Abstract: In addition to iron and manganese, deep sea ferromanganese deposits, including nodules and crusts, contain significant amounts of economically interesting metals, such as cobalt (Co), nickel (Ni), copper (Cu), and rare Earth elements and yttrium (REY). Some of these metals are essential in the development of emerging and new-generation green technologies. However, the resource potential of these deposits is variable, and likely related to environmental conditions that prevail as they form. To better assess the environmental controls on the resource potential of ferromanganese deposits, we have undertaken a detailed study of the chemical composition of ferromanganese nodules and one crust sample from different oceanic regions. Textural and chemical characteristics of nodules from the North Atlantic and a crust from the South Pacific suggest that they acquire metals from a hydrogenous source. These deposits are potentially an economically important source of Co and the REY. On the other hand, nodules from the Pacific Ocean represent a marginal resource of these metals, due to their relatively fast growth rate caused by diagenetic precipitation. By contrast, they have relatively high concentrations of Ni and Cu. A nodule from the Arctic Ocean is characterised by the presence of significant quantities of detrital silicate material, which significantly reduces their metal resource.

Keywords: polymetallic nodules; deep sea mining; ferromanganese crusts; diagenesis; Arctic nodules

1. Introduction

Marine ferromanganese deposits, including polymetallic nodules and crusts, are important resources of metals such as Co, Ni, Cu, Mo, Li, and Te, as well as the rare Earth elements and yttrium (REY) [1]. Crusts also contain relatively high concentrations of platinum [2,3], as well as smaller amounts of Rh, Ru, Os, Pd, and Ir. Ferromanganese deposits are distributed throughout the world's ocean basins, but their chemical and mineralogical compositions and, hence, their resource potential, can be variable (e.g., [2–7]).

Polymetallic ferromanganese nodules generally occur in the deepest parts of the ocean basins at depths ranging between 3500 to 6500 m [8], although they can also be found at much shallower depths [5].

Ferromanganese crusts usually form on the top and slopes of seamounts, ridges, and plateaus. Both types of deposits have a complex internal structure, and some can form extremely slowly (~1 to up

to 250 mm/Ma) [9] by deposition of Fe- and Mn-rich microlayers around a nucleus. These microlayers have distinct chemical and mineralogical compositions which reflect the environmental conditions in both the ocean and the host sediments at the time of deposition. Three different types of ferromanganese deposit have been recognised: (1) hydrogenous, whereby the deposit acquires metals from the overlying oxic water column [10]; (2) diagenetic, whereby metals are acquired from either oxic or sub-oxic sediment pore waters [11]; and (3) hydrothermal, where hydrothermal vent fluids are the principal source of metals [10]. The chemical and mineralogical composition of ferromanganese crusts can also be modified after deposition by diagenetic processes, including phosphatization (e.g., [12]).

Hydrogenous deposits typically have rather low Mn/Fe ratios, ≤3, and low quantities of Ni and Cu, whereas diagenetic deposits have higher Mn/Fe (3 to >10) and high Ni and Cu [13]. Hydrothermal deposits, in turn show the lowest average Mn/Fe ratios of <1, as well as the lowest content of trace metals [14].

The REY composition of the deposits can also be a useful tracer of the environment of deposition. Hydrogenetic nodules and non-phosphatized crusts tend to have positive Ce anomalies, negative Y anomalies and high Nd concentrations (>100 ppm), whereas diagenetic precipitates usually have negative Ce anomalies, negative Y anomalies, and intermediate Nd concentrations of between 10 and 100 ppm [12]. The REY content of hydrothermal deposits is highly variable (e.g., [14], but, in general, these deposits have negative Ce anomalies, positive Eu and Y anomalies, and are strongly depleted in the light rare Earth elements (LREE) relative to the heavy rare Earth elements (HREE) (e.g., [10,14]). Phosphatized crusts can be identified by positive Ce and positive Y anomalies, and depletion in the LREE relative to the HREE [12].

Changes in environmental conditions mean that the mode of formation may change over time. The oldest (27.8–24.5 Ma) layers in ferromanganese crusts from seamounts in the northeastern tropical Atlantic have relatively high Mn/Fe related to low oxygen conditions, whereas layers deposited during the interval 24.5–16 Ma have lower Mn/Fe, reflecting increased ventilation due to upwelling of oxygenated bottom waters [15]. Similarly, the outermost layers of nodules from the equatorial Eastern Pacific have relatively low Mn/Fe relecting hydrogenetic precipitation from oxygenated waters, whereas some layers in the innermost parts of the nodule have much higher Mn/Fe that are thought to reflect reduced oxygen concentrations due to increased biological productivity in surface waters and/or increased ventilation of bottom waters [16]. Phosphatization of ferromanganese crusts have also been shown to occur under reduced oxygen (sub-oxic) conditions (e.g., [17]).

The mode of formation of ferromanganese deposits usually assessed on the basis of analysis of bulk samples. However, it is clear from studies of nodules from the eastern equatorial Pacific (Clarion-Clipperton Fracture Zone and Peru Basin) that there can be significant differences in the compositions of the individual layers that make up a deposit [18], which reflect changes in the environment of deposition over time. Thus, to better evaluate the environmental controls on the resource potential of deep-ocean ferromanganese deposits, we have undertaken detailed geochemical and textural studies of individual layers within ferromanganese deposits from different environmental settings within the North Atlantic, Central and South Pacific, and Arctic Oceans.

2. Geological Setting

Nodules and crusts for this study were obtained from a number of locations in the Northeast and West Atlantic, the Northeast Kara Sea in the Arctic Ocean, the South and Central Pacific, and the Clarion Clipperton Fracture Zone (CCFZ) in the eastern equatorial Pacific Ocean (Figure 1 and Table 1).

The North Atlantic is characterised by relatively high sedimentation rates due to deposition of authigenic carbonates and a high input of terrigenous material delivered by turbidites (e.g., [19,20]). Ferromanganese nodules are generally confined to deep basins below the carbonate compensation depth (CCD) [21]. The Madeira Basin in East North Atlantic is the deepest part of the Canary Basin, extending from approximately 40° N, 30° E to 20° N, −5° E. Most of its surface is covered by thick turbiditic muds, however, nodule-hosting thin pelagic intervals with lower sedimentation rates also

occur in some parts of the basin [22]. The Nares Abyssal Plain in the Western North Atlantic (~22° N, −65° E to ~20° N, −62° E) is characterised by the presence of NW–SE trending fractures, which generate turbidite-rich valleys and red clay-rich abyssal hills, where nodules are found [21]. Both the Madeira and the Nares Abyssal Plains are affected by the presence of large gyre systems that keep surface biological productivity low [21,22]. As a result, the total organic carbon content of the sediments is low and the surface sediments are usually oxic. Nodules, therefore, usually form via hydrogenous, rather than diagenetic, processes (e.g., [20,21]).

A similar scenario is found in the Southwest Pacific nodule-forming basin. The sediments in this area are affected by the South Pacific gyre, and subsequently the extremely low respiration rates in the sediments allow oxygen to penetrate the sediment column to the basement [23]. Nodules in this area are found on top of the pelagic brown-red zeolitic clays of the Samoa and Penrhyn basins, extending from approximately −5° N, −170° E to −40° N, −155° E. Nodule formation in these basins is mainly hydrogenetic, being further favoured by the low sedimentation rates, the presence of strong bottom currents and the abundant nuclei particulates [24].

Nodule fields in the Pacific are more extensive than in the other ocean basins, due to lower sedimentation rates and a shallower CCD, which favours the existence of large areas of brown clay-rich sediments where nodules can grow (e.g., [25,26]). The Clarion-Clipperton Fracture Zone (CCFZ) hosts one of the largest nodule fields in the Pacific (e.g., [6]) and it is located in the Central Eastern Pacific Ocean, north of the equatorial high-productivity zone [27]. It extends from approximately 20° N, −120° E to 5° N, −160° E, and is constrained by the Clarion Fracture Zone to the north and the Clipperton Fracture Zone to the south, with a total length of ~7240 km. These fractures are SW–NE trending, as they respond to the north-westward migration of the Pacific Plate [28]. Nodules in the CCFZ are thought to be formed through metal precipitation from both sediment porewaters (diagenetic) and bottom waters (hydrogenetic) [6,18]. Fluctuations in surface bioproductivity caused by plate motion since the Miocene has likely influenced the mode of nodule growth [6]. Present day bioproductivity is lower than it was in the past, and increases from east to west [28].

The crust-forming region of the Cook Austral Chain is part of the larger Southwestern Pacific seamount province [29], located to the west of the Northeast Pacific basin (−30° N, −140° E to 0° N, −150° E). The Western Pacific is characterised by active tectonics and associated volcanism, which has originated a series of NW–SE trending chains of islands and seamounts extending for several thousands of km. Due to the action of the South Pacific Gyre, oxygenated sediment-free conditions prevail throughout the area and, as a consequence, Fe-Mn crusts precipitate from bottom waters (hydrogenetic) onto the surface of seamounts [11]. The greatest abundance of ferromanganese crusts is found on slopes of 0–20° on the top of the seamounts, and crust thicknesses have been found to increase from south to north and from east to west [29].

The Kara Sea is a marginal sea on the continental shelf of Northern Eurasia extending north from the West Siberian Basin from approximately 85° N, 55° E to 70° N, 90° E. It is characterized by a complicated bottom relief with depths not exceeding 150 m. With the exception of a few months in the summer, the Kara Sea is covered by an ice sheet up to 4 m thick for most of the year, which depresses biological productivity in the area [30]. Surface circulation in the southwest part of the sea is controlled by a cyclonic gyre, whereas in the central part it is strongly affected by discharge of northward propagating fresh waters from the Ob and Yenisei Rivers [31]. The distribution of sediment facies is controlled by river discharge of terrigenous material and bottom topography. Sediments on the inner shelf generally consist of silty-sandy clays, while sediments deposited on the outer shelf generally consist of brown to dark brown clays with a small amount of silt and sand [30]. Flat, discoidal-shaped ferromanganese concretions with growth rings are found only on sediments that have a thin oxic surface layer [32].

3. Materials and Methods

3.1. Samples

Samples E Atl-N4 and NAP-N4 in this study were supplied by the British Ocean Sediment Core Facility (BOSCORF); samples EW9602-09RD and RC12-192GS came from the Lamont-Doherty Earth Observatory, New York (LDEO); sample PSh-125.29(1) was supplied by the Shirshov Institute of Oceanology (Russia) during the RSS *Professor Shtockman* cruise in October 2013; and sample JC120-104 was collected from CCFZ (UK Claim Area) during the RRS *James Cook* cruise JC120 in spring 2015.
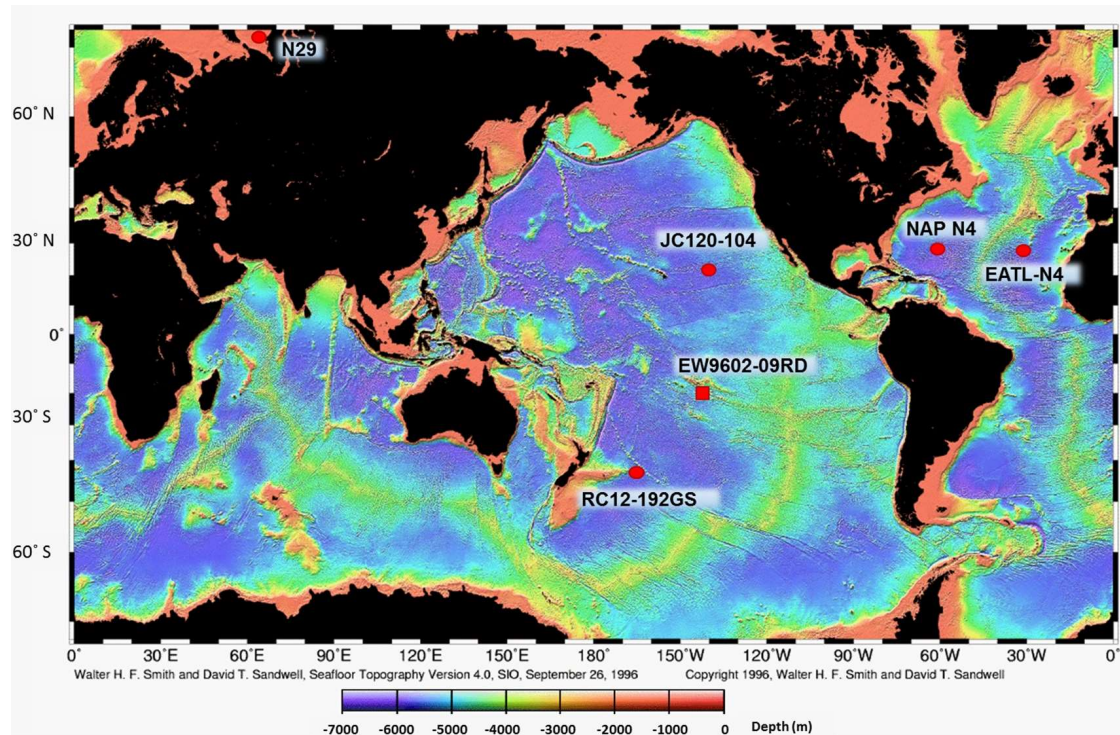

Figure 1. Location of crust and nodule samples used in this study. Seafloor topography is from [33], National Oceanographic and Atmospheric Administration (NOAA).

Table 1. Location, water depth and description of samples.

Sample	Lat (°N)	Long (°E)	Location	Water Depth (m)	OPD (m)	Description
			Pacific			
EW9602-09RD	−27.0	−143.2	Taukina Seamount (Cook-Austral volcanic chain)	1520–1540	~75 [a]	~3 cm botryoidal crust around volcanic clast
JC120-104	13.3	−116.3	UK claim area, CCFZ	4130	~1 [b]	~10 cm nodule, low sphericity, irregular bottom
RC12-192GS	−39.5	−157.7	Southwest Pacific Basin	4830	~75 [a]	~1 cm nodule, low sphericity
			Atlantic			
EATL N4	31.2	−25.2	Great Meteor East	5100–5400	>3 [c]	~3 cm, round, smooth nodule
NAP N4	23.5	−63.0	NW Atlantic	5900–6200	~18 [d]	~3 cm, round, smooth nodule
			Arctic			
PSh-125.29(1)	75.5	89.4	NE Kara Sea	51	~0.5 [e]	~5 cm flat nodule

[a] [23]; [b] In situ measurements on board the JC120 (May 2015); [c] [20]; [d] [34]; [e] [30]. OPD = oxygen penetration depth.

The nodules range in size from ~1 cm to ~12 cm in diameter. The nodules from the Southwest Pacific Basin and the Atlantic Ocean are generally rounded and have a smooth surface. Similar morphological features have been described in nodules from the vicinity of the Cook Islands [24],

and in nodules from the North Atlantic [21], at water depths of >5000 m. By contrast, the larger nodule from the CCFZ has a botryoidal appearance and a complex internal structure. These features are typical of nodules from this area at depths of 3000–4000 m (e.g., [6,8,18]).

The nodule from the Kara Sea in the Arctic Ocean (sample PSh-125.29(1)) is, by contrast, oblate and has a discoid shape with a long axis of ~7 cm. Similar flattened concretions have been reported in other shallow-water regions of the Kara Sea [35], as well as in the Chukchi and East Siberian Seas [36].

The ferromanganese crust sample EW9602-09RD was dredged from a seamount from the western part of the Challenger Fracture Zone. It has a botryoidal, slightly irregular appearance, similar to crusts recovered from other South Pacific seamount chains at depths of between 400 and 4000 m [11].

3.2. Analytical Methods

3.2.1. Scanning Electron Microscopy (SEM)

The crust and the nodules were prepared for SEM analysis by sectioning, and grinding and polishing with epoxy resin until a flat surface was obtained. Sections were then ground down to a thickness of ~100 μm, and mounted onto a glass sample holder.

SEM work was carried out at the University of Southampton using a LEO1450 variable pressure scanning electron microscope (Carl Zeiss, Oxford Instruments, Abingdon, UK). The microstructure of the sectioned crusts and nodules was assessed using both a secondary electron detector (for topographic imaging) and a backscattered electron detector (for compositional analysis). Major element concentrations were determined using energy-dispersive X-ray spectroscopy (EDS; Oxford Instruments, Abingdon, UK, X-Act 10 mm^2 area SDD with a silicon drift detector) combined with Aztec Energy software (Oxford Instruments, Abingdon, UK). Analyses were conducted at 20 kV, using a probe current of 700 pA and a working distance of 15 mm. The probe current was calibrated on a Faraday cup, and element concentrations were calibrated against various mineral standards from Micro-Analysis Consultants Ltd., Cambridge, UK, and the Natural History Museum, UK. A basalt glass standard reference material (BRR-1) was used to monitor the accuracy of the analyses. Elemental maps were made using a nominal probe current of 2.5–3.0 nA.

3.2.2. Laser Ablation Inductively-Coupled Plasma Mass Spectrometry (LA ICP-MS) Analysis

Laser ablation ICP-MS analyses were used to assess element concentrations in individual layers within the crust and nodules. The analyses were carried out on 100 μm-thick polished sections. Polished chips of NIST 610, NIST 612 and NIST 614 glass standard reference materials were mounted on a glass sample holder. Analyses were conducted at the University of Southampton using a 193 nm excimer laser (New Wave Research model UP193X, New Wave Research, Inc., Fremont, CA, USA) coupled to a quadrupole ICP-MS (Thermo X-Series II). Element concentrations of major elements (Mn and Fe) and trace elements (Ti, V, Co, Ni, Cu, Zn, Ba, Th, and U) and REY (La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Y, Ho, Er, Tm, Yb, and Lu) were determined on 50–75 μm diameter spots targeting individual layers in the nodules. Point analyses were performed at intervals of 0.2 to 1 mm. Ablations were conducted with a laser power of ~75% and a repetition rate of 5 Hz, in a He atmosphere. For each analysis, the gas blank was measured first with the laser beam blocked by a shutter. The shutter was then removed, and the transient signals from the analyte were collected for the ablation period. Raw counts were processed offline using standard spreadsheet software, and counts were calibrated using pressed pellets of nodule reference materials NOD-A-1 and NOD-P-1. The accuracy and reproducibility of the measurements was assessed by multiple ($n = 60$) analyses of NIST 614, NIST 612, and NIST 610 certified reference materials. The external reproducibility of the analyses was better than ±9% for the major elements, better than ±10% for most of the trace elements and better than ±7% for most of the REY, except for Ni (±21%), Cu (±17%), Zn (±13%), Nd (±9%), Sm (±8%), and Gd (±10%). Measured concentrations were within the certified or recommended values for all elements, except Ti (±20%), Mn (±25%), Fe (±16%), Ni (±11%), and Zn (±27%).

4. Results

4.1. Internal Structure of Nodules and Crust

Backscatter images (Figures 2, 3, 4, 5, 6, 7 and 8a) reveal that the nodules and crust have layered growth patterns which tend to be concentric in the smaller nodules (EATL N4, NAP N4, and RC12-192), but more complex and irregular in the larger nodules and the crust. Individual layers are distinguished by differences in reflectivity, with dark, low reflectivity layers alternating with bright, highly-reflective layers. Elemental mapping (Figures 2, 3, 4, 5, 6, 7 and 8b,c) was used to map the distribution of major elements throughout the nodule structure.
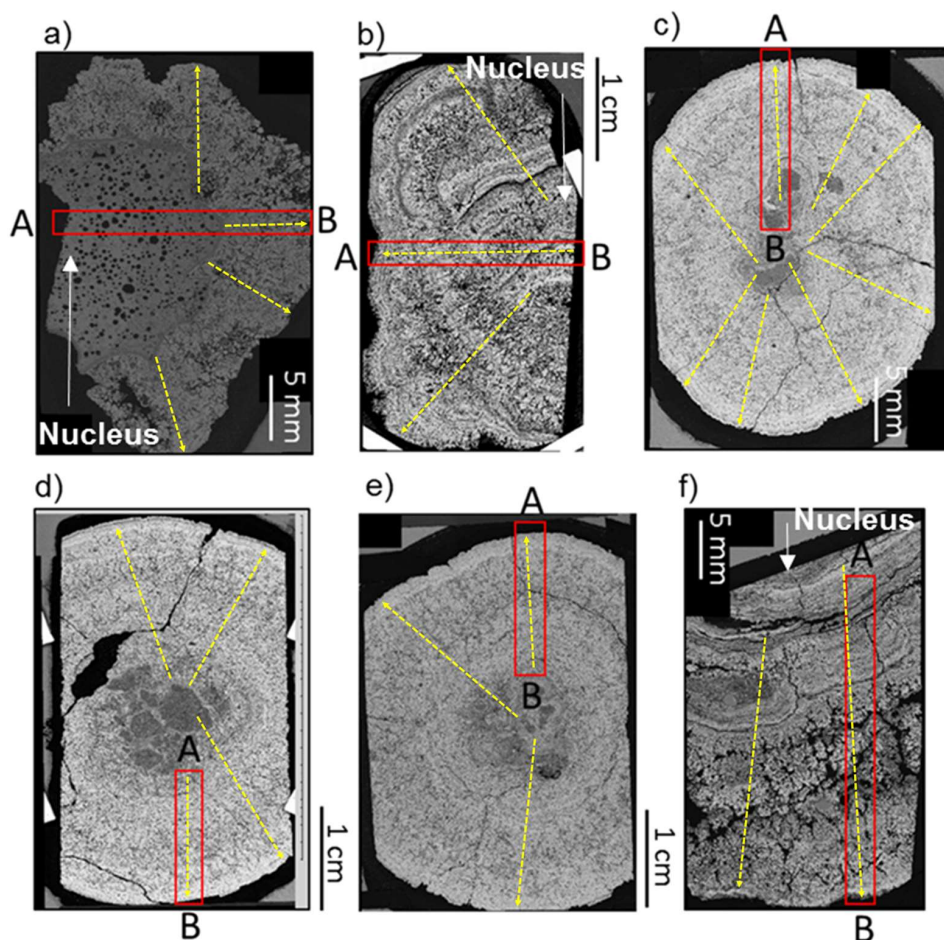

Figure 2. Backscattered (BSD) images of crust (**a**) EW9602-09RD, and nodule sections (**b**) JC120-104, (**c**) RC12-192GS, (**d**) NAP N4, (**e**) EATL N4, and (**f**) PSh-125.29(1). Red squares show areas where SEM elemental mapping was performed (from A, start of mapping to B, end of mapping, as in Figures 3–8). Yellow dashed arrows denote the approximate locations of laser ablation sampling tracks.

Nodule JC120-104 (Figures 2 and 3) is characterised by an irregular distribution of layers that reveals a complex growth history. There are at least two generations of nodule growth (Figure 1b), and the central part of the nodule is formed from a fragment of an older nodule over which new layers have precipitated. Both the older nodule and the newer layers are characterised by dendritic Mn-rich oxides that appear bright in the backscatter image, surrounded by pore spaces that are generally filled with aluminosilicate or Ca-phosphate detrital material. Occasional parallel layers of Mn-Fe oxides that appear dark in the backscatter image alternate with the dendritic structure. These are often intercalated with aluminosilicate material. Aluminosilicate material can also found filling cracks within the nodule structure.
Figure 3. Microtextures and element distribution for nodule sample JC120-104 (CCFZ, Central Pacific Ocean). Side A represents the outer part of the nodule, migrating inwards towards B. (**a**) Backscattered (BSD) image; (**b**) Fe-Mn distribution; and (**c**) distribution of major element associations.
Figure 4. Microtextures and element distribution for crust sample EW9602-09RD (South Pacific Ocean). (**a**) Backscattered (BSD) image; (**b**) Fe-Mn distribution; and (**c**) distribution of major element associations.

The crust sample (EW9602-09RD; Figure 4) is composed of a large porous basaltic glass fragment on which finely-crystallised Fe-Mn oxides have precipitated in a dendritic pattern. Some of the pores in the basaltic glass are empty and rimmed by aluminosilicate material that is likely a product of alteration. Other pores are filled in with Ca-phosphate. At the contact between the glass and the Fe-Mn crust, there is an Al-rich alteration front (Figure 4c). The Fe-Mn oxides beyond the alteration front are finely crystalline and appear bright in backscatter images (Figure 4a), and Fe-oxides (usually in the form of aluminosilicates) can be observed filling the pore spaces (Figure 4c). Sub-angular aluminosilicate clasts are common in the pore spaces towards the outer part of the crust structure.

Nodule samples RC12-192GS (Figure 5), EATL N4 (Figure 6), and NAP N4 (Figure 7) have similar morphological and chemical characteristics. They are composed by finely-crystallised Fe-Mn oxides that appear bright in backscatter images, have a dense, massive structure and surround a nucleus composed of multiple silicate-rich (e.g., Figure 5c), aluminosilicate (Figures 5, 6, and 7c) or Ca-phosphate (Figures 5, 6, and 7c) clasts. Fe-rich aluminosilicate material that appears dark in backscatter images can be found in pores and cracks throughout the nodule structure. Thin Mn-oxide rich layers that appear bright in backscatter images are also sparsely present in the nodules (Figures 5 and 6c).
Figure 5. Microtextures and element distribution for nodule sample RC12-192GS (South Pacific Ocean). (**a**) Backscattered (BSD) image; (**b**) Fe-Mn distribution; and (**c**) distribution of major element associations.
Figure 6. Microtextures and element distribution for nodule sample NAP-N4 (Northwest Atlantic Ocean).

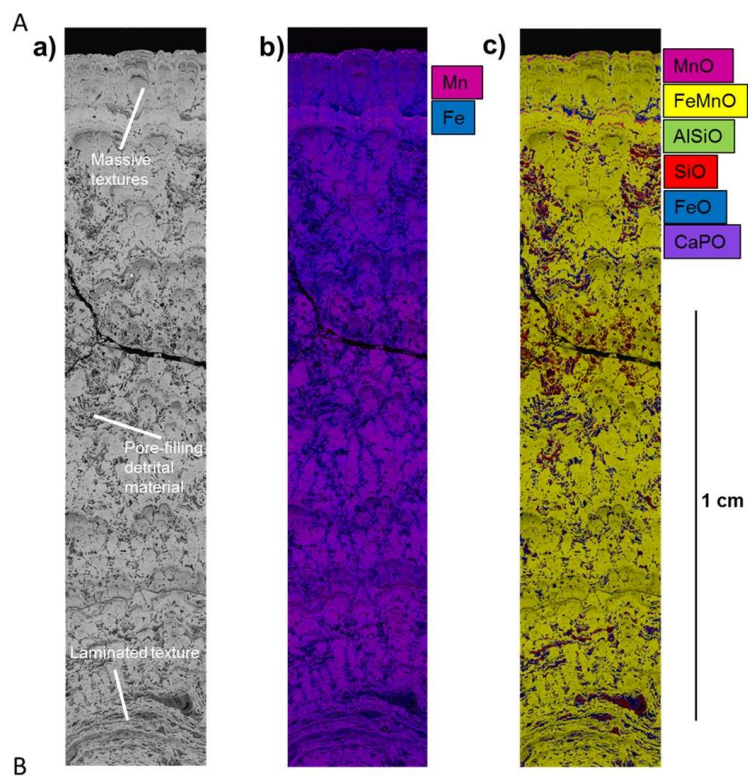

Figure 7. Microtextures and element distribution for nodule sample EATL-N4 (East Atlantic Ocean).
(**a**) Backscattered (BSD) image; (**b**) Fe-Mn distribution; and (**c**) distribution of major element associations.

Nodule sample PSh-125.29(1) (Figure 8) is characterised by large dendritic Mn-rich structures infilled with angular aluminosilicate detrital material. The Mn-rich oxides overlap the nucleus, and alternate with Fe-Mn oxide-rich layers that appear dark in backscatter images (Figure 8c). Fe oxides occur in discrete dark layers both towards the edge of the nodule and towards the nucleus.

4.2. Chemical Composition of Internal Layers

Laser ablation analyses shows that nodule layers that appear dark in backscatter images have relatively low Mn/Fe ratios (<3) and low Ni + Cu (<1.5 wt %), and relatively high concentrations of Co (>0.2 wt %) and REY (>1600 ppm). By contrast, layers that appear bright in backscatter images have high Mn/Fe ratios (>3) and high Ni + Cu (>1 wt %), but low Co (<0.2 wt %) and low REY (<1600 ppm) (Tables 2 and 3). Average metal concentrations in the layers are in general agreement with bulk data from the same locations reported by other authors (Tables 2 and 3).

Table 2. Concentrations of major and trace elements in selected individual layers of crust and nodules. In general, Layer #1 has relatively low Mn/Fe, Layer #2 has intermediate Mn/Fe and Layer #3 has high Mn/Fe. GR = growth rate = $0.68/(Co_n)^{1.67}$, where $Co_n = Co \times 50/Fe + Mn$, with Co, Fe, and Mn in wt % [21]. Where available, bulk nodule and crust data from [1,18,24,32,37] are shown for comparison, [*,a,b] Layer types 1 (dark, low Mn/Fe) and 2.1 (bright, high Mn/Fe), respectively, as defined in [18].

Table 3. Concentrations rare earth elements and yttrium (REY) in individual layers of crust and nodules. Ce* = (2 × Ce^{SN})/(La^{SN} + Nd^{SN}), where SN = shale normalised. LREE/HREE = (La^{SN} + 2 × Pr^{SN} + Nd^{SN})/(Er^{SN} + Tm^{SN} + Yb^{SN} + Lu^{SN}). Layer numbers #1, #2, and #3 were selected as three representative layers within each nodule; Layer #1 has relatively low Mn/Fe and Layer #3 has relatively high Mn/Fe. Where available, bulk nodule and crust data from [1,24,32,38] are shown for comparison.

[32]	Bulk Avg.	44.4	65.9	9.2	40.6	10.0	2.3	10.4	1.4	8.8	42	1.6	4.8	0.63	3.6	0.48	247	0.77	0.90	26.3

The crust sample has highest concentrations of both Mn (~42 wt %) and Fe (~24 wt %), and there is little variation in the Mn/Fe ratio of individual layers, ranging from ~1.3 to ~2.8. The crust has relatively high concentrations of Co (~0.7–3.7 wt %), Ti (~1.7–2.1 wt %), V (~840–1170 ppm), and Ba (~2570–2900 ppm). The nodule from the CCFZ (JC120-104) has the highest average Mn/Fe ratio (~8.8); this nodule incorporates layers that have extremely high Mn/Fe, up to ~80, as well as layers with lower Mn/Fe, ~1.6. Ni, Cu, and Zn also show high concentrations in the high Mn/Fe layers (~1.10 wt %, ~0.90 wt % and ~3740 ppm, respectively), and lower concentrations in the low Mn/Fe layers (~0.4 wt %, 0.18 wt % and ~617 ppm).

South Pacific nodule sample RC12-192GS mainly consists of low Mn/Fe layers (~1.5–1.7), although a few layers have slightly higher Mn/Fe (up to ~6). Layers with higher Mn/Fe also tend to have high Ni + Cu and Zn (~3.14 wt % and ~1310 ppm, respectively), whereas the layers with low Mn/Fe tend to have higher Co (~0.38 wt %), Ti (~0.7–1.2 wt %), and Ba (~1290–3510 ppm).

Atlantic nodules NAP N4 and EATL N4 have relatively low average Mn/Fe, ~1.2 and ~1.4, respectively. Some layers are moderately enriched in Mn relative to Fe, with Mn/Fe of ~8.9. These nodules have relatively high concentrations of Co (~0.6–0.5 wt %), Ti (~1.1–1 wt %), V (~721–680 ppm), Th (~140–130 ppm), and U (11.4–10.4 ppm).

The Arctic nodule PSh-125.29(1) has a moderate Mn content of ~23 wt %, but relatively low Fe (~7.5 wt %). This nodule has relatively low concentrations of other metals, with Co, Ni, and Cu concentrations of ~0.01 wt %, Ti = ~0.1 wt %, V = ~228 ppm, Zn = ~50 ppm, Ba = ~770 ppm, Th = ~6.3 ppm, and U = ~4.7 ppm. Some layers have relatively high Mn/Fe (~10), and these tend to have higher concentrations of Co + Ni + Cu.

Nodules from the Atlantic Ocean, EATL N4, and NAP N4 that have relatively low Mn/Fe, have the highest concentrations of REY, with average ΣREY concentrations of, respectively, ~3360 and ~3880 ppm. ΣREY concentrations in the Pacific nodule RC12-192GS and crust EW9602-09RD are lower, ~2670 and ~2500 ppm, respectively, whereas the Pacific nodule that has highest Mn/Fe (JC120-104) has much lower ΣREY (~990 ppm). The Arctic nodule PSh-125.29(1) has extremely low ΣREY (~123 ppm). Most of the individual nodule layers have positive Ce anomalies, whereas high Mn/Fe layers in nodule JC120-104 and most layers in nodule PSh-125.29(1) have negative Ce anomalies. All layers are generally depleted in the LREE relative to the HREE, especially in JC120-104 (LREE/HREE = 0.46).

4.3. Factor Analysis

To assess the controls on the chemical composition of the nodules and crust, the elemental data were subjected to statistical factor analysis [38] using the RStudio Inc. Varimax rotation scheme with Kaiser normalisation (RStudio.Inc., Boston, MA, USA). The results of this analysis are shown in Table 4, and in Tables A1–A6 in Appendix A. Most of the total variance in the chemical composition within nodule JC120-104 and the crust (EW9602-09RD) can be accounted for by five factors, and most of the variance in nodules RC12-192GS, EATL N4 and NAP N4 can be accounted for by four factors. The variance in the chemical composition of the nodule from the Arctic (PSh-125.29(1)) is mainly accounted for by three factors.

Table 4. Varimax rotated factor matrix for samples in this study. Numbers in bold denote elements that appear to be loaded in the factor.

Factor 1 is the most important control on REY concentrations in all samples (excluding Ce in the crust and nodules JC120-104 and PSh-125.29(1)), and Ti, V, Fe, and Co in Atlantic nodules NAP N4 and EATL N4, and the South Pacific nodule RC12-192GS. In the Arctic nodule this factor controls V, Fe, and the REY. Factor 1 accounts for 50–77% of the total variance of the samples. In most of the samples it has negative loadings for Mn, Ni, Cu, and Zn. This factor likely represents the hydrogenous Fe-Mn-(oxyhydr)oxide fraction of the Atlantic and South Pacific nodules (represented by FeMnO in the elemental maps, Figures 3–8) and identified as Fraction 3 by [39]. In the Arctic nodule it likely represents detrital aluminosilicate material (SiO in Figure 8) and is identified as Fraction 4 by [39]. In nodule JC120-104 and the crust it most likely represents a Ca-rich phosphate (CaP in Figure 3) in association with Fe-(oxyhydr)oxides, although this cannot be confirmed as no Ca or P data were acquired.

Factor 2 controls Mn, Ni, Cu, and Zn in the Atlantic nodules NAP N4 and EATL N4, the South Pacific nodule RC12-192GS, and the Arctic nodule PSh-125.29(1). In these samples it has negative loadings for Fe, Cr, and Th. In sample JC120-104 this factor controls Fe, Ce, Th, and U, and it has significant negative loadings for Mn and Zn. In the crust this factor controls Ti, V, Fe, Co, Ba, Ce, U, and partially Mn. Factor 2 most likely represents the Mn-rich diagenetic fraction of the nodules (identified as MnO in Figures 3–8) and is similar to Fraction 2 reported by [39]. This factor may also be associated with Fe-oxides in nodule JC120-104 (FeO in Figure 3). In the crust this factor most likely represents an additional hydrogenous phase (FeMnO in Figure 4) and is denoted Fraction 3 in [39]. This factor accounts for the 13–24% of the total variance in the chemical composition of all of the ferromanganese deposits sampled in this study.

Factor 3 controls Ti, V, Cr, and Fe in most of the nodules, and Co, Ti, Nd, Gd, Dy, and U in the crust. This factor likely represents the material (AlSiO in Figures 3–8), and it accounts for 4–10% of the total variance in the chemical composition. This fraction is part of the residual group identified by [39] as Fraction 4.

Factor 4 controls Co in the Atlantic nodule EATL N4, Ni, and Cu in JC120-104 and Mn, Ni, Cu, and Zn in the crust, but it does not have a significant loading in any of the other samples. It accounts for the 1–6% of the total variance. The element distribution suggest that Factor 4 represents an additional hydrogenous oxide in the nodules (likely included in the FeMnO phase in Figures 3–8, and part of Fraction 3 in [39], and a pure diagenetic Mn-oxide fraction in the crust (MnO in Figure 4, that is identified as Fraction 2 in [39].

Factor 5 is only present in the crust sample EW9602-09RD, and it only shows a significant loading for Mn in the crust and for Co in the CCFZ nodule JC120-104, which might be indicative of additional minor amounts of Mn-Fe oxides. It accounts for 5% of the total sample variance.

5. Discussion

5.1. Genesis of Deep-Sea Ferromanganese Deposits

SEM analyses reveals that the internal structure of deep-sea ferromanganese deposits is highly heterogeneous. In turn, our LA-ICP-MS analyses indicate that the chemical composition of the crust and nodules is also heterogeneous, and factor analysis shows that individual deposits can acquire metals and REYs from a variety of different sources, including seawater, sediment pore waters, and aluminosilicate material. Based on the relative abundances of Mn, Fe, and Ni + Cu + Co [40], the ferromanganese crust and nodules from the Atlantic Ocean mainly acquire metals from seawater, whereas different layers within the nodules from the Pacific Ocean acquire metals either from seawater or sediment pore waters (Figure 9), which would not be apparent from measurements of their bulk chemical composition.
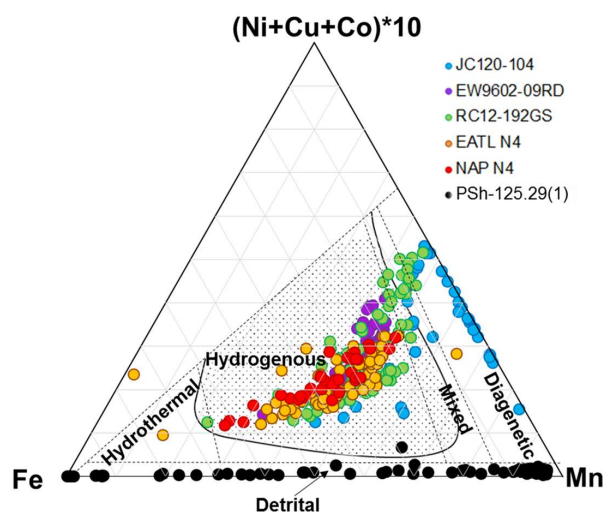

Figure 9. Ratios of Fe:Mn:(Cu + Ni + Co) for layers within ferromanganese crust and nodule samples. Black lines define different modes of formation, according to [18,40] and this study (see below). The dotted area denotes nodules that are REY-enriched.

High-resolution mapping of individual layers within nodules from the German license area E1 in the easternmost part of the CCFZ also reveals the presence of both dense, dark layers with low average Mn/Fe (1.8) and low average Ni + Cu (0.81 wt %), and bright dendritic layers with high average Mn/Fe (96) and high Ni + Cu (~4 wt %) [18]. The former were referred to as "layer type 1" and were attributed to hydrogenetic precipitation from oxic waters, whereas the latter were referred to as "layer type 2" and attributed to metal precipitation from sub-oxic pore waters. Most of the nodule and crust layers analysed in this study have relatively low Mn/Fe (<~3; Table 2) and the only layers that have very high Mn/Fe (up to 80.4) come from the nodule sample JC120-104, which is also from the CCFZ. Thin microlayers in Atlantic nodules NAP N4 and EATL N4 and in the South Pacific nodule RC12-192GS have intermediate Mn/Fe values of between 3 and 10 and intermediate Ni + Cu concentrations of 2–3 wt %. These microlayers appear bright in the backscatter images shown in Figures 5–7. Although many authors have observed "mixed" hydrogenetic-diagenetic signals, they are typically attributed to the mixing of type 1 and type 2 layers during bulk analysis [18]; however, we note that some of the layers with intermediate Mn/Fe values have higher Cu + Ni, which suggests that these layers form from an oxic diagenetic, rather than a hydrogenous, source.

REY analyses may also be useful for assessing the principal mode of formation of different layers [12,41–43]. REY distribution patterns for different layers within the Atlantic nodules are relatively homogeneous, with strong positive Ce anomalies (~2.5–4), and enrichment of Ho with respect to Y (Figure 10). This pattern is typical for surface complexation of REY from ambient seawater and subsequent hydrogenetic precipitation [10,20,21,26,43]. The crust sample also has a positive Ce anomaly (2.31–4.45), but it is more strongly enriched in the HREE relative to the LREE compared to the Atlantic nodules. This is characteristic of hydrogenetic crusts that are phosphatised [44], consistent with our SEM observations of the presence of Ca-phosphate filled cavities within the crust structure (Figure 4c).

Layers that have relatively high Mn/Fe (principally those within the nodule from the CCFZ, sample JC120-104) by contrast have negative Ce anomalies (~0.75 compared to ~1.5 for layers with low Mn/Fe), as well as lower REY concentrations (~230 vs. ~1620 ppm for layers with low Mn/Fe). Early diagenesis of organic material mobilises Mn and the trivalent REY, but not Ce^{4+} [12,45,46]. Mn and the trivalent REY subsequently precipitate at the sub-oxic/oxic interface, so Ce^{4+} is depleted relative to the trivalent REEs in ferromanganese precipitates. The lower REY content of these layers is likely due to the relatively fast nature of diagenetic precipitation [10,46], as the REY are complexed in seawater and REY complexes are scavenged very slowly [12,20,26]. Mn deposit in slow-precipitating,

colloidal related elements, such as the REY. Additionally, diagenesis can induce the dissolution of Fe-Mn-(oxyhydr)oxides, releasing associated REY to sediment pore waters [42].
Figure 10. REY distribution patterns for relatively high Mn/Fe (closed circles) and relatively low Mn/Fe (open circles) layers in each sample, normalised to North America Shale Composite (NASC; [47]).

Plots of the Ce anomaly vs. Y/Ho and Nd concentration (Figure 11) support the REY distributions. The only layers that have a diagenetic signature are from the Arctic nodule and some of those from the CCFZ nodule; all of the other layers represents hydrogenetic precipitates. As our high-resolution data clearly distinguishes hydrogenous and diagenetic precipitates, we can better assess their relative growth rates based on Co content [48]:

$$\text{Growth Rate} = 0.68/(\text{Co}_n)^{1.67}, \tag{1}$$

where $\text{Co}_n = \text{Co} \times 50/\text{Fe} + \text{Mn}$, with Co, Fe and Mn in wt %. This method does not account for any hiatuses in precipitation of Co (e.g., [48]) and, therefore, only provides a minimum age. Bearing this in mind, our data indicate that the hydrogenetic layers have relatively slow growth rates (~1–2 mm/Ma), whereas the diagenetic layers form much more rapidly (up to ~10–17 mm/Ma in the nodule JC120-104). This is consistent with results of other studies based on bulk compositions (e.g., [9]).
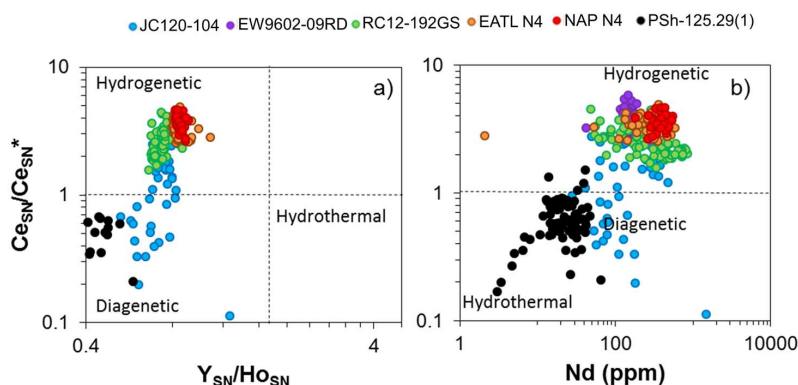

Figure 11. Relationship between (**a**) $\text{Ce}_{SN}/\text{Ce}_{SN}*$ ratio vs. Nd concentration and (**b**) $\text{Ce}_{SN}/\text{Ce}_{SN}*$ ratio vs. $\text{Y}_{SN}/\text{Ho}_{SN}$ ratio in individual layers of nodule and crust samples, where $\text{Ce}_{SN}* = 0.5 \times \text{La}_{SN} + 0.5 \times \text{Pr}_{SN}$ and SN = shale normalised. Crust sample EW9602-09RD is not shown in (**a**) because it is phosphatised (see text for details). Fields for hydrothermal, hydrogenous and diagenetic layers are defined according to [12].

A model summarising the different modes of nodule formation revealed in this study is shown in Figure 12. The greater diagenetic component of the nodule from the CCFZ in comparison with the other deposits indicates that conditions in surface sediments must have been sub-oxic for sustained periods at this site during nodule formation. The oxygen penetration depth (OPD) into sediments in the CCFZ at the present day is ~1 m (Table 1). However, in the past, at the time the nodule started to form (~17 Ma, based on its size and growth rate), this site was located closer to the equator, which is a zone of high primary productivity. The higher availability of organic matter in the bottom sediments at this time suggests that the oxic/sub-oxic boundary within the sediments was located closer to the seafloor, facilitating nodule growth by diagenetic processes (Figure 12a). By contrast, the typical oxygen penetration depth (OPD) in the deep North Atlantic Ocean at the present day is much deeper, ~18 m [27], and bottom waters are highly oxygenated [43]. The OPD in the South Pacific abyssal plain, close to the location of nodule sample RC12-192GS and crust sample EW9602-09RD, is also deep (up to 75 m; [23]) due to low primary productivity in the South Pacific Gyre. Hence, nodules and crusts that form on sediments that have a low organic carbon content tend to have a hydrogenous source, whereas nodules that rest on sediments with a relatively shallow OPD also contain a diagenetic signature (Figure 12).
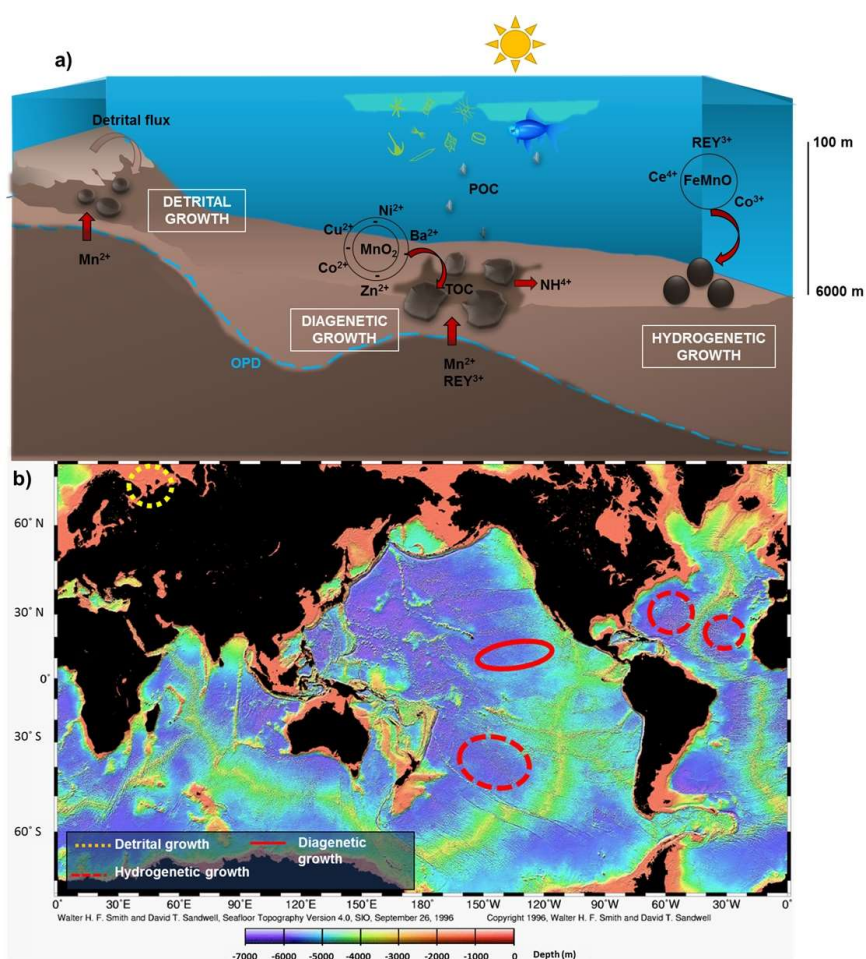

Figure 12. (**a**) Schematic diagram based on [1] showing detrital, hydrogenetic, and diagenetic processes of nodule formation; and (**b**) map showing the relative importance of these processes relative to geographical location of samples analysed in this study. OPD = oxygen penetration depth, separating underlying anoxic sediments from overlying oxygenated sediments. TOC = total organic carbon and POC = particulate organic carbon, concentrations of which are a function of surface productivity. See text for a more detailed explanation.

The transition metal and REY composition of the Arctic nodule is clearly different from the other nodules and the crust (Figures 9 and 10). This nodule has exceptionally low Ni + Cu + Co and very variable Mn and Fe, similar to the bulk composition of nodules from the Kara Sea [36]. This type of composition is usually attributed to a hydrothermal source [40], but the nodules have negative, rather than positive, Y anomalies (Figure 10) that preclude hydrothermal input [12]. Additionally, the REY distribution pattern and REY concentration of the Arctic nodules is rather similar to shale (Figure 10), consistent with statistical element associations (Table 3) that indicate that the principal source of the REY is the input of detrital material. For this reason, we have delimited a new field for detritally-sourced nodules on Figure 9. Mn/Fe ratios within individual nodule layers are highly variable (0.74–10), and much higher than NASC (0.016; [47]). Together with negative Ce anomalies (Figures 9 and 10) this is strong evidence for diagenetic precipitation from sub-oxic pore waters [12]. Consequently, nodules are only found in those parts of the Kara Sea that host a thin layer of oxic sediments (Figure 12), and they are absent in anoxic sediments presumably because Mn (and Fe) oxyhydroxides cannot precipitate [30]. In addition, the Arctic nodule has an extremely high growth rate (Equation (1); up to ~8080 mm/Ma), similar to that estimated for shallow water nodules from the Gulf of Cadiz (~1400–5000 mm/Ma; [5]). Thus, dilution of the authigenic phases by detrital material, combined with high nodule growth rates and rapid burial rates [4] preclude significant enrichment in Ni + Cu + Co and the REY; models for the genesis of nodules based on geochemical relationships observed in deep-sea settings cannot, therefore, be applied to nodules that form in shallow waters.

5.2. Controls on the Resource Potential of Deep-Sea Ferromanganese Deposits

The economic resource of ferromanganese deposits is mainly based on their high content of Ni, Co, and Cu, with a growing interest in their potential as a REY resource.

Our study nevertheless reveals that the metal content of ferromanganese deposits can be highly variable, depending on their environmental setting. Table 5 provides an estimate of metal resource potential based on the average of all of our LA-ICP-MS analyses. Overall, dominantly hydrogenetic deposits tend to offer a better resource potential for Co and REY, while dominantly diagenetic deposits have higher concentrations of Ni and Cu. Shallow-water nodules from the Kara Sea do not contain high quantities of any of these metals, and estimated resources of Ni and Cu are much lower than the global annual consumption (Table 5).

Nodules from the Northwest Atlantic basin could supply significant quantities of Co (~up to 72×10^5 T) and REY (~up to 38×10^5 T), representing ~90 times the current global annual consumption of Co and ~36 times that of the REY (Table 5). As hydrogenetic nodules tend to be smaller, the nodule density is lower, so only very large fields of hydrogenetic nodules are likely to represent a viable resource. As discussed in Section 2, large nodule fields are, however, scarce in the Atlantic Oceans as they are confined to relatively small, deep basins because sedimentation rates are too high in the rest of the ocean to support nodule formation [20]. On the other hand, lower sedimentation rates and a shallower carbonate compensation depth (CCD) makes nodule-rich deep basins in the Pacific more common and extensive. For these reasons, large-sized diagenetic nodules from the CCFZ provide a similar metal tonnage to hydrogenetic nodules (up to ~68×10^5 T of Co, and up to ~34×10^5 T of REY), even though they are less enriched in Co and REY. Similarly, the high quantities of ferromanganese crusts in the large Southwestern Pacific seamount province (up to ~75 kg/m^2, [29]) provide up to ~14.2×10^5 T of Co (~16 times the global annual demand) and ~2.3×10^5 T of REY (~2 times the global annual demand), even though the crusts are only found on the top of seamounts that have a maximum surface area of ~1200 km^2.

Table 5. Average Co, Ni, Cu, and ΣREY content of ferromanganese crusts and nodules measured in this study, and estimated average resources. [a] Based on 2012 global annual demand (g.a.d.) of 105,000 T [49]; [b] Based on 2015 g.a.d. of 87,000 T [50]; [c] Based on 2010 g.a.d.of 1465 mT [51]; [d] Based on 2015 g.a.d. of 22.5 mT [52]; [e1] Resource characteristics of Western Pacific ferromanganese crusts on submarine seamounts in [29]; [e2] Seamount dimensions and abundance in the Austral Volcanic chain from [53]; [f1] and [f2,], data collected during JC120 cruise at the CCFZ in May 2015; [g1] Nodule resource and dimensions in Southwest Pacific basins from [24]; [h1] Data on nodule distribution in deep Atlantic basins are extremely sparse and numbers given here are based on similar nodules from the Angola Basin from [42]; [h2] Compiled data from [44]; [i1] From [21]; [i2] Dimensions of the NW Atlantic basin from [54]; [j1] Density of nodules in the Kara Sea from [4]; [j2] Estimated from data collected during the R/V Professor Shtockman cruise in October 2013.

Resource		Cook-Austral Volcanic Chain	UK Claim (CCFZ)	SW Pacific Basin	East Atlantic	North West Atlantic	Kara Sea

Cu	Avg. content (ppm)	2300	8900	4100	1600	1100	100
	Mass of metals (T × 10^5)	1.38–2.06	9.08–304	4.92–47.6	2.25–7.69	3.15–10.8	≤0.08
	Mass/Global annual demand [d]	≤0.009	≤1.35	≤0.21	≤0.03	≤0.05	≤3 × 10^{-4}

The diagenetically-influenced nodules from the CCFZ have the potential to yield the highest tonnages in Ni and Cu, up to ~376 and ~304 × 10^5 T, respectively (Table 5), which represents ~0.03 times the global annual consumption of Ni and ~1.35 times that of Cu. In comparison, the amounts of Cu and Ni contained in hydrogenetic deposits are ca. one order of magnitude lower.

6. Conclusions

Analyses of the structure and chemical composition within individual nodules and crusts reveal great internal variability. Nodules from the Atlantic Ocean, and the ferromanganese crust sample, tend to consist of layers of Fe-Mn-rich oxides with relatively low Mn/Fe (<3) that precipitate from oxic seawater. These nodules are enriched in ΣREY, Fe, and Co, and they grow only slowly (~1 mm/Ma). The crust sample has experienced diagenetic phosphatization. Large nodules from the CCFZ in the Pacific Ocean also contain layers that have much higher Mn/Fe (up to ~60) and Cu, Ni, and Zn, that precipitate from sub-oxic sediment pore waters. These layers grow much faster (~7 mm/Ma) compared to the layers that have low Mn/Fe (~1–2 mm/Ma). Nodules from the shallow Arctic Ocean have highly variable textures, with high concentrations of detrital material and relatively low concentrations of transition metals and ΣREY. The Arctic nodules are extremely fast-growing (~500 mm/Ma).

The mode of genesis of ferromanganese deposits, as well as their growth rate and the oxygen penetration depth of their host sediments, all affect the final resource potential. Although hydrogenetic deposits are generally better resources of Co and the REY, diagenetic deposits have higher quantities of Ni and Cu, and they also tend to have higher nodule densities because they grow more quickly. Arctic nodules are a poor resource because they have a high detrital component. Deep sea nodules and ferromanganese crusts contain significant quantities of ΣREY and Co with respect to the global annual demand, but are less important resources of Ni and Cu.

Appendix A

Varimax rotated correlation matrices for samples in this study are shown. Numbers in bold denote elements that appear to have a significant correlation ($p < 0.05$).
