assess potential confounding and allow estimation of a corrected strength of association between predictive factor and outcome conditional on other factors. Where data were missing in factors for multi-variable modelling, a subset dataset of complete observations on variables of interest was used. The multi-variable models were simplified to minimise Akaike's Information Criteria (AIC) – a parameter count penalised measure of model fit. A $P \leq 0.05$ was considered statistically significant for reporting of final variables from the models. The study involved multiple comparisons and hypothesis tests. No explicit corrections are made for this and P -values from hypothesis tests are presented as is.

Results

Dog and tumour characteristics

Thirty-four dogs were enrolled in the study. Clinical characteristics for all dogs are listed in Table 2. Median age at the time of first dose of vinblastine was 6 years, and median weight was 24.8 kg. Three dogs weighed less than 10 kg.

A diagnosis of MCT was achieved histopathologically in 33 dogs and cytologically in one dog. In all cases where histopathology was available, tumours were graded via the Patnaik and/or Kiupel grading system. The median MI for all tumours was 1 (range: 0–39). Multiple pathologists in several laboratories evaluated biopsy specimens. Histopathological

margins were evaluated in all cases where surgery was performed (30 dogs; Table 3). Complete margins were achieved in 17 dogs (56.6%), incomplete margins were achieved in 11 dogs (36.6%) and narrow margins were achieved in two dogs (6.6%).

Tumour characteristics at the time of chemotherapy initiation are provided in Table 3. Twenty-nine dogs had high-risk MCTs and received VPP as a first-line adjuvant treatment for microscopic disease. Eight dogs received concurrent definitive-intent RT. One dog received VPP for potential improved local control of an incompletely excised Kiupel low-grade subcutaneous MCT after declining RT. Three dogs received VPP as treatment for multifocal macroscopic disease, and one dog with a high-risk MCT received four doses of cytoreductive chemotherapy followed by definitive intent RT concurrently with the remaining doses of vinblastine.

Out of the dogs with high-risk MCTs, several dogs had multiple factors associated with aggressive disease: three dogs with grade 3 MCTs, one dog with a scrotal MCT, one dog with splenic and hepatic metastases and one dog with diffuse macroscopic cutaneous MCT (two of which were recurrent) had concurrent regional lymph node metastasis. All dogs

with lymph node metastasis had at least one metastatic lymph node confirmed histopathologically.

Treatment

Of the nine dogs that received RT, three were treated with conformal RT utilising computerised treatment plans (Eclipse, Varian Medical Systems, Palo Alto, CA) while the remainder were manually

treated with 6–12 MeV electrons ($n=3$) or 6 MV photons ($n=3$). Five dogs with confirmed metastatic lymph nodes that had been surgically removed had regional lymph node beds irradiated in conjunction with the primary MCT site. Radiation was prescribed to the planning target volume (PTV) in all cases; the radiation prescription consisted of 48 Gy in seven dogs, with six dogs prescribed 16 fractions of 3 Gy and one dog prescribed 15 fractions of 3.2 Gy. Two dogs were prescribed 18 fractions of 2.8 Gy to 48.6 Gy due to dose-limiting normal tissues adjacent to the surgical sites. For conformal treatments, the clinical target volume (CTV) was defined by post-surgical changes evident on CT with a 5 mm margin in all directions unless a natural barrier was present. The PTV was expanded from the CTV by 3 mm in all directions. For manual photon and electron plans, the CTV included 2.5 cm of margins to account for non-visible/non-palpable microscopic disease and the PTV included an additional margin of 0.5 cm where possible. Seven of nine dogs developed grade 3 radiation-induced skin toxicity, while two dogs developed grade 2 radiation-induced skin toxicity; all resolved within 3 weeks of completion of RT.

A total of 220 treatments of vinblastine were administered with a median dosage of 3.00 mg/m² (range: 2.00–3.00 mg/m²); the median number of doses administered to each dog was 8 (range: 1–8). Despite the intended dosages in the protocol, variable doses administered as adverse events caused dose adjustments (Table 4). Twenty-four of the 34 dogs initially enrolled (70%) tolerated 3.00 mg/m² administered at day 14 and 21.

Eight dogs (23.5%) required dose reductions, although 11 dogs (32%) would have required dose reductions had treatment not been discontinued in three dogs that developed DLT. Six of the eight dogs that required dose reductions were subsequently escalated by 5% increments in the dosage at each dose. One dog developed an additional DLT at 2.20 mg/m², while the remaining five dogs tolerated dose escalations well. One dog was escalated to 3.0 mg/m².

Twenty-three dogs (68%) completed the 12-week protocol. In total, 24 dogs tolerated 3.00 mg/m² administered at days 14 and 21 with 17 dogs

Table 4. Chemotherapy-induced toxicity at various dosage levels. Rows with text in bold represent the intended dosage in the VPP protocol at initiation. Alternative dosages represent dogs that required dosage reductions due to dose-limiting toxicities

*Percentages calculated as the number of toxicities per dosage divided by the total number of doses administered at that dosage multiplied by 100. [†]One dog in each group developed concurrent toxicities of the same grade, and thus were counted as two separate instances.

completing the protocol at the planned dosages and schedule. The remaining seven dogs required protocol alterations in the latter half of the protocol: two dogs developed DLT, one dog was dose-reduced at the client's request following grade 2 gastrointestinal toxicity, three dogs developed progressive disease and discontinued VPP and one dog terminated treatment early at the client's request following possible vinblastine extravasation, although extravasation was not confirmed and an extravasation reaction did not develop. Ten dogs did not receive 3.00 mg/m² on day 14 and 21 for variable reasons: eight dogs developed DLT earlier in the protocol, while two dogs had progressive disease after the first dose of vinblastine and were therefore not escalated.

Toxicity

Neutropenia was the primary DLT and occurred across multiple dosages (Table 4). A total of 11 episodes of dose-limiting neutropenia occurred: one episode following a dosage less than 2.30 mg/m², seven episodes following dosages between 2.30 and 3.00 mg/m² and two episodes following administration of 3.00 mg/m². Five of these episodes caused dose delay, therefore negatively impacted the intended dose intensity. In four dogs that discontinued the protocol early, four additional dose delays would have occurred if affected dogs had continued

VPP. None of the other dogs in the study required a dose delay for any other reasons.

Four dogs (12%) developed asymptomatic grade 2 neutropenia at a dosage of 2.30 mg/m² ($N=3$) and 2.60 mg/m² ($N=1$). As their subsequent scheduled dose of vinblastine was delayed, these four dogs were dose-reduced. Two dogs (5%) developed asymptomatic grade 3 neutropenia at a dose of 2.30 mg/m²: one dog was dose-reduced, while the remaining dog also had concurrent grade 3 thrombocytopenia but stopped VPP due to progressive disease. One dog (2%) developed grade 3 neutropenia at a dosage of 3.00 mg/m² and required prophylactic antibiotics. Four dogs (12%) developed febrile grade 4 neutropenia. Out of these four dogs, one died following acute respiratory distress and upper airway obstruction approximately 10 days following vinblastine administered at a reduced dosage of 2.20 mg/m²; the neutrophil count had recovered at the time of respiratory distress. This dog had previously required a dose reduction after developing grade 3 neutropenia at a dosage of vinblastine of 2.30 mg/m² and was being slowly escalated with 5% increase intervals. Post-mortem examination was consistent with pharyngeal oedema and inflammation as well as necrosuppurative pneumonia and disseminated intravascular coagulation (DIC). This dog completed definitive intent RT 12 days prior to developing febrile neutropenia, however, the pharynx and larynx

were not in the irradiated field. One dog with febrile grade 4 neutropenia and concurrent grade 4 thrombocytopenia 5 days following vinblastine at 2.60 mg/m² was euthanized on presentation, as the client declined supportive treatment. The remaining two dogs with febrile neutropenia recovered following 24 h of supportive care: one dog had received a dosage of 2.60 mg/m², while the other had received 3.00 mg/m². Three of the four dogs with grade 4 neutropenia underwent concurrent RT upon starting VPP chemotherapy: only one dog developed neutropenia while undergoing RT; the other two dogs had completed RT a minimum of 14 days prior. None of the other dogs receiving RT developed any DLT. Asymptomatic grade 4 neutropenia was not detected in any dog, although a CBC was only consistently performed at the expected nadir in 12 out of 27 dogs that received more than three doses. In the latter half of the protocol, one dog developed grade 3 neutropenia, while a second dog developed grade 4 neutropenia following vinblastine administered at 3.00 mg/m² even though both dogs had previously tolerated 3.00 mg/m² at days 14 and 21.

Low-grade myelosuppression and gastrointestinal toxicity were common. Twenty dogs (58%) developed grade 1 neutropenia at a range of dosages (2.30–3.00 mg/m²), and two dogs (5%) developed

grade 2 neutropenia that did not disrupt the dose intensity of the protocol as the neutrophil count recovered by the time of the next scheduled dose of vinblastine. Grade 1 thrombocytopenia occurred in seven dogs (20%) at dosages ranging from 2.10 to 3.00 mg/m² and one dog developed grade 2 thrombocytopenia following vinblastine administered at 2.60 mg/m². None of these toxicities affected dose intensity. No gastrointestinal DLT was recorded, however, 10 dogs (29%) developed at least one episode of grade 1 or 2 gastrointestinal toxicity during the protocol. Five dogs developed multiple episodes of gastrointestinal toxicity at various vinblastine dosages (2.30–3.00 mg/m²). One dog developed one episode of grade 2 anorexia (2.30 mg/m²), two episodes of grade 2 diarrhoea and anorexia (both at 3.00 mg/m²) and one episode of grade 2 diarrhoea (at 2.9 mg/m²). Despite the lack of conventional gastrointestinal DLT, this dog was dose-reduced because the owner considered these adverse effects unacceptable.

Variables associated with toxicity or tolerability

Univariable analysis (Table 5) for toxicity suggested that dogs receiving concurrent RT ($P = 0.048$) and intact dogs ($P = 0.033$) were more likely to develop

Table 5. Univariable analysis of factors potentially associated with increased toxicity with VPP and likelihood of tolerability of vinblastine administered at 3.00 mg/m² weekly

	Grade 3 neutropenia	Grade 4 neutropenia	Increased risk of dose reduction	Decreased tolerability of vinblastine 3.00 mg/m ² weekly administered once
Age	0.042*	0.872	0.074*	0.179*
Weight	0.172*	0.748	0.127*	0.155*
Sex	0.230	0.604	0.152*	0.446

grade 4 neutropenia, while younger dogs ($P = 0.042$) were more likely to develop grade 3 neutropenia.

On multi-variable analysis, no variables were associated with toxicity or tolerability of VPP with the exception of MI. Dogs with a MI >5 were more likely to require a dose reduction ($P = 0.048$ odds ratio 15.9 95% CI 1.44–500.0).

Discussion

The purpose of this study was to evaluate the tolerability of VPP. The demographics and staging of dogs in this study were similar to other studies evaluating canine MCTs (White *et al.* 2011). Intermediate grade (Patnaik) MCTs were more common in this population of dogs but all of the dogs with intermediate grade MCTs had recurrent or metastatic disease. Although most dogs included in the study had high-risk MCT, the low median MI is not surprising, as this marker lacks sensitivity as a negative prognostic factor (Lelyveld *et al.* 2015).

As expected, the DLT in this study was neutropenia. While the primary hypothesis was correct in fewer than 20% of dogs that developed grade 4 neutropenia, an unexpected finding was that at least 11% of dogs developed grade 4 febrile neutropenia, which is higher than has been reported in other studies using lower dosages of vinblastine (0–7%) (Davies *et al.* 2004; Rassnick *et al.* 2008; Thamm *et al.* 1999, 2006; Trumel *et al.* 2005). However, this compares favourably to the 46% of dogs that developed grade 4 neutropenia treated with vinblastine at 3.50 mg/m² every other week, a protocol that carries similar dose intensity to VPP (Rassnick *et al.* 2008). Also surprising was the fact that two dogs (6%) died following grade 4 febrile neutropenia, although one of them was euthanized without attempting supportive care.

Interestingly, the only two dogs that developed dose-limiting neutropenia (grade 3 and febrile grade 4 neutropenia) after receiving 3.00 mg/m² vinblastine had previously tolerated the same dosage given weekly. Vinblastine has not been previously reported in humans or dogs to cause cumulative toxicity; indeed, some authors have suggested that tolerance may develop following prior vinblastine drug

exposure (Rowinsky 2011; Vickery *et al.* 2008). This study suggests that tolerance is unlikely with two dogs developing dose-limiting neutropenia in the latter every other week aspect of the protocol despite previously tolerating the same vinblastine dosage at a 7-day interval. This finding highlights the importance of performing a CBC (or minimally a neutrophil count) approximately 6–7 days following every dose of vinblastine, even if the dosage was previously well tolerated.

No episodes of gastrointestinal DLT were reported, however, 29% of dogs developed grade 1 or grade 2 gastrointestinal toxicity during the protocol. This rate of gastrointestinal adverse effects is slightly higher than the rates previously reported (8–21%) in other studies using the dosage of 2.00 mg/m² (Rassnick *et al.* 2008; Thamm *et al.* 1999, 2006; Trumel *et al.* 2005). The use of the quality-of-life questionnaire at every visit ensured that owners reflected and reported on any clinical signs. The rate reported here was unlikely to have been under-reported as any adverse gastrointestinal event, whether witnessed by the clinician or reported by the client, was attributed to chemotherapy. It is possible that other reports may have underestimated the rate of low-grade toxicity if clients were not specifically queried. Alternatively, it is possible that this study overestimated gastrointestinal toxicity as not all episodes of diarrhoea, inappetence or vomiting may have been related to chemotherapy.

On univariable analysis, dogs that received RT were at increased risk of grade 4 neutropenia, although this lost significance in multi-variable analysis. While three dogs (33%) developed grade 4 neutropenia, only one occurred during the radiation protocol, while two developed 14 days or longer after completion of RT, following escalated vinblastine dosage. When considering the location and size of the irradiated fields, the three dogs that developed grade four neutropenia had three of the four smallest treatment volumes and contained no or minimal active marrow sites in adult dogs. The remaining six dogs (67%) that received RT tolerated the chemotherapy protocol without dosage reductions or toxicity. Of the 25 dogs that did not receive RT, 25% required dosage reductions during the protocol even

though only one (4%) developed grade 4 neutropenia. Previous studies assessing tolerability of dose-escalating vinblastine protocols also did not find that RT was associated with increased risk of toxicity despite the use of radiation units that may increase dose to bone (Vickery *et al.* 2008). Larger number of dogs would be needed to determine if this is a type II error on multi-variable analysis. As suggested by recent literature, RT alone may control some dogs with locoregional disease for extended periods of time, thus questioning the utility of systemic therapy (Baginski *et al.* 2014; Chaffin & Thrall 2002; Hume *et al.* 2011; Schulman 2015). A randomized trial would be useful to compare adequate local control with and without adjuvant VPP to assess if chemotherapy is beneficial in this setting.

Although dogs with a MI >5 were found to be more likely to require a dose reduction in multi-variable analysis, neither Patnaik nor Kiupel grade were associated with toxicity or tolerability of VPP. It is difficult to hypothesise why dogs with high MI would be more likely to require a dose reduction compared to dogs with low MI, particularly in the adjuvant setting following local control. As no correction was made for multiple comparisons, the correlation of MI >5 and toxicity could be due to a type I error.

To the authors' knowledge, there are no previous published studies assessing the tolerability of vinblastine given at 3.00 mg/m² 7 days apart. This study only included administration of 3.00 mg/m² at day 14 and day 21 before switching to administration of 3.00 mg/m² every other week. Dose escalation tolerability could not be assessed in two dogs due to progressive disease following the first dose of vinblastine. Of the remaining 32 dogs, 24 (75%) tolerated 3.00 mg/m² at a 7-day interval at one point in the protocol, however, two of those dogs required dose reductions once switching to every other week administration of the same dosage. Due to the fact that 26% of dogs required dose reductions, and almost 10% of dogs discontinued the protocol due to toxicity, it is unlikely that a vinblastine protocol can be started at 3.00 mg/m² and administered weekly for six doses, as was the authors' proposal prior to this study. More importantly, of the DLTs that occurred, 81% developed following a dosage lower

than 3.00 mg/m². It is also unlikely based on results of this study and previous reports, that the dosage can be systematically further increased without an associated increase in the rate of grade 4 neutropenia (Bailey *et al.* 2008; Rassnick *et al.* 2008).

One of the reasons to explain the difference in tolerability of this protocol among different dogs is the significant inter-individual variation in the pharmacologic behaviour of vinblastine (Beck *et al.* 1979). Several attempts were made to model the data collected in order to identify any algorithms that could predict the 'ideal' characteristics to predict tolerability of weekly vinblastine at 3.00 mg/m², but it was not possible given the small number of dogs. It is important to emphasise that statistical analysis must be interpreted with caution given the low numbers and lack of information on known prognostic factors for toxicity. This is a limitation of statistical analysis with only a small number of dogs, however, the goal was to identify any patterns that could guide further studies with more robust analysis.

Most chemotherapy dosages for companion animals and humans are prescribed on the basis of the patient's body surface area (BSA), which tends to correlate poorly with drug pharmacokinetics (Arrington *et al.* 1994; Frazier & Price 1998a; Page *et al.* 1988; Frazier & Price 1998b; Walko & McLeod 2009). BSA is proportional to blood volume and glomerular filtration rate, despite that neither contribute to chemotherapy efficacy nor toxicity as much as liver function or other metabolic variations (Freireich *et al.* 1966; Gao *et al.* 2008; Goldsmith *et al.* 1975; Gurney 1996). However, it provides a method by which the maximum tolerated dose of many chemotherapy drugs in various species including humans, dogs, rats and mice is normalised (Freireich *et al.* 1966; Gao *et al.* 2008; Goldsmith *et al.* 1975; Pinkel 1958). To date, there is no clear relationship between pharmacokinetic parameters and BSA for common chemotherapy drugs; in some BSA-calculated doses administered to people, up to 20-fold variation in pharmacokinetics may routinely occur (Gurney 1996). For drugs like vinblastine that are metabolised, the use of BSA may not be ideal as tumour effects and adverse effects are based on complex processes such as metabolism and genetics,

making it challenging to develop a system that works for all dosing (Frazier & Price 1998a; Greek & Rice 2012; Frazier & Price 1998b). Tumour and patient chemosensitivity variations likely depend on pharmacokinetic, pharmacodynamic and pharmacogenomic differences, which are early areas of active research in veterinary medicine. In this particular group of dogs, multi-drug resistance 1 gene (MDR-1) polymorphisms and/or concurrent prednisolone administration may have altered drug disposition (Sathiapalan & El-Soth 2001).

As previous studies have suggested, myelosuppression may be predictive of cancer response to chemotherapy (Sorenmo *et al.* 2010; Vaughan *et al.* 2007). Therefore, dogs that do not develop substantial neutropenia may benefit from individual dosage escalations, even above 3.00 mg/m^2 , in order to achieve a lower neutrophil count. An alternative strategy to further optimise the dose intensity of the protocol would be to increase dose density. Dose-dense chemotherapy regimens aim to potentiate response by decreasing the inter-treatment interval (Chabner 2011; Norton 1997). The decision to administer vinblastine every other week after the fourth treatment was initially empirically extrapolated, and as this drug has not been reported to have cumulative toxicity and typically causes a neutrophil nadir between 5 and 7 days after administration, dogs would be expected to tolerate weekly treatments (Golden & Langston 1988; Rowinsky 2011; William *et al.* 1975). Theoretically, Norton's model of fractional cell kill supports a benefit from maximising dose intensity, and dose intensity optimisation may reduce hospital visits and shorten the duration of the protocol (Norton 1997). Both dose density and administered dosage are known to affect response of cancer to chemotherapy, and they both determine the dose intensity of a protocol (Citron *et al.* 2003; Frei & Canellos 1980; Loibl *et al.* 2011). Dose reductions and dose delays have both shown to be associated to a more negative outcome in human patients with cancer (Citron *et al.* 2003; Loibl *et al.* 2011). In this study, when toxicity caused dose delay, the authors preferred to dose-reduce affected dogs, in order to standardise an approach and ensure tolerability for the pet and owner. Notably, dose delays

within an institution may vary from 2 to 7 or more days depending on the client's ability to return. Dogs in this study were dose-reduced in an attempt to standardise administration time points and enable more consistent assessment of dose intensity. Grade 2 neutropenias that required dose delay were also dose-reduced in order to maintain a consistent schedule, although if dogs were switching to administration every 14 days, dose reductions were not necessary. Only 10% dose reductions were performed, as an attempt to limit any negative effect in treatment efficacy. It is important to reiterate that a prospective trial is required to definitively determine if increasing dose intensity or altering dose density improves efficacy and outcome, particularly as quality-of-life measures are vital when considering chemotherapy regimens in pet dogs.

Multiple reports of chemotherapy have suggested that the use of BSA to calculate chemotherapeutic doses results in smaller dogs to be overdosed (Arrington *et al.* 1994; Frazier & Price 1998a; Page *et al.* 1988; Frazier & Price 1998b). Although there were few dogs weighing less than 10 kg in this study, they were not at a higher risk of developing toxicities, which correlates well with results in other work investigating mitotic spindle inhibitors (Bailey *et al.* 2008). The authors were surprised at the range of vinblastine dosages that caused DLT and disruption of the intended protocol. There are obvious flaws in the use of BSA dosing of chemotherapy in dogs, and drug regimen design in human pharmacology and oncology have considered an integrative system to incorporate pharmacokinetics, pharmacodynamics and pharmacogenomics (Frazier & Price 1998a; Frazier & Price 1998b; Swen *et al.* 2011; Walko & Ike-diobi 2012). While veterinary literature currently lacks sufficient information regarding pharmacogenomics differences across dog breeds, it may be that as veterinary knowledge of both genetic and metabolic differences increases, alternative strategies for chemotherapy dosing may be feasible (Lawrence *et al.* 2015).

Overall, this rapid dose-escalating vinblastine-prednisolone protocol was well tolerated and reported adverse effects were acceptable. Although there is a higher rate of toxicity compared to protocols utilising

a lower dosage of vinblastine, this protocol increases dose intensity by 45% compared to the conventional protocol using the static 2.00 mg/m² dosage protocol, and a 5% increase over the initial dose-escalating protocol (Vickery *et al.* 2008). Toxicity was similar to that reported in the initial dose escalation protocol in which of 136 doses administered, 3% resulted in grade 3 or 4 adverse event (Vickery *et al.* 2008). Of 220 doses of vinblastine administered, there were only nine episodes of grade 3 or 4 toxicity (4%) in this study. Although this was a tolerability study and dogs with both microscopic and macroscopic disease were included, the majority of dogs in this study had microscopic disease that was adequately locally controlled ($N = 29$), whereas in previous studies, many dogs had measurable disease (Rassnick *et al.* 2008; Thamm *et al.* 1999). Retrospective comparison between different protocols is problematic due to different sample sizes, patient demographics and response criteria among studies. A prospective randomised trial evaluating a uniform population of dogs with MCTs with similar histopathologic and clinical features should be done to compare protocols.

This study had multiple limitations, many of which have been discussed. It was not a randomised controlled study, therefore historical data were used for comparison of toxicity and tolerability of VPP and the conventional protocol using a dosage of 2.00 mg/m². As the study was not funded, not all dogs were treated as per clinician recommendations. Specifically, one dog was euthanized due to toxicity, and another dog was dose-reduced despite grade 2 gastrointestinal toxicity. During dose escalation, CBCs were only performed 7 days post-vinblastine administration and were not consistently performed during the latter half of the protocol, therefore episodes of silent grade 4 neutropenia may have been missed. The detection of non-haematological toxicity was dependent on owner's recollection of events, and therefore, the grading and frequency of toxicity events could have been under- or overestimated depending on the owner's perception. Dogs were included based on their initial histopathologic report and review of slides by one pathologist was not performed. As grade was assessed statistically, this may

have influenced the statistical significance. Lastly, although an effort was made to look for factors predictive of toxicity, the small number of dogs included in the study precluded a clinically useful result.

In conclusion, this dose-escalating vinblastine and prednisolone protocol was well-tolerated overall with 4% grade 3 or 4 toxicity following administration of 220 doses of vinblastine. Of the 34 dogs included, 70% tolerated 3.00 mg/m² given 7 days apart at days 14 and 21 and 68% completed the protocol; 26% of the dogs required dose reductions and 8% discontinued VPP due to toxicity. It is unlikely that vinblastine can be started at 3.00 mg/m² weekly without incurring unacceptable rates of toxicity. Optimisation of vinblastine dose intensity may be achieved by reducing the inter-treatment interval or by identifying those dogs that can safely be treated with higher dosages. Further investigation to determine if dose intensity is linked to outcome in high-risk canine MCTs is necessary.
