1 **Abstract**

2 Eddies in the Southwestern Atlantic were detected from more than 18 years of

3 satellite altimetry data using a modified version of the Okubo–Weiss method. The

4 spatial distribution and polarity of eddies were examined. A larger concentration of

5 cyclonic (anticyclonic) eddies was found on the left (right) side when looking

6 downstream on some of the largest current systems in the region, such as the South

7 Atlantic Current, the anticyclonic circulation associated with the Zapiola Drift (ZD)

8 and the northern branch of the Antarctic Circumpolar Current. In the region isolated

9 by the anticyclonic Zapiola Current, 91% of eddies were cyclonic. The observed

10 distribution of eddies is in agreement with the generation of eddies from meanders of

11 the above-mentioned currents: cyclonic (anticyclonic) eddies might detach from a

12 meander of the current on the left (right) side when looking downstream on the

13 current. Furthermore, in the ZD area, the bottom topography plays a key role in

14 determining the trajectory of eddies: the anticyclonic current associated with the ZD

15 meanders and eventually generates a cyclonic eddy that enters the ZD region only

16 across the northeastern border, where the gradient of potential vorticity is lower.

17 Finally, average surface chlorophyll-a concentration inside cyclonic and anticyclonic

18 eddies shows that the former have higher chlorophyll-a values. Thus, on average, the

19 classical eddy-pumping theory explains the difference in chlorophyll-a concentration

20 within eddies in the Southwestern Atlantic.

21

1 **1. Introduction**

2 Eddies are important to all aspects of oceanography and often involve the overlap of
3 research areas such as physical and biogeochemical oceanography. From a physical
4 point of view their importance resides in the fact that they play an important part in
5 the mixing processes in the surface layer of the ocean and for transporting energy, like
6 heat. Eddies can contribute significantly to the transfer of the temperature and salinity
7 characteristics of one region to another, very different, region. Thus they play an
8 important role in the meridional overturning circulation, the strength of which is a key
9 parameter for monitoring and predicting climate change [e.g. Mazllof et al., 2010;
10 Farneti et al., 2010]. From a biogeochemical point of view, cold-core (cyclonic)
11 eddies bring nutrients to the surface which become available for photosynthesis.
12 Hence they can fertilize the upper ocean to support phytoplankton blooms. Eddies
13 also play an important ecological role, since they can trap, transport and disperse
14 different communities of organisms. Thus eddies play a crucial role at regional and
15 global scales in several domains. Improving the knowledge of the spatial distribution
16 and polarity of eddies will contribute to a better understanding of their role in the
17 ocean.

18 In the Southwestern Atlantic (SWA), the eddy kinetic energy can be as high as 1700
19 cm^2 s^{-2} (Figure 1). The confluence of the Malvinas Current (MC) and the Brazil
20 Current (BC) near 38ºS, forms the Brazil/Malvinas Confluence region (BMC,
21 hereafter), one of the most energetic regions of the world ocean [Gordon, 1981;
22 Chelton et al., 1990]. The meanders, eddies and filaments in the BMC are
23 extraordinary in terms of their shape, size and abundance compared to other regions
24 of the ocean. High-resolution images of sea surface temperature (SST) and
25 chlorophyll-*a* concentration suggest that the associated mesoscale processes enhance
26 the productivity in the region [e.g. Barré et al., 2006; Saraceno et al., 2005].
27 The BMC is characterized by the confluence of the Subantarctic Front (SAF) and the
28 Subtropical Front (STF), which are, respectively, the northern limit of the subantarctic
29 waters and the southern limit of the subtropical waters. The region where the SAF and
30 STF merge at about 39ºS is usually referred to as the Brazil/Malvinas front [e.g.
31 Saraceno et al., 2004]. A scheme of the upper circulation of the region, including the
32 position of these fronts, is shown in Figure 1. The MC is part of the northern branch
33 of the Antarctic Circumpolar Current (ACC), which carries the cold (<7ºC at the

3

1 surface in winter) and relatively fresh Subantarctic Mode Water (SAMW)
2 equatorwards along the western edge of the Argentine continental shelf. The BC
3 flows polewards along the continental margin of South America as part of the western
4 boundary current of the South Atlantic subtropical gyre. It transports the warm
5 (higher than 26ºC at the surface) and salty South Atlantic Central Water (SACW).
6 After its confluence with the MC, the BC separates into two branches [Peterson and
7 Stramma, 1991]. One branch turns to the north forming a recirculation cell while the
8 other branch flows southwards and returns northeastwards at about 44ºS. This second
9 branch is commonly referred to as the overshoot of the Brazil Current and, east of
10 45ºW, it forms the South Atlantic Current [Peterson and Stramma, 1991]. After the
11 collision with the BC, the main flow of the MC describes a sharp loop forming the
12 Malvinas return flow. The Malvinas return flow flows southwards and turns eastwards
13 at 49ºS.

14 Further towards the center of the South Atlantic, an important feature that affects the
15 large-scale circulation is the presence of a large zonal sedimentary deposit known as
16 the Zapiola Drift (ZD). The effect of this submarine feature on the surface of the
17 ocean is clearly observed in the satellite images of SST, SST gradient, chlorophyll-*a*
18 and sea surface height (SSH) [Saraceno et al., 2005]. The anticyclonic circulation
19 around the ZD is eddy-driven [Dewar, 1998]. A meridional transport of 80 Sverdrups
20 (1 Sverdrup = 10^6 m^3 s^{-1}) on the western and eastern flanks of the ZD with southgoing
21 and northgoing currents, respectively, of about equal magnitude, has been estimated
22 from in situ measurements during the WOCE A11 cruise [Saunders and King, 1995b].
23 Satellite altimetry data [Saraceno et al., 2009] and model outputs [Bigorre and Dewar,
24 2009; Venaille et al., 2011] suggest that the anticyclonic circulation associated with
25 the ZD is characterized by an important interannual variability. Despite the
26 importance of eddies in the ZD circulation, a precise description of the interaction
27 between eddies and the anticyclonic circulation has not been provided yet.

28 Eddies have been detected in the Southwestern Atlantic since the first global satellite
29 infrared images of SST were acquired [Legeckis and Gordon, 1982]. Despite their
30 high spatial resolution, sea surface temperature (SST) images are limited by the cloud
31 coverage. In contrast, satellite radar altimetry sensors provide "cloud-free" SSH
32 images. Using a combination of along-track SSH, climatological temperature and
33 salinity fields, Lentini et al. [2006] showed that 40 warm-core eddies were released by
34 the BC in the period 1993-1998. Analysis of gridded SSH maps suggested that a

1 much larger number of eddies is present in the region [Saraceno, 2010]. Mesoscale

2 surface circulation can be accurately estimated from SSH data when two or more

3 satellite missions are used to construct gridded fields [Pascual et al., 2006; Chelton et

4 al., 2011a]. Thus, gridded maps of SSH data are particularly useful in the study of

5 mesoscale structures and of the interaction between mean currents and eddies in the

6 ocean. Several studies have therefore used satellite SSH data to detect and track

7 eddies in the ocean [e.g. Chaigneau et al., 2008; Chaigneau et al., 2009; Chelton et al.,

8 2011a].

9 We took advantage of the 18-year-long altimetry time-series to detect eddies and track

10 them in the Southwestern Atlantic. We used one of the most popular techniques to

11 detect eddies, the Okubo–Weiss (OW) algorithm [Okubo, 1970; Weiss, 1991; Isern-

12 Fontanet et al., 2003]. The OW algorithm is based on physical criteria, whereas other

13 methods of eddy detection are more geometrical. Because of the complex nature of

14 the flow field in the Southwestern Atlantic and in order to distinguish eddies from

15 meanders we had to modify the OW method slightly. We validated the modified

16 method and then applied it to the whole altimetry time-series. We examined the

17 distribution of eddies and of eddy polarity and discuss their relation with the

18 circulation in the region.

19 The article is organized as follows. Section 2 provides a brief description of the

20 datasets. The methodology and the validation strategy are explained in section 3.

21 Section 4 presents and discusses the results. Section 5 summarizes the results and

22 outlines perspectives.

23

1   **2. Data**

2

3   2.1 <u>Satellite sea-level anomaly</u>

4   We used the reference, delayed time-series of the gridded data fields of sea level

5   anomaly (SLA) produced by Ssalto/Duacs and distributed by AVISO

6   (www.aviso.oceanobs.com). SLA AVISO fields are computed with reference to a

7   mean for the period 1993–1999. We extracted the gridded data fields of SLA for the

8   region of interest ($60°W–35°W$, $50°S–35°S$) from the global SLA fields for the period

9   14 October 1992–1 December 2010 (18+ years).

10   Satellite altimetry missions have accurately determined sea surface height (SSH) since

11   the launch of the TOPEX/Poseidon (T/P) satellite in 1992 [Fu and Cazenave, 2001].

12   Six satellite altimetry missions (Jason-1, ERS-1, ERS-2, Envisat, GFO and Jason-2)

13   have been launched since then. The processing of along-track data from the altimetric

14   missions into gridded fields of SSH was described by Le Traon et al. [2003]. The

15   reference time-series always uses two contemporary satellite missions to construct the

16   interpolated SSH fields: one in a 10-day repeat orbit (T/P, followed by Jason-1 and

17   Jason-2) and another one in a 35-day repeat orbit (ERS-1, followed by ERS-2 and

18   Envisat). The time-series is produced weekly on a $1/3°\times1/3°$ grid in a Mercator

19   projection. The objective procedure to obtain the gridded fields of SSH by AVISO

20   includes a spatial filtering that has half-power filter cut-off wavelengths of about 2º in

21   latitude and 2º in longitude, which corresponds to an e-folding radius of about 0.4º, or

22   about 40 km at mid-latitudes [Chelton et al., 2011a]. The dataset can then be used to

23   detect eddies whose radii are larger than 40 km. We only considered eddies detected

24   offshore in depths greater than 200 m. Indeed, intrinsic difficulties affect the

25   corrections applied to the altimeter data on the Patagonian shelf (e.g. wet tropospheric

26   component, tidal component) and data are usually flagged as unreliable within a

27   certain distance of the coast. Moreover, the interpolation of along-track data provides

28   only marginal resolution of high-frequency and small-scale structures which are

29   abundant on the Patagonian shelf [Acha et al., 2004].

30

31   2.2 <u>SeaWiFS-derived chlorophyll-*a* concentrations</u>

32   Near-surface chlorophyll-a concentrations used in this study consist of 8-day, 9-km

33   gridded estimates derived from satellite measurements of ocean color by the Sea-

6

1   viewing Wide Field-of-view Sensor (SeaWiFS) [McClain et al., 1998] using the

2   Garver–Siegel–Maritorena (GSM) semi-analytical ocean color algorithm [Garver and

3   Siegel, 1997; Maritorena et al., 2002]. These chlorophyll-*a* concentration fields are

4   available   online   at

5   ftp://ftp.oceancolor.ucsb.edu/pub/org/oceancolor/MEaSUREs/Seawifs/. Despite the

6   fact that cloud cover places a strong limitation on this dataset, the composite average

7   minimizes the cloud-cover problem and keeps a reasonable time resolution to allow

8   detection of mesoscale features in the ocean surface layer. Color images are used in

9   the validation strategy described in Section 3.3 and to composite chlorophyll-*a*

10   concentrations within eddies of the same polarity. The most common explanation for

11   the different chlorophyll-*a* concentration in the eddy interior is that the geostrophic

12   adjustment required to maintain the circulation implies a thermocline rise inside the

13   cyclonic eddies and a depression in the anticyclonic eddy. When the nutricline and the

14   thermocline are coincident, then enhanced production is expected within cyclonic

15   eddies. However this simple explanation has its shortcomings: complex non-linear

16   biophysical dynamics control the phytoplankton growth, which depends on the critical

17   balance of stirring, mixed-layer depth, stability of the water column, temperature and

18   availability of light.

19

20   2.3 Surface-buoy trajectories

21   Satellite-tracked drifter data used in this work are part of the global data set available

22   from the Drifter Data Assembly Center (DAC) at the National Oceanographic and

23   Atmospheric Administration's Atlantic Oceanographic and Meteorological Laboratory

24   (NOAA/AOML). The data set is public and can be downloaded from AOML's ftp

25   server (ftp://ftp.aoml.noaa.gov/phod/pub/buoydata).

26   Quality control at DAC involves the interpolation of the raw fixes (16 to 20 satellite

27   fixes per day per drifter) uniformly at six-hour intervals using a kriging interpolation

28   scheme [Hansen and Poulain, 1996]. The data from drifters with no drogue attached

29   were discarded, as were all interpolated positions with an uncertainty greater than 1

30   km. The remaining trajectories were low-pass-filtered with a 2-day Gaussian filter in

31   order to remove tidal fluctuations and other high-frequency variability of no interest

32   in the present study. The Ekman component, estimated following Ralph and Niiler

4 [1999], was excluded: in the region under consideration, the estimated Ekman

5 velocity is similar to the velocity uncertainty (less than 1 cm s^{-1}, even with strong

6 winds).

5

6 **3. Methodology**

7 3.1 Eddy-detection

9 The Okubo–Weiss method may be summarized as follows. First, surface velocities

10 are estimated from SLA following the geostrophic approximation:

$$v = \frac{g}{f}\frac{\partial \eta}{\partial x} \quad (1) \qquad u = -\frac{g}{f}\frac{\partial \eta}{\partial y} \quad (2)$$

10

14 where u and v are, respectively, the zonal and meridional geostrophic surface velocity

15 components, η is SLA, g is the gravity and f is the Coriolis factor. The relative

16 vorticity (ω), normal strain (S_n) and shear strain (S_s) deformation rates can then be

17 computed:

$$\omega = v_x - u_y \quad (3) \qquad S_n = u_x - v_y \quad (4) \qquad S_s = v_x + u_y \quad (5)$$

15

16 The Okubo–Weiss parameter (W) can be then computed as:

$$W = S_n^2 + S_s^2 - \omega^2 \quad (6)$$

17

22 W was developed first by Okubo [1970] and later by Weiss [1991]; the automatization

23 of the method was first implemented by Isern-Fontanet et al. [2003]. The method

24 identifies regions of the flow where the relative vorticity component dominates the

25 strain tensors, defined as the center of the eddy. Considering horizontally non-

26 divergent flows, i.e. where $u_x + v_y = 0$, equation 6 simplifies to:

$$W = 4(v_x u_y + u_x^2) \quad (7)$$

23

26 Eddies are identified as the regions where $W < b\sigma$, σ being the standard deviation of

27 the geostrophic velocity field at each time, b being a constant value. We used a value

28 for b that has been successfully used in several regions: 0.2 [Chaigneau et al., 2008].

1 Results (not shown) obtained with the classical OW algorithm described above
2 indicated that several eddies were identified in regions where non-closed contours of
3 SLA were present. This happens in regions where a strong curvature of the
4 geostrophic velocities exists; i.e. where strong meanders are present. The
5 Brazil/Malvinas Confluence and overshoot regions are the two regions where most of
6 the eddies corresponding to non-closed contours were detected. To overcome this
7 difficulty we adopted the following strategy: Once we obtained the center of the eddy
8 by applying the OW algorithm described above, we looked for the corresponding
9 SLA value and searched for the highest (lowest) closed contour for cyclonic
10 (anticyclonic) eddies. The center of the eddy was then re-estimated based on the new
11 contour. We stopped the algorithm when one of the following two conditions first
12 arose: (i) the length of the eddy contour was larger than the previous one by more than
13 7 pixels; (ii) the distance between any pair of points within the contour considered
14 must be less than 400 km. These two conditions avoid cases of multiple centers and
15 preserve the usual notion of a compact form for rotating vortices. The second
16 condition is the same as in Chelton et al. [2011a]. We then estimated the amplitude of
17 each eddy as the absolute difference between the SLA at the center of the eddy and
18 the average of the SLA at the corresponding contour. We considered only eddies with
19 amplitudes greater than 2 cm. The 2-cm threshold was chosen after a sensitivity study
20 (section 3.3).

21 The simple technique described above combines the physical criteria of the OW
22 method with the conventional geometric definition of an eddy as a closed contour of
23 SLA.

24 3.2 Eddy tracking

25 The eddy-tracking algorithm was adapted from Penven et al. [2005] and follows the
26 approach used by Chaigneau et al. [2008]. The method minimizes a distance D
27 between the detected eddies of two consecutive maps. For each eddy (e1) identified
28 on a given map at time t1 and for each eddy (e2) identified on the next map at time t2
29 and rotating in the same sense as e1, the non-dimensional distance $D_{e1;e2}$ is defined as:

30
$$D_{e1;e2} = \sqrt{\left(\frac{\Delta D}{D_0}\right)^2 + \left(\frac{\Delta R}{R_0}\right)^2 + \left(\frac{\Delta \mu}{\mu_0}\right)^2 + \left(\frac{\Delta EKE}{EKE_0}\right)^2}$$
(8)

31

1   where ΔD is the spatial distance between e1 and e2, and ΔR, $\Delta \mu$ and ΔEKE are,

2   respectively, the radius, the vorticity and the eddy kinetic energy (EKE) differences

3   between e1 and e2. D_0, R_0, μ_0 and EKE_0 are, respectively, the characteristic length

4   scale ($D_0 = 100$ km), the characteristic radius ($R_0 = 50$ km), the characteristic vorticity

5   ($\mu_0 = 10^{-6}$ s^{-1}) and the characteristic EKE ($EKE_0 = 100$ cm^2 s^{-2}). $D_{e1;e2}$ represents the

6   degree of similarity between two eddies (the smaller the value, the higher the

7   similarity between e1 and e2). Thus, the algorithm selects the eddy pair (e1, e2) that

8   minimizes $D_{e1;e2}$ and considers this pair to be the same eddy that is tracked from t1 to

9   t2. To avoid jumping from one track to another, the search distance, ΔD, was

10   restricted to 150 km. Eddies may also disappear between consecutive maps,

11   particularly if they pass into the gaps between satellite ground tracks. To minimize

12   this problem, we searched for the same eddy for two weeks after its disappearance.

13   3.3 <u>Validation strategy</u>

14   To determine the accuracy of the methodology described above we applied an

15   objective validation protocol similar to the one described by Chaigneau et al. [2008].

16   The location and number of eddies detected with the modified OW method were

17   compared with the location and number of eddies detected by two different methods,

18   one using drifting buoys (method A1), the other using composite images of

19   chlorophyll-*a* concentration and SLA (method B1). The two methods are described

20   below. An example illustrating eddies detected by the three methods (modified OW,

21   A1 and B1) is shown in Figure 2.

22   3.3.1 Method A1: eddy detection using drifting buoys

23   We selected buoy trajectories that clearly showed loops suggesting eddy-trapping,

24   that is trajectories that made more than two complete loops (clockwise or

25   anticlockwise) in a geographical region no larger than 3° by 3°. This way, fifty-two

26   trajectories were selected. For each section of the trajectory considered as

27   corresponding to an eddy, the center and radius were computed taking into account

28   the positions of the buoy in the region where the buoy made at least two complete

29   loops. The center was estimated as the intersection of the average latitude and

30   longitude of the selected buoy positions. The radius was estimated as half of the

31   largest distance between positions.

1   3.3.2 Method B1: eddy detection using images of chlorophyll-*a* concentration and

2   SLA

3   Ten randomly selected maps of SLA were used in combination with the

4   corresponding chlorophyll-*a* concentration images. An example is shown in Figure 2.

5   We chose the center and radius of each vortex present in the ten composite images by

6   a careful inspection of the closed contours of SLA and the spatial distribution of

7   chlorophyll-*a* concentration. Each composite image was displayed in a PC screen and

8   using an interactive program we selected the center and radius of each eddy. We

9   repeated the procedure separately for cyclonic and anticyclonic eddies.

10   3.3.3 Comparison strategy

11   To quantify the differences between the number of eddies detected by methods A1

12   and B1 with those detected by the modified OW method, we computed, for the

13   cyclonic and anticyclonic eddies separately, the intersection and complementary areas

14   of each eddy. If the intersection area was larger than 50% of the complementary area,

15   we considered the eddy detection to be correct. A sensitivity study (results not shown)

16   in which we modified the radius and position of two overlapping eddies showed us

17   that the 50% value is a good choice for the correct detection of eddies whose radii do

18   not differ by more than 50% and for which the distance between the centers is shorter

19   than the average of the two eddies' radii.

20   While method A1 could only be used to compare 52 eddies, we counted a total of 223

21   eddies in the 10 images selected at random (method B1). Results are presented in

22   Section 4.1.

23

24   **4. Results**

25   4.1 <u>Validation</u>

26   As discussed in the data section (2.1), we do not consider the continental platform.

27   The total number of eddies detected by each method (A1, B1, OW) and their polarity,

28   whether cyclonic or anticyclonic, are reported in Table 1.

29   According to the criteria defined in section 3.3.3, of the 52 eddies detected using

30   method A1 (drifting buoys), 42 matched those detected by the OW method, leading to

31   a 81% agreement between the A1 and OW methods.

1 The B1 method (composite color images and SLA maps) and the OW method

2 detected 223 and 264 eddies, respectively, in the 10 randomly selected images that

3 lead to an agreement of 80% between the A1 and OW methods. Inspection of the 41

4 mismatched eddies showed that they were randomly distributed and equally

5 proportioned between cyclonic and anticyclonic ones. On the other hand, methods B1

6 and OW both gave a slightly larger number of cyclonic than anticyclonic eddies

7 (Table 1).

8 Thus, the comparison of the OW method with methods A1 and B1 suggests that the

9 uncertainty associated with the automated eddy-detection methodology used in this

10 work is less than 20%. Detecting eddies with amplitudes smaller than 2 cm led to

11 larger differences between the methods, so we kept the 2-cm threshold, which

12 corresponds to the accuracy of SLA maps. We consider that the modified OW method

13 is validated and applied it to the entire altimetric time series.

14

15 4.2 Eddy distribution

16 Figure 3 shows the distribution of cyclonic (C) and anticyclonic (A) eddies in the

17 Southwestern Atlantic. First, there are more C than A eddies inside the area defined

18 by the ZD. In the rectangular box contained inside the longest potential vorticity

19 contour that encloses the ZD (see Figure 3), the number of C eddies is 10 times

20 greater than the number of A eddies (182 and 18, respectively, for the period

21 considered). On the other hand, just outside the ZD, the number of A eddies (236) is

22 greater than the number of C eddies (180). The region defined as outside the ZD was

23 estimated as a one-degree margin that follows the closed potential vorticity contour

24 depicted in Figure 3. The two results described above are compatible with the

25 following explanation, schematically shown in Figure 4. The ZD is a dynamically

26 isolated region [Dewar, 1998; Saraceno et al., 2005, 2009] which is contoured by an

27 A circulation. We propose that eddies that can enter the ZD isolated area are

28 detachments attributable to meanders in the A circulation associated with the ZD

29 (Figure 4). This mechanism may also explain why the number of A eddies is higher

30 than the number of C eddies just outside the ZD area. The eddy-formation mechanism

31 is the same as that used to explain the formation of A (C) eddies north (south) of the

32 Gulf Stream in the North Atlantic [e.g. Schmitz and Holland, 1982].

Second, as expected, the number of eddies is maximum in regions where the EKE is higher, such as the BMC region or the region between the SAF and the ZD, south of 46ºS (Figure 1 and Figure 3). C eddies are more numerous north of the STF, while A eddies are more numerous along or south of the STF (Figure 3). Meanders of the BC and the consequent generation of A (C) eddies south (north) of the mean position of the STF is a potential mechanism explaining the distribution of eddies in the BMC region. Detachments of eddies from meanders of the Antarctic Circumpolar Current (ACC), which flows westwards along the SAF, may also explain the larger concentration of C eddies north of the SAF between 50ºW and 35ºW (Figure 3). However, a larger concentration of A eddies south of the SAF is not observed. Two spots centered approximately at 50ºS, 48ºW and 50ºS, 37ºW with a significant number of eddies (both C and A) are located south of the SAF and correspond to regions where the sea floor is shallower than it is in the surrounding regions, enhancing the formation of meanders and eddies. This is also reflected by large values of EKE (Figure 1).

Third, eddies are mostly observed within the region with potential vorticity larger than -2.1×10^{-8} m^{-1} s^{-1} (Figure 3). Indeed, the -2.1×10^{-8} m^{-1} s^{-1} potential vorticity contour appears as a barrier for eddies except for the two locations south of the SAF mentioned above and for the region north of Brazil/Malvinas front. The modified OW algorithm did not find eddies either in the MC itself or in the Malvinas return-flow area. Evidently, the Brazil/Malvinas front is a barrier for eddies. The position of the Brazil/Malvinas front, indicated in Figure 3, has been estimated from infrared sea surface temperature images [Saraceno et al., 2004], hence a completely independent dataset.

Fourth, there is a local maximum in the number of C eddies centered just over the top of the ZD; that is, where the ZD reaches its maximum height (see Figure 3 at 44.5ºW, 45.5ºS). This can be explained by considering that, once C eddies are generated inside the ZD area, the bottom topography favors their location over the top of the ZD: assuming that bottom friction is weak, the conservation of potential vorticity implies that a vorticity anomaly travelling upslope would need to decrease its relative vorticity (neglecting the *beta* effect for simplicity), so that anticyclones would weaken, whereas cyclones would be reinforced on their way towards the peak of the ZD.

1   Finally, comparison of potential vorticity contours (Figure 5) with the trajectories of

2   the C and A eddies that we could follow for more than 6 weeks (Figure 6) also

3   suggests a relevant observation: most of the C eddies that enter the ZD region did so

4   from the northeastern flank. This is the region where the slope of the potential

5   vorticity contours is less pronounced (Figure 6). It is therefore more likely that the A

6   current associated with the ZD is able to meander more vigorously in this region or, in

7   other words, is less controlled by the topographic gradient that defines the ZD. As a

8   consequence, C eddies generated as illustrated in Figure 4 enter the ZD area more

9   frequently on the northeastern flank of the ZD region.

10

11   4.3 Temporal evolution of cyclonic eddies inside the Zapiola Drift area

12   The time-series of the number of C eddies inside the ZD area suggests that eddies

13   entered at specific dates (Figure 7). The time-series is compared with an estimation of

14   the transport around the ZD (Figure 7). Using satellite altimetry data for the period

15   1993–2006, Saraceno et al. [2009] showed that the 4-year low-pass-filtered transport

16   time-series associated with the ZD had a local minimum during the years 1998–2003.

17   We extended the transport estimation to compare it with the time-series of the number

18   of C eddies that enter the ZD area produced in this work (Figure 7). The comparison

19   suggests that when the low-frequency component of the transport associated with the

20   ZD is less than 25 Sverdrups, more eddies are able to enter the ZD area and, when the

21   transport is larger than 25 Sverdrups, fewer C eddies enter the ZD area. On the other

22   hand, the non-filtered transport time-series (not shown) does not significantly

23   correlate at any time lag with the number of C eddies inside the ZD area. While the

24   low-frequency transport may affect the distribution of eddies, an instantaneous

25   response is not necessarily expected. In other words, the foregoing results suggest that

26   the low-frequency component of the transport of the anticyclonic current associated

27   with the ZD may be associated with the number of C eddies inside the ZD area,

28   whereas this is not observed at higher frequencies.

29   The yearly average temporal distribution of A eddies that entered the ZD area (18 in

30   total) shows that a maximum of three eddies per year entered during the years 2003

31   and 2007, whereas during the other years a maximum of two eddies per year entered

32   (not shown). The low number of A eddies does not allow any robust statistical

14

1 analysis. Furthermore, trajectories of long-lived eddies (Figure 6) suggest that A

2 eddies that entered the ZD area dissipated very quickly.

3

5. Summary and discussion

5 Eddies in the Southwestern Atlantic are detected from satellite altimetry data using a

6 modified version of the OW method. Distribution of eddies in the region shows two

7 salient observations: (i) the number of C eddies detected inside the ZD area is ten

8 times larger than the number of A eddies; and (ii) a larger number of A eddies were

9 detected just outside the ZD area. We proposed that perturbations of the A circulation

10 associated with the ZD may generate meanders which, when occurring inside the ZD

11 area, could detach from the main current and generate a C eddy (Figure 4). A similar

12 mechanism may explain the higher number of A eddies observed outside the ZD area.

13 The absence of A eddies inside the ZD anticyclone is a strong indication that

14 meandering is occurring. Although very few anticyclonic eddies made their way to

15 the center of the ZD region, this happened when the associated circulation was at its

16 weakest (Figure 7) and indicates the key role of the mean anticyclonic Zapiola

17 Current in selecting what type of eddies can enter the ZD anticyclone.

18 However, another explanation for a preference for cyclonic eddies near the ZD is

19 linked to the conservation of potential vorticity, assuming that bottom friction is

20 weak. Indeed a vorticity anomaly traveling upslope would need to decrease its relative

21 vorticity, so that anticyclonic eddies would weaken, whereas cyclonic eddies would

22 be reinforced on their way towards the ZD center. Figure 6 supports this mechanism,

23 since it shows that anticyclones quickly disappear after entering the ZD area.

24 The preferred path for C eddies to enter the ZD area is the northeastern side of the

25 region, where the potential vorticity gradient is lower compared to other sides (Figure

26 5). Thus, the distribution of eddies described in this work is coherent with an

27 anticyclonic ZD circulation that might meander and release more eddies on the

28 northeastern side of the region.

29 As the elevation of the ZD results in a selection mechanism to filter A eddies, we

30 could anticipate that a similar result should occur in other places with similar

31 characteristics. In the North Atlantic, the Azores Plateau (AP) is an anomaly of the

1   Mid-Atlantic Ridge (MAR), located approximately at 40ºN, 30ºW. The AP appears as

2   a local topographic elevation of roughly 1200 m altitude relative to the MAR, and a

3   lateral extent of 1500 km in both the meridional and zonal directions, and therefore

4   with similar characteristics to the ZD. Evidence also exists that there is an

5   anticyclonic gyre over the AP [Klein and Siedler, 1989; Pollard et al, 1996], but of

6   one to two orders of magnitude lower intensity in transport compared to the

7   anticyclonic ZD Current (100 Sv, according to Saunders and King [1995a]). Since we

8   do not estimate eddies in the AP region, we compared eddy censuses in both the ZD

9   and AP regions by looking at figures from Chelton et al. [2011a]. Their figures 4a and

10 8 clearly show that more cyclonic than anticyclonic eddies entered the ZD region, as

11 we illustrated in the present article. A white spot coincident with the AP region is

12 visible in their Figure 4a [Chelton et al., 2011a], clearly suggesting the bathymetric

13 forcing. However, no predominance of a given eddy polarity is observed in the AP

14 region (their Figure 8). This may be due to the difference in strength of the two

15 anticyclonic currents associated with the seabed elevations.

16 The prospects for continuing the work presented here include a study of the

17 contribution of eddies to an explanation of the spatio-temporal distribution of

18 chlorophyll-*a* in the Southwestern Atlantic. As a preliminary result, Figure 8 shows

19 that the average surface chlorophyll-*a* concentration in C eddies is higher than that in

20 A eddies. Thus, on average, the classical eddy pumping theory, i.e. uplift of the upper

21 thermocline inside the eddy to bring nutrients into the euphotic zone [e.g.

22 McGillicuddy et al., 1998; Siegel et al., 1999], explains the difference in chlorophyll-

23 *a* concentration in the two types of eddies in the SWA. However, careful inspection of

24 the different mechanisms (e.g. eddy pumping, eddy advection, wind-forced Ekman

25 pumping and submesoscale effects) that might explain the spatio-temporal

26 distribution of the chlorophyll-*a* concentration forced by the eddies is necessary

27 before assessing which mechanism makes the largest contribution. Given the wide

28 range of eddy energy (e.g. 10^2 to 2×10^3 cm^2 s^{-2}) and the sharp contrasts in

29 chlorophyll-*a* concentration (0.05 to 10 mg m^{-3}), the SWA is a useful region to test

30 the role of eddies in the chlorophyll-*a* distribution in different environments.

4   Figure 1: Colors indicate the EKE values (units $cm^2 s^{-2}$) of sea-level anomalies for the

5   period 1992–2010 estimated from satellite altimetry data (see text for details of the

6   dataset). *Black lines* indicate potential vorticity isolines (units -1×10^{-8} m^{-1} s^{-1}) and

7   range from -2.1×10^{-8} m^{-1} s^{-1} to -1.92×10^{-8} m^{-1} s^{-1}. The *boldface* closed potential

8   vorticity contour centred at 43ºW, 45ºS corresponds to the -1.92×10^{-8} m^{-1} s^{-1} value

9   and is used to represent the Zapiola Drift area [Saraceno et al., 2009]. The mean

10 positions of the Subtropical Front (STF) and the Subantarctic Front (SAF) are from

11 Saraceno et al. [2004] and are indicated by *black* and *magenta dash-dotted lines*,

12 respectively. Representative positions of the Brazil Current (BC), Malvinas Current

13 (MC), Malvinas Return Flow (MRF), Antarctic Circumpolar Current (ACC), South

14 Atlantic Current (SAC) and overshoot region are indicated.

15

16 Figure 2: **a)** chlorophyll-*a* concentration (mg m^{-3}) in the background; *thin black* and

17 *red contour lines* are SLA isolines contoured every 10 cm from –100cm to 0 cm and

18 from +10 cm to +150 cm; the *blue dotted line* is the trajectory of the buoy # 2529260.

19 **b)** and **c)** are enlarged regions from (**a**). *Black* (*red*) *circles* correspond to the cyclonic

20 (anticyclonic) eddies detected by the OW method (*boldfaced-line circles*), method A1

21 (*dashed-line circle,* see panel **b**) and method B1 (*thin-line circles*). On panel **(b)**,

22 *black dots* correspond to the part of the buoy trajectory considered to compute the

23 date of the SLA and chlorophyll-*a* concentration images displayed (27 February

24 2008). Colorbar on the right refers to the background chlorophyll-*a* concentration

25 field and is common to the three panels.

26

27 Figure 3: Normalized spatial distribution of the concentration of cyclonic (*panel a*)

28 and anticyclonic (*panel b*) eddies in the SWA. The total number of eddies whose

29 centers fall in the area of a given pixel is divided by the largest common value (36).

30 *Black* and *magenta lines* are as in Figure 1 except for the *boldface black line* which

31 here corresponds to the -2.1×10^{-8} m^{-1} s^{-1} potential vorticity contour.. The *red line*

32 corresponds to the area considered in the count of the number of A and C eddies
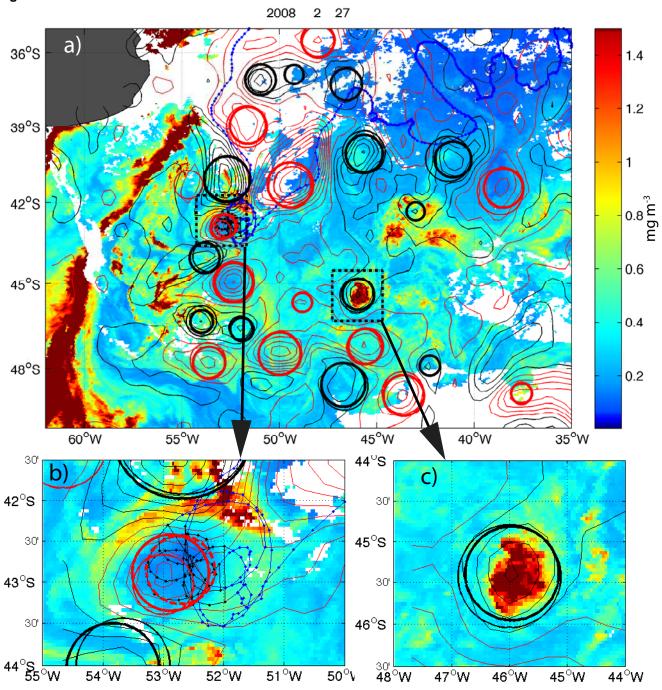

33 inside the ZD.

1

2   Figure 4: Schematic representation of the mechanism proposed to explain the larger

3   number of C (A) eddies inside (outside) the ZD area. *Left panel*: The anticyclonic

4   Zapiola Current (*black arrows*) may generate meanders inside (loop with *blue*

5   *arrows*) and outside the ZD (loop with *red arrows*). *Right panel*: meanders may

6   eventually separate from the main current, creating a C eddy (*blue arrows*) inside the

7   ZD area and an A eddy (*red arrows*) outside the ZD area.

8

9   Figure 5: Potential vorticity contours (units -1×10^{-8} m^{-1} s^{-1}). *Boldface black line*

10 corresponds to the -1.92×10^{-8} m^{-1} s^{-1} contour.

11

12 Figure 6: Trajectories corresponding to the cyclonic (*panel a*) and anticyclonic (*panel*

13 *b*) eddies detected. SAF and STF are represented by *magenta* and *black dash-dotted*

14 lines, respectively. The potential vorticity contour -1.92×10^{-8} m^{-1} s^{-1} is plotted with a

15 *boldface black line*.

16

17 Figure 7: Number of cyclonic eddies inside the ZD area (*black line*) and a 4-year low-

18 pass-filtered transport time-series associated with the Zapiola Current (*red line*, units

19 Sverdrups, 1 Sverdrup = 10^6 m^3 s^{-1}).

20

21 Figure 8: Composite average of chlorophyll-*a* concentration within cyclonic (left

22 panel) and anticyclonic (right panel) eddy interiors in a translating and normalized

23 coordinate system. Only eddies with more than 50% of pixels without clouds have
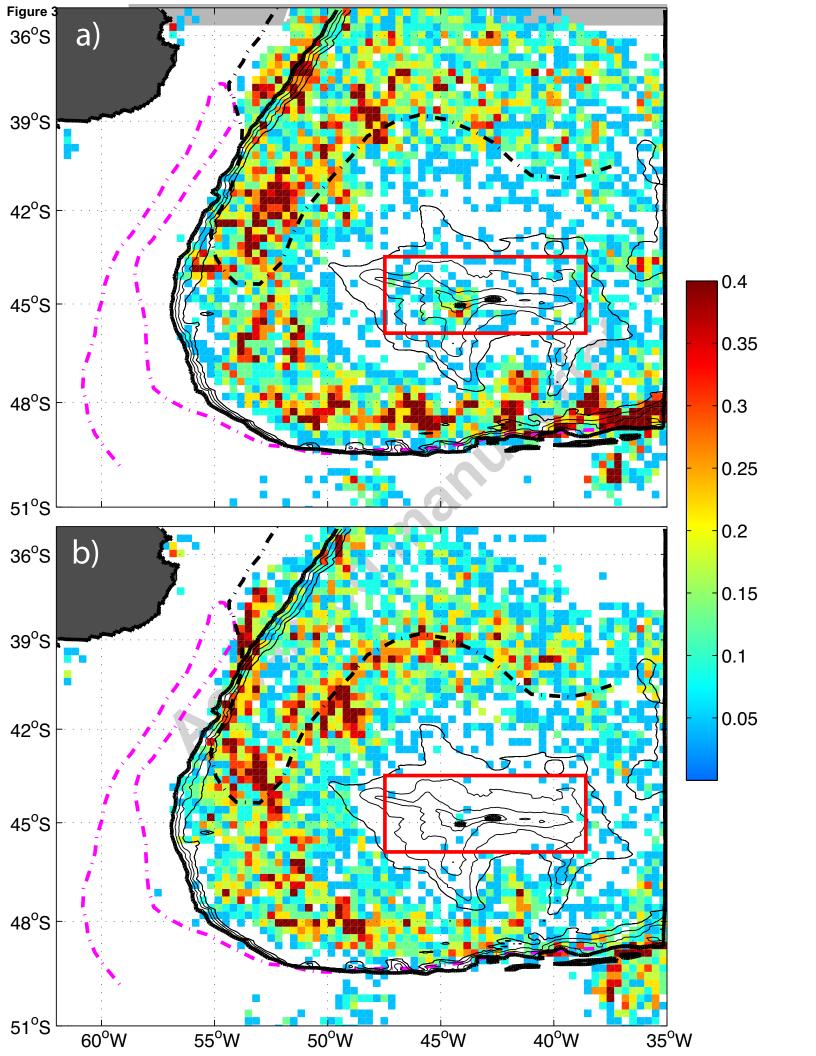

24 been considered.

2

3   Title: On eddy polarity distribution in the Southwestern Atlantic

4

5   Authors: Martin Saraceno and Christine Provost

6

7

8   Highlights

9

10   • Eddies in the Southwestern Atlantic are detected from 18 years of satellite
11   altimetry data.
12   • A larger concentration of cyclonic (anticyclonic) eddies is found on the left
13   (right) side when looking downstream on some of the largest current systems
14   in the region.
15   • The observed distribution of eddies is in agreement with the generation of
16   eddies from meanders of the currents.
17   • In the region isolated by the anticyclonic Zapiola Current, 91% of eddies are
18   cyclonic and enter through the region where the gradient of potential vorticity
19   is lower.
20   • Classical eddy-pumping theory explains the difference in surface chlorophyll-
21   *a* concentration within eddies: average values inside cyclonic eddies are larger
22   than into anticyclonic ones.
