(1. Transportation School of Southeast University, Nanjing, Jiangsu, China; 2. School of Engineering, University of Warwick, Coventry, UK; 3. Hunan Provincial Communications Planning, Survey & Design Institute, Changsha, China)

Abstract: As the crucial components among the tied-arch bridge, the local failure of hangers may trigger a progressive collapse through the entire tied-arch bridge. However, the current design guidance as regards hangers still lacks consideration of structure robustness under an extreme hazard. To improve the structural robustness of tied-arch bridge under extreme conditions, a new hanger design method is proposed, which is termed as asymmetric parallel double-hanger system. Based on Miner's linear cumulative damage law, an analysis on the fatigue life of the double-hanger system was conducted to verify the feasibility of the proposal, and then a dynamic time-history analysis was employed to simulate the transitory fracture impact due to one or more hangers fracturing. According to the simulation results, the structural robustness is greatly enhanced with asymmetric parallel-double hanger system design, when compared with single hanger system design. When one or more hangers reveal local damage, it will not trigger a progress failure to the whole structure in particular. Several practical suggestions of bridge system's load-carrying capacity are also put forward for the future arch bridge design at the end of this paper.

Keywords: Tied-arch bridge; Alternative load path; Double hanger system; Sudden removal; Fatigue life.

24 1. Introduction

25 Structural systems optimized to meet member design criteria as specified in current design
26 standards and specifications may not provide sufficient levels of robustness to withstand a
27 possible local failure under an unforeseen extreme event. In fact, local failure in one structural
28 element may result in the failure of another. The chain reaction of failures that progress throughout
29 the structure will cause a level of damage disproportionate to the initial damage, even a
30 catastrophic collapse of the whole structure. (ASCE, 2002; Ellingwood and Dusenberry, 2005).
31 Such progressive collapse occurs, because a sudden local change in structural geometry due to the
32 loss of load-carrying members will result in extra dynamic force in surrounding elements, which
33 may exceed the bearing capacities of them (Buscemi and Marjanishvili, 2005).

34 Catastrophic events, such as the collapse of the Alfred P. Murrah Federal Building in Oklahoma
35 City in 1995, the I-35W Mississippi River Bridge in Minnesota in 2007 and the I-5 Mount Vernon
36 WA Bridge in 2013, have given an alarm about the structural survivability after an initial local
37 failure. Meanwhile, the lack provisions of structural integrity or robustness in current design codes
38 have got more attention from structural engineering community. Some efforts have been
39 contributed, for instance, by the US General Service Administration and US Department of
40 Defense, which have announced the guidelines of progressive collapse assessment method (GSA,
41 2003; US DoD, 2005). Furthermore, enhancing structural robustness in design codes has also been
42 considered in other countries (Pearson and Delatte, 2005).

43 As the reliable structural damage detection is still a big challenge, a rational design approach
44 should be a threat-independent method, by which it could avoid designing for an extreme event

45 with specific action magnitude that may exceed the normal loading condition during the service
46 life. This can be achieved through structural robustness, which is defined as “the ability of a
47 structure to withstand events like fire, explosion, impact or consequence of human error, without
48 being damaged to an extent disproportionate to the original cause”, according to EN1991-1-7 Euro
49 code 1 (BSI, 2006). According to Euro code 1, the local damage is acceptable only if the following
50 two principles can be guaranteed. The first is that the local damage will not endanger the whole
51 structure. The second is that the overall load-carrying is maintained during an appropriate length
52 of time to allow the necessary emergency measures to be taken (Gulvanessian and Vrouwenvelder ,
53 2006).

54 According to the mentioned design principle, the alternative load path design method is the
55 pragmatic option for structure engineers, instead of tying force method (Starossek,2007) and
56 specific load resistance method (Paramasivam, 2008) due to their limitations in real applications
57 (Byfield, 2004; Byfield and Paramasivam, 2007; Ellingwood et al., 2007).

58 By the alternative load path design method, the structure is designed so that a new load path could
59 be developed to pass through the local failure zone. The alternative load path relies on the
60 ‘robustness’ of the structure (Agarwal, 2011), which is achieved through continuity and ductility
61 of members to redistribute force following localized damage. The more important point from this
62 design method is to direct the designer’s attention towards the behavior of the structure after some
63 damage has occurred (Starossek, 2007; Morison et al., 2014).

64 The basic procedure of the alternative load path analysis, given by ASCE, US GSA and US DoD,
65 is analyzing the damaged structure with a specific loading to check if the initial damage

66 propagates. The damage is introduced by notional removal of one primary load-bearing member at
 67 a time. Four analytical approaches for alternative load path analysis have been approved by the US
 68 GSA and the US DoD, which are linear static, non linear static, linear dynamic and non-linear
 69 dynamic analysis (ASCE, 2002; GSA, 2003; US DoD, 2005). However, these existing guidelines
 70 were developed for buildings and may not be suitable for bridges, because of the differences in
 71 their topologies, configurations and load conditions. Therefore, much more efforts are desired for
 72 the development of bridge design guidelines. (Starossek, 2007; Giorgio et al, 2013).

73 The through tied-arch bridges have been widely constructed in China since 1990s. However, there
 74 is still a big gap between the research outcome and the mature design theory. Unexpected
 75 accidents, i.e. structure collapse of tied-arch bridge, cannot be ignored anymore (Chen and Wang,
 76 2009), which are listed partially in Table 1.

77 Among all the listed bridges in Table 1, hanger fracture and overload is responsible for most
 78 bridges' collapse, except Qijiang Rainbow Bridge in Chongqing city. According to Chen and
 79 Wang (2009), the hanger fracture is generally the result of hanger stand corrosion or anchor head
 80 corrosion, protective layer damage or short hanger damage, or anchor head joint damage.

81 **Table 1-Through tied-arch bridge accident in China since 1999**

Bridge Name	Collapse Date	Collapse cause
Qijiang rainbow bridge in Chongqing	Jan. 11,1999	Low construction quality
Yibin South Gate Bridge in Sichuan	Nov. 7,2001	Hanger fracture and overload
Changzhou Canal Bridge in Jiangsu	May 14,2007	Hanger fracture
Yuping Mountain Bridge in Fujian	Jan. 11,2010	Hanger fracture and overload
Peacock River Bridge in Xinjiang	Apr. 12,2011	Hanger fracture and overload
Tongyu River Bridge in Jiangsu	Jul. 11,2011	Hanger fracture
Wuyishan mansion Bridge in Fujian	Jul. 11,2011	Hanger fracture
Luoguo Jinsha River Bridge in Sichuan	Dec.10,2012	Hanger fracture

82 Due to its vulnerability to fatigue phenomena, hangers can be treated as one of the most
83 significant components in a through-arch bridge system. Local damage at a hanger may lead to
84 subsequent damage of various components in the vicinity or even progressive collapse of the
85 whole bridge. Hong and Khudeira introduced an innovative application of a new design technique
86 by providing a pair of structural strands at each hanger location, which is the way for advancing
87 part of the load-path redundancy (Hong and Khudeira, 2014). Instead of using two identical
88 hangers in the conventional design of double-hanger system, Jiang et al (2013) suggested to use
89 two different hangers to increase the safety factor of the members in the vicinity of local damage,
90 in order to improve the robustness of the through-arch bridge. However, few efforts are devoted to
91 enhance the robustness of tied-arch bridge by improving hanger design approach. Hence, for
92 attenuating the probability of the progressive collapse, this paper put forward a new design
93 concept for tied-arch bridge hangers, which is named as asymmetric parallel double-hanger
94 system. Its mechanism will be analyzed to evaluate its feasibility for enhancing the bridge's
95 robustness.

96

97 2. Introduction of Asymmetric Parallel Double Hanger System

98 The double-hanger anchorage (Fig.1a) is often used with its higher safety and more convenience
99 of hanger replacement, when compared with the single-hanger anchorage (Hong, 2014). The two
100 hangers at the same anchorage are generally designed with the same material and cross-section
101 area. Theoretically, the probability of fracture of those two hangers is the same because they are
102 exposed to the same loading circumstance. In this case, this design method has two important
103 limitations . There is a great uncertainty regarding which of the two hangers is the first one to fail,

104 and the resulting impact due to the sudden fracture of one hanger would cause another hanger at
105 the same anchorage fracturing promptly. Furthermore, it would trig a chain reaction of progressive
106 collapse of tied-arch bridge. Therefore, the current design method cannot improve the safety and
107 the convenience of hanger replacement.

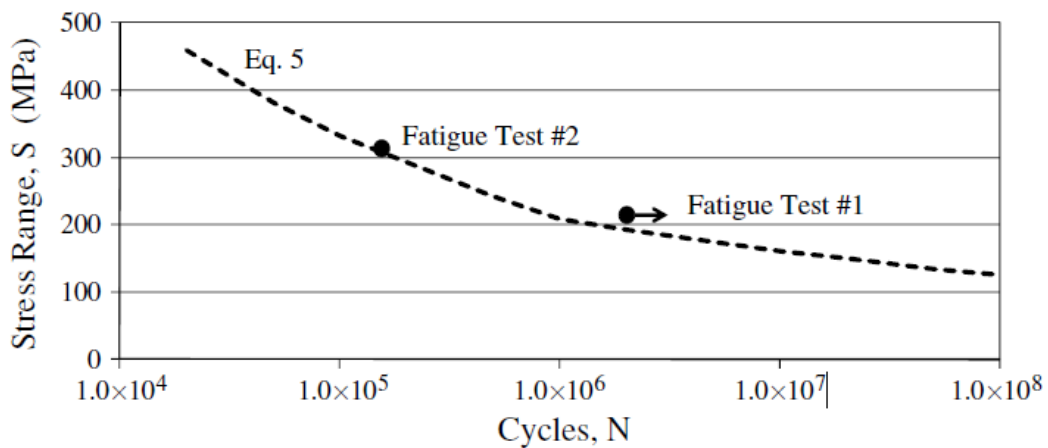

108
109 a) Symmetrical parallel double hanger system b) Asymmetric parallel double hanger system

110 **Fig. 1 Two systems of parallel double-hanger**

111 According to the alternative load path, one of hangers at the same anchorage has to be designed
112 with a different parameter from another, for ensuring that the two hangers could not fracture
113 simultaneously. For that purpose, a new design concept, which is named as asymmetric parallel
114 double-hanger system, is proposed firstly in this paper, as shown in Fig.1b. Analysis on its
115 function mechanism is then focused in this paper for improving the robustness of tied-arch bridge.

116 According to the fatigue S - N curve for steel strands in Fig.2, the hanger fatigue life is quite
117 sensitive to the stress level. For instance, two hangers will have an obviously different fatigue life,
118 when their stress difference increases to a certain proportion, i.e. 10% (Soltani et al, 2012). This is
119 the prerequisite to use the asymmetric parallel double hanger system to limit the local damage of
120 tied-arch bridge.

121

122

Fig. 2 Predicted and experimental S-N data

123 The asymmetric parallel double-hanger system has two hangers with different cross-sectional

124 areas, as shown in Fig. 1b. One of them with smaller cross-sectional area is defined as the failure

125 hanger, referred to as *F* hanger, provided that it is the first fracturing hanger in case of local

126 damage. Another one with a larger cross-sectional area is defined as the safety hanger, referred to

127 as *S* hanger, as shown in Fig. 1b, provided that the hanger could not fracture simultaneously in case

128 of local damage. This paper only considers the damage caused by fatigue loads, and the material

129 defects and manufacturing defects are not considered. Based on the mentioned fatigue life theory,

130 the fatigue life difference between two hangers could occur due to the cross-section area

131 difference.

132 In this case, once the *F* hanger fractures, the *S* hanger will temporarily endure all loads. For this

133 purpose, two design objectives need to be reached as follows. Firstly, the fracture of the failure

134 hanger will not cause the fracture of the safety hanger immediately. Secondly, after the failure

135 hanger fractures, the rest of the hanger system, which stands all the structural force, should work

136 properly for a certain period, to provide enough time for hanger replacement.

137 3. Analysis on the fatigue life difference of asymmetric parallel
138 double hangers

139 A through-type tied-arch bridge is employed here to study the function mechanism of the proposed
140 design method. The Luoguo Arch Bridge is located at Yalong River estuary near Yinjiang Town,
141 Panzhihua City, Sichuan Province of China. The bridge is a half-through tied-arch bridge with a
142 160 m main span, floating deck system and reinforced concrete arch rib. The longitudinal beams
143 are the structure of the floating deck system of this bridge, composed by a number of simply
144 supported longitudinal segments. The segments within a range of central span arch are supported
145 by the transverse beams, while others are supported by transverse caps. This bridge was originally
146 designed with a vertical single hanger system.

147 In order to assess the feasibility of the proposed method for structure robustness enhancement,
148 Luoguo Arch Bridge will be redesigned by the author, with the asymmetric double-hanger system
149 in this paper. Figure 3 shows the geometry overview of the redesigned bridge. There are 13 pairs
150 of hangers in the north side of the bridge deck, which are numbered as 1-13 from west to east,
151 while another 13 pairs of hangers in the south side follow the same rule for convenience. The two
152 hangers, sharing the same anchorage, are termed as a and b for the south arch and a' and b' for the
153 north arch (see Fig.4).

154
155 **Fig. 3 Overview of the redesigned bridge with asymmetric parallel double-hanger system (Unit : m)**

156

157

a) Single hanger system

158

south side

159

north side

160

b) Asymmetric parallel double-hangers system

161

Fig.4 Hangers numbering rule for tied arch bridge

162 For the asymmetric parallel double-hanger system as shown in the Fig.4b, Number 1a to 13a

163 represent the failure hangers in the south, while the corresponding number, 1b to 13b, stand for

164 safety hangers, and the same pattern is employed in the north arch.

165 It is assumed that one of two hangers (hanger a) bears most of load, acting as the failure element,

166 and the other one (hanger b) at the same anchorage could bear a partial load, acting as a safe

167 element, therefore a fail-safe unit (FSU) is formed. The stress of failure element need to reach

168 about 10% more than that of safe element, so the use of the cross-section area of failure hanger is

169 0.905 times that of related safety hanger ,such as $A_{1a} = 0.905A_{1b}$, while their gross area is the same

170 as that of the single hanger in traditional design system, e.g. $A_{1a}+A_{1b}$ in Fig. 4b is equal to A_1 in

171 Figure 4a. The way to achieve the stress difference between two hangers is that an elastic cushion
 172 with a smaller stiffness is mounted between the anchorage at the lower end of hanger b and the
 173 bearing surface of transverse beam. The maximum elastic resistance is equal to about 10% of the
 174 design internal force of the conventional parallel double hanger, and the maximum compressible
 175 height is equal to 10% of the elastic elongation of hangers. Be clear to see Fig. 1, the FSU element
 176 is the same with the conventional parallel double suspender as its shape, but is not the same as the
 177 design theory, and also with a variance in structure pattern and parameters, their structure function
 178 is not the same at all.

179 3.1 Introduction to Palmgren-Miner linear cumulative damage law

180 The vehicle loads, which cause structural fatigue damage, are assumed as variable amplitude
 181 cyclic loading, and then they are treated as a combination of a series of unvaried amplitude cyclic
 182 loading (Fatemi and Yang, 1998). The Palmgren-Miner linear cumulative damage law shows that
 183 when a structure endures a series of unvaried amplitude cyclic stresses σ_i , its corresponding
 184 fatigue life can be assumed as N_i , then the fatigue life N of the hanger under variable amplitude
 185 cyclic stress can be calculated by the formula as follow (Fatemi and Yang, 1998):

$$186 \quad N = \frac{1}{\sum_{i=1}^k \left(\frac{n_i^T}{N_i}\right)} = \frac{1}{\frac{n_1^T}{N_1} + \frac{n_2^T}{N_2} + \dots + \frac{n_k^T}{N_k}} \quad (1)$$

187 Where, N_i is the fatigue life of hanger under unvaried amplitude stress σ_i , calculated by a specific
 188 S-N curve, n_i^T is the cycle number under unvaried amplitude stress for each hanger, which can be
 189 obtained from the fatigue loading spectrum of the traffic flow data of vehicle. The specific S-N
 190 curve is proposed by the University of Texas in the United States (Esslinger, 1992), and calculated

191 by the following formulas (2).

$$192 \quad \lg N_i = 14.36 - 3.5 \lg \Delta \sigma_i, \quad \Delta \sigma_i \geq 200 \quad (2a)$$

$$193 \quad \lg N_i = 37.187 - 13.423 \lg \Delta \sigma_i, \quad \Delta \sigma_i < 200 \quad (2b)$$

194 Where, $\Delta \sigma_i$ is the stress range of the hanger under typical vehicle loading.

195 3.2 Fatigue life prediction of double hangers of tied arch bridge

196 The fatigue loading model of this bridge, which is taken from a related literature to calculate the
197 fatigue life of hangers (Xia, et al 2014), has 4 kinds of fatigue check-calculation vehicle loading,
198 which are labeled as M1, M2, M3 and M4 respectively. Due to its symmetry, the anchorages No.1
199 to No.7 are selected for further study. Based on the result calculated with FEM (see Fig. 5), their
200 stress amplitude under typical vehicle loading is given in Table 2.

201 Based on the stress amplitude of hangers mentioned above, the fatigue lives of all hangers can be
202 predicted, by using the Palmgren-Miner linear cumulative damage law and finite element analyst,
203 which is shown in Table 3.

204 **Table 2 Stress amplitude of hangers for double-hanger system (Unit: MPa)**

Hanger number \ load case		load case			
		M1	M2	M3	M4
1	a	48.9	132	178	184
	b	43.0	116	156	161
2	a	47.8	129	175	180
	b	43.6	118	159	164
3	a	47.5	128	174	179
	b	43.7	118	160	165
4	a	47.4	128	173	179
	b	43.7	118	160	165
5	a	47.3	128	173	179
	b	43.7	118	160	165
6	a	47.2	128	173	178
	b	43.7	118	160	165
7	a	47.1	127	172	178

	b	43.7	118	160	165
--	---	------	-----	-----	-----

205 It is obvious that the fatigue life of safety hanger, represented as b , is significantly longer than that
206 of failure hanger, labeled as a , in the same anchorage. This can also demonstrate that the different
207 stress amplitude in two hangers could lead to their different fatigue lives. Therefore, the failure
208 hanger (hanger a) should fail first, instead of simultaneously fracturing with safety hanger (hanger
209 b).

210 When compared with conventional design method, i.e. the single hanger system, this
211 double-hanger system has two major contributions as follows. First, a slight variance in cross
212 sections of two hangers could induce a remarkable difference in their fatigue lives, as the fatigue
213 lives of the safety hanger can be extended as 3 times as that of the failure hanger in this new
214 system, with just 10% variance in their cross-section areas. Second, the hanger's effective live
215 could reduce significantly if corrosion on steel strands occurs, as the fatigue life of hanger a with
216 smaller cross section is much shorter than that of hanger b .

217 **Table 3 The fatigue lives of all hangers**

Hanger number	Fatigue life /year	
	a	b
1	22.05	126.61
2	28.02	97.58
3	30.49	93.53
4	31.70	93.52
5	32.70	93.52
6	33.22	92.74
7	33.73	91.94

218 4. Dynamic analysis on failure safety for hangers of tied arch bridge

219 A real tied-arch bridge is considered with two types of hanger arrangement, the single hanger
220 system and the asymmetric parallel double-hanger system. In both hanger systems, if a hanger

221 fractures suddenly, the dynamic stress in adjacent hangers will increase dramatically, and will
222 oscillate for a while before getting the stable value of the new increased static stress. If this
223 maximum stress in the adjacent hanger due to transient impact effects is high enough to fracture
224 this hanger, it may cause progress failure of the whole structure. To guarantee the bridge's
225 robustness, the impact effect, caused by sudden hanger fracturing on components in the vicinity
226 and the remaining structure, should be first evaluated in detail. To simulate the sudden fracturing
227 of a hanger, the fractured member is removed from the model and replaced by a set of internal
228 dynamic loading to the remaining structure. The set of applied load is modeled by using a steady
229 internal force in service there, which is then assumed to linearly decrease to zero within a duration
230 δt described in a related reference(Jiang, et al ,2013).

231 In the next three subsections, the dynamic analysis of new designed Luoguo Tied-arch Bridge with
232 asymmetric parallel double-hanger system will be discussed and compared with the original one,
233 which is designed with single hanger system.

234 4.1 Finite element analysis model

235 The finite element model of the arch bridge with single hanger system has 2935 nodes and 4510
236 elements, as shown in Fig.5a, while the other one with the asymmetrical parallel double- hanger
237 system has 2987 nodes and 4536 elements, referring to Fig.5b. In these two models, the arch foot
238 is restricted to 6 degrees of freedom, and the arch crown is restricted to the vertical degree of
239 freedom. The vehicle live load and dead load are taken into account in this paper, in which the
240 vehicle live load is arranged in a form of concentrated load P according to the most unfavorable
241 position.

242
243

a) Single hanger system

b) Double hanger system

244
245

Fig. 5 Finite element model of the whole bridge

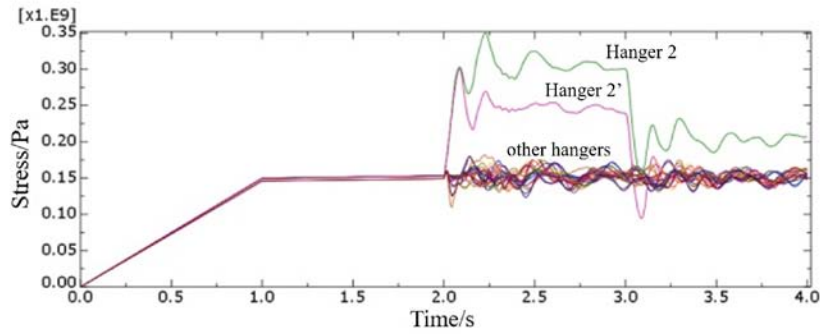

246

247 4.2 Maximum stress of remaining hangers after one short hanger fracturing

248 Many accidents reveal that the fracture of hangers began with the shorter hanger near the end of
249 arch (Kondoh, et al, 2001). It is clear that the shortest hanger 1a has the maximum stress
250 amplitude under 4 types of fatigue vehicle loading, as shown in Table 2, and the same hanger has
251 the shortest fatigue life in Table 3. Therefore, it can be assumed that hanger 1a will fracture first in
252 the double-hanger system, same as the single hanger system.

253 Assuming that the average duration of hanger fracture δt ranges from 0.01s to 1s(Jiang, et
254 al ,2013) , δt is taken as 0.01s in this paper, for considering the most negative condition. The
255 dynamic analysis of sudden fracture of hanger 1 in the singer hanger system is referred as case 1,
256 while the sudden fracture of hanger 1a in the parallel double-hanger system is termed as case 2.

257 Figure 6a shows the tensile stress variation of remaining hangers in case 1, while in Figure 6b the
258 same information is depicted for case 2.

259
260

a) For single hanger system (Case 1)

261
262

b) For asymmetrical parallel double-hanger system (Case 2)

263 **Fig.6 Tensile stress variation of the remaining hangers due to one hanger sudden fracture**

264 It can be seen from Figure 6 that:

265 1) In single hanger system (Case 1), after hanger 1 fractured, the tensile stress in adjacent
266 hangers, i.e. hanger 2 and 2', have a obvious increase, while relatively slight variations can be
267 observed among other hangers. The maximum stress variation is 200MPa in hanger 2, increasing
268 the total stress about 133% when compared with its static loading stress, 150MPa. Therefore,
269 hanger 2 is most likely to be damaged.

270 2) In the asymmetric parallel double hanger system (Case 2), if hanger 1a at the south arch
271 suddenly fractured, the maximum stress response would be noticed in hanger 1a' at the north arch,
272 while hanger 1b at the south arch would also suffer a high stress, just slightly lower than hanger
273 1a'. The maximum stress amplification is 275MPa in hanger 1a', increasing about 53% when
274 compared with the static loading stress, 180MPa. Because the design tensile strength of

275 high-strength steel strands of hangers is 1130MPa, the safety factor of 1a' reaches to 4.11, which is
276 larger than the lower limit of 2.5 proposed by the Design Rules for Highway Cable-Stayed Bridge
277 of China (MTPRC, 1996). Therefore, the fact shows that if tied-arch bridge is designed with the
278 asymmetric parallel double-hanger system, the fracture of failure hanger does not trigger a
279 progress failure of safety hanger at the same anchorage. Because an alternative load path is formed
280 by the safety hanger in the vicinity of local damage zone after the failure hanger fracturing, then
281 the robustness of the whole structure is enhanced to a great extent.

282 3) In the case of a hanger sudden fracturing at the end anchorage, the maximum impact stress in
283 hanger 2 under the single hanger system is larger than that of the hanger 1a' under the asymmetric
284 parallel double-hanger system. In both two hanger systems, the hanger sudden fracturing at the
285 end anchorage will lead to an obvious increase of stress in other hangers at a vicinity of local
286 damage, as a loading impact was applied.

287 4.3 Maximum stress of remaining hangers after two short hangers continuously fracturing
288 After the sudden fracturing of short hangers (hanger 1 or hanger 1a) near the end of arch rib for
289 two hanger design systems, the maximum tensile stress can be observed in hanger 2 in single
290 hanger system or hanger 1a' in parallel double-hanger system, which suggests these two hangers
291 would be the next broken hanger for each case. As a result, the analysis of maximum tensile stress
292 of remaining hangers should be divided into two parts, one with hanger 1 and 2 fracturing
293 continuously in single hanger system, the other with hanger 1a and 1a' fracturing continuously in
294 double-hanger system.

295 Figure 7 shows the tensile stress variation of remaining hangers for the single hanger system (Fig.
 296 7a) and the asymmetrical parallel double-hanger system (Fig. 7b), which is influenced by sudden
 297 continuous fracturing of two short hangers near the end of arch rib.

298 a) Single-hanger system (Case 1)

301 b) Asymmetrical parallel double-hanger system (Case 2)

302 **Fig.7 Maximum stress of remaining hangers under continuous fracturing of two hangers**

303 It can be seen from Figure 7 that the maximum tensile stress is 459 MPa in hanger 3 for the single
 304 hanger system, and 253 MPa in hanger 1b for the parallel double-hanger system. The tensile stress
 305 in hanger 1b is relatively small and beneficial to the safety of the residual structure.
 306

307 As a result, if the tied-arch bridge is redesigned with the asymmetrical parallel double hanger
 308 system, the residual structure can still work with enough structural safety, in the case of failure and
 309 safety hanger at the same end anchorage fracturing continuously. The fact shows that a tied-arch
 310 bridge with the asymmetrical parallel double-hanger system will become a robust structure, when

311 following a sudden fracturing of one or more short hangers. Instead, compared with the new
312 design approach discussed in the paper, the residual structure with the single hanger system has
313 less safety, because hanger 3 will be most likely to be the third broken hanger. Therefore this fact
314 indicates that the remaining hangers may fracture continuously in a tied arch bridge with the
315 single hanger system, which most likely will lead to the progress failure of the whole bridge.

316 5. Discussion and conclusions

317 In order to enhance tied-arch bridge robustness and avoid subsequent collapse due to hangers'
318 local damage, a practical and novel design concept, named as the asymmetric parallel
319 double-hanger system, has been proposed and evaluated in this paper. The asymmetric parallel
320 double-hanger system is designed with one failure hanger and another safety hanger at each deck
321 suspension point. The feasibility of this new design concept has been further evaluated and
322 demonstrated by authors through the fatigue life analysis and dynamic time-history analysis of a
323 case study, supported by a finite element model.

324 According to the fatigue life analysis, which is based on Miner linear cumulative damage law, the
325 fatigue lives of two hangers are various due to the distinct stress amplitude inside. Therefore, the
326 failure hanger, with higher stress, loses bearing capacity first, instead of fracturing simultaneous ly
327 with safety hanger. Moreover, a dynamic time-history analysis has been conducted to simulate the
328 transitory loading fracture impact due to one or more hangers fracturing.

329 A numerical model of the full-scale tied-arch bridge was also employed to compare the
330 performance of proposed new double-hanger design system with the traditional one. Based on the
331 results, it can be confirmed that the stress inside the safety hangers along the bridge have slight
332 variations if one or two short failure hangers are broken, which subsequently can be the safety

333 assurance for the rest of the structure. On the contrary, the bridge with traditional single-hanger
334 system is more likely to experience further continuous fracture, thus triggering a whole bridge
335 collapsing, when compared with proposed parallel double-hanger system.

336 In short, the robustness of tied arch bridge can be highly enhanced by implement the asymmetric
337 parallel double-hanger system. The feasibility of developed double-hanger system has also been
338 demonstrated by the alternative load path theory in the paper. In order to keep its perform ability,
339 further analysis would be made in detail available.
