**Abstract**

This study assesses the relationship between social, environmental and operational practices and performance with financial performance, focusing on small- and medium-sized enterprises (SMEs). We seek to establish a relationship between the sustainability and the financial performance of SMEs in economic development, as expressed by the indicators of turnover and business growth. A dataset derived from 119 British, French and Indian firms is used and links between sustainability and the financial performance of SMEs are examined. Bayesian regression modeling was chosen and a model comparison approach was used to assess the robustness of the results to the specific choice of analysis with respect to the shape of the dependent variable's distribution. Overall findings indicate robust regression results especially for the highly significant covariates, but caution should be exercised when interpreting the borderline results. A significant positive association between certain items of sustainability and firms' financial performance is identified as we found that different indicators of sustainability display associations with the two economic indicators and adoption of the former may influence SME performance.

## 1 | INTRODUCTION

Nowadays, driven by the increasingly pressing concerns raised around environmental, social and economic issues, the multifaceted constructs of sustainability are of high priority for the business world and for the key players in the various chains of production (Sancha, Wong, & Gimenez Thomsen, 2016). In this regard, the notion of organizational sustainability has received considerable interest by practitioners and researchers alike (e.g., Linnenluecke, Russell, & Griffiths, 2009), describing proactive activities aiming to contribute to sustainability equilibria. Such equilibria pertain to the integration of aspects of socio-economic and environmental performance, as well as underlying interrelations within and throughout the time dimension while addressing the organizational system as a whole and its critical stakeholders (Lozano, 2012; Lozano, Carpenter, & Huisingsh, 2015). Indeed, since the 1990s, the concept of sustainability and the various aspects

comprising its agenda for action have become increasingly widespread in the business community. Such integration of environmental and social aspects with profit-seeking goals, also defined as a triple-bottom-line performance toward organizational sustainability (Elkington, 2004), is becoming increasingly relevant to the managerial practice and decision-making of businesses regarding redefining operations management (Drake & Spinler, 2013) as well as its supply chains (Carter & Rogers, 2008). Reflecting a systems thinking approach and intertemporal tensions, the concept of sustainability is consistent with the notion of long-term planning and impact assessment (Bansal & DesJardine, 2014). In this respect, organizational sustainability refers to the configuration of business strategies and practices that contribute to sustainable development by endorsing social cohesion and environmental conservation in the long term while simultaneously meeting the economic imperatives of profitability and growth (Robèrt et al., 2002; Seuring & Müller, 2008). Sustainability in a business entity

context indicates “a company’s activities, voluntary by definition, demonstrating the inclusion of social and environmental concerns in business operations and in interactions with stakeholders” (Van Marrewijk & Werre, 2003). In this context, and from a macrolevel perspective, small- and medium-sized enterprises (SMEs) have a key role in sustainable development as they dominate the business sector of any country, and therefore their cumulative impact is far from negligible (Cassells & Lewis, 2011; Revell, Stokes, & Chen, 2010). Several empirical studies suggest that sustainability practices and performance is of great importance and should be part of companies’ operational strategies (e.g., Pullman, Maloni, & Carter, 2009).

Such considerations are no longer confined to large corporations and multinational business entities (Madsen & Ulhøi, 2016; Masurel, 2007; Revell et al., 2010; Revell & Blackburn, 2007; Siegel, 2010). Under the scope of an ever increasing globalized economy and through the complex and extensive supply chain networks, they are expanding to SMEs and posing significant managerial and operational risks as well as opportunities (Bos-Brouwers, 2010; Brammer, Hoejmoose, & Marchant, 2012; Hofmann, Theyel, & Wood, 2012; Hörisch, Johnson, & Schaltegger, 2015; Jansson, Nilsson, Modig, & Hed Vall, 2017; Lawrence, Collins, Pavlovich, & Arunachalam, 2006; López-Pérez, Melero, & Javier Sese, 2017).

While securing shareholder value remains the overarching tenet of for-profit organizations, today’s business environment presents additional challenges to SMEs, which usually respond reactively to emerging and pressing stakeholder expectations or demands (Lewis, Cassells, & Roxas, 2015). Indeed, over the past few years business research has established the need for framing and developing effective performance-related measures (e.g., Rao, Singh, la O’Castillo, Intal, & Sajid, 2009; Shepherd & Günter, 2006; Taticchi, Tonelli, & Cagnazzo, 2010) with formal modeling and decision support systems to offer win–win solutions in terms of economic results and sustainability outputs (Bai, Sarkis, Wei, & Koh, 2012). Carter and Rogers (2008) assert that actively engaging in sustainability practices is no longer optional but rather sheer necessity, involving the long-term amelioration of economic results and helping managers formulate a long-term vision for their enterprise.

In this respect, critical questions posed to researchers, practitioners and policy-makers are the following: Are sustainability-related practices and performance having an impact on SME growth? Which specific sustainability aspects contribute to an SME’s economic performance? Which is the most appropriate association between the latter regarding a statistical modeling perspective?

The aforementioned questions, along with some recent relevant studies (e.g., Brammer et al., 2012; Hörisch et al., 2015; Jansson et al., 2017; López-Pérez et al., 2017; Revell et al., 2010), motivated us to assess the potential impact of specific sustainability practices and performances on SME economic growth. Moreover, of particular interest is an assessment of the most suitable model choice strategies for the selection of the appropriate patterns of association between the response and the predictor variables as well as to identify which of the predictor variables are important via the implementation of a covariate selection methodology. To achieve this, novel statistical methodology has been used for model and variable selection with the aim of obtaining valid and robust results, especially when considering the specific nature of the collected data.

The remainder of the paper is structured as follows. The next section presents a brief background on relevant research. In Section 3, the methodological aspects of the current study are presented and then the main results. In Section 4, a discussion of the findings is outlined. Finally, the paper concludes with an outline of research implications and future research perspectives.

## 2 | BACKGROUND

Previous research applications examining associations between various aspects of SME sustainability draw on linear regression models as the basis of a statistical modeling specification. In particular, Ong, Teh, and Ang (2014) examine the impact of environmental improvements on the financial performance of large companies in Malaysia using multiple regression analysis, with the dependent economic variables being the return on total assets and return on equity. In another study, Jayeola (2015) empirically examines, through multiple regression, the relationship between environmental sustainability practice and the financial performance of SMEs, using as a sample 98 SMEs in manufacturing and industry, business services and retail sectors in Sussex, UK. King and Lenox (2001), analyzing data on 652 United States manufacturing firms between 1987 and 1996, examine the effects of environmental performance on the companies’ financial performance using a multiple regression model including both fixed and random effects covariates. As a dependent variable, Tobin’s Q was used, which measures the market valuation of a company relative to the replacement costs of tangible assets (Lindenberg & Ross, 1981). Other studies on the topic include Waddock and Graves (1997) and Hart and Ahuja (1996).

However, in many applications the dependent variable used for expressing the economic performance is discrete, or the data tend to be skewed (e.g., response variables that present the answers in a dichotomous format, on a Likert scale or as percentages and proportions) (e.g., Almeida, Franco, & Kruglianskas, 2014; Ngwakwe, Nyirenda, & Ambe, 2013; Ong et al., 2014). Given that the main assumption of the continuous nature of the dependent variable in ordinary least squares (OLS) regression is then violated, OLS regression may not always be the most suitable option for analyzing such data as it is to likely yield erroneous results. To correct for this, the vast majority of attempts to approximate normality focus on applying the logarithmic transformation to the response variable (e.g., Jayeola, 2015). However, there is no literature examining the potential implications of such types of transformations and their impact on the results of regression analysis, for instance the differentiations that may appear on the covariate selection.

Other attempts (Hessels, Bouman, & Vijfvinkel, 2011; Vijfvinkel, Bouman, & Hessels, 2011) include using binary logistic regression modeling, after recoding the continuous dependent variables reflecting companies’ financial performance into a dichotomous format (0 and 1 values). This approach, however, can be criticized for overlooking important information regarding the variability of the initial dependent variables.

Such methodological weaknesses led us to address the following research questions: Do sustainability practices and performance

impact SME economic results linearly? What is the relationship between sustainability practices and performance variables with SME economic growth? What are the implications of transforming the variable of SME economic growth in terms of covariate significance? Which are the most dominant sustainability practices and performances?

Providing answers to such research questions contributes to the debate over the links between the environmental-social aspects of SME performance and their economic performance. Hoffman and Bazerman (2005, p. 16) point out that “. . .the key to resolving this debate is the recognition that (social and environmental) behaviors are sometimes profit-compatible and sometimes *not*” and go on to stress that when key actors acknowledge this, it can be easier to convince for-profit entities to adopt mutually beneficial sustainability practices and move beyond the mere questioning of whether it pays to be socially and environmentally responsible. Hence, this study attempts to contribute to this issue by comparing and discussing the performance of linear regression for analyzing non-normal data, in comparison to potentially more suitable model specifications. In particular, our assessment employs a methodologically rigorous approach utilizing OLS regression, OLS regression with a transformed dependent variable, Poisson regression and Negative Binomial regression.

### 3 | METHODOLOGY

#### 3.1 | Data description

The sample includes SMEs only of firms with up to 250 employees. SMEs of three countries are studied to examine the influence of geographic locations on the relationship of sustainable supply chain practices and performance with economic growth. SMEs from developed (the UK and France) and emerging economies (i.e., India, a typical example of an emerging economy) are used as samples to gain the perspectives of varied economies. The random sample of SMEs ensures the validity of the results. Specifically, for sample size selection, we have used  $\hat{p} = 0.5$  as an estimate of the population proportion that share a certain characteristic on one of the (categorical) explanatory variables in the survey. A margin of error of  $e = 10\%$  is acceptable and with  $t$  we denote the value from the standard normal distribution reflecting the confidence level ( $t = 1.96$  for a 95% confidence level). Thereafter, by relying on the simple random sampling formula we should select approximately 96 SMEs. Exceeding the suggested sample size, a total number of 119 SMEs in the UK, France and India were sampled, from the manufacturing or processing industry sector (30 SMEs in the UK, 54 in France and 35 in India). Three-country data were gathered to examine the influence of economic status, comparing two developed economies with one emerging.

A questionnaire was distributed to the 119 SMEs' managers/owners including closed-form questions on several sustainability indicators of SME practices and performance, with particular emphasis on the social, environmental and operational perspective of the company. The questionnaires were completed through personal interviews. Data collected are measured on the Likert scale from 1 to 5 and 1 to 10, with managers/owners ranking their company's practices

and performances from very low (1) to very high (5 and/or 10). The variables are subject to limitations in the sense that having sustainable activities is to some extent subjective and can be interpreted differently from firm to firm, however we believe that this limitation is largely alleviated by the careful selection of the SME sample, the proper design and construction of the questionnaire and methodical personal interviews with the managers/owners. Specifically, the questionnaire was formed in line with the themes that emerged from the relevant literature. A pilot survey in each country was undertaken to resolve a few issues related to the interpretation of the questions and language issues. The collected raw data were validated through undertaking case studies in a couple of SMEs in each country that revealed the synergy between responses and reality. Cleaning of the final sample of collected data was also performed with great care.

The dependent variables used for the research attempt to reflect the SMEs' economic performance, measured based on the answers and rating of the managers on the variables of turnover and business growth (1–10 on the Likert scale). Appendix Table A1 analytically presents the variables used as independents for our analysis. The sample characteristics of the variables used are presented in Table 1. The questionnaire will be made available as supplementary material.

In addition to the sustainability practices and performance described above, geographic effects on business turnover and growth are also of interest, due to the diverse selection of our sample. To this end, the dummy indicators of French and Indian SMEs are included as covariates, and compared with the reference category of British SMEs.

## 3.2 | Model

### 3.2.1 | Modeling the response variable

A regression-type analysis approach was used by following the Bayesian paradigm to look for the potential associations between the economic performance of SMEs and their sustainability practice and performance indicators collected from the questionnaire. In our study, the dependent variables correspond to the measurement of turnover and business growth, as it was depicted by the answers of SME managers. The predictors are the 22 individual items measuring operational, environmental and social practices and performance indicators, along with the country indicators of France and India.

To account for the discrete nature of the collected response data, in addition to the standard multiple linear regression model, we fit a variety of alternative specifications as regards the link distribution of the regression equation.

Hence, the results from various regression-type Bayesian models will be fitted and compared assuming different distributions for the response variables. More specifically, continuous-type distributions, such as the Gaussian fitted to the raw data as well as corresponding transformations of the raw data, are assumed. In addition, the responses are modeled using distributions more suitable to count data, such as the Poisson and the negative binomial (NB) distributions. The latter is frequently considered as an alternative to the Poisson distribution in cases of over dispersed data.

We assume that  $y_{ik}$  denotes the  $i$ -th response of the  $k$ -th independent variable ( $i = 1, 2, \dots, 119$ ;  $k = 1, 2, \dots, 24$ ) and that  $\mathbf{X}^T$  denotes the  $(24 \times 119)$  matrix comprising the values of the independent variables. Hence, the regression-type models fitted to our raw data are described by the following equations:

Normal:

$$y_{ik} \sim N(\mu_{ik}, \sigma^2); \quad e_{ik} \sim N(0, \sigma^2) \quad (1)$$

$$\mu_{ik} = \mathbf{X}^t \cdot \boldsymbol{\beta}$$

Poisson:

$$y_{ik} \sim \text{Poisson}(\lambda_{ik})$$

$$\log(\lambda_{ik}) = \mathbf{X}^t \cdot \boldsymbol{\beta} \quad (2)$$

Negative binomial (NB):

$$y_{ik} \sim \text{NB}\left(\mu_{ik} = \frac{r(1-q_{ik})}{q_{ik}}, q_{ik}\right)$$

$$\frac{r(1-q_{ik})}{q_{ik}} = \mathbf{X}^t \cdot \boldsymbol{\beta} \quad (3)$$

where  $\mu_{ik}$  and  $\sigma^2$  are the mean and variance of the dependent variables under a Gaussian distribution,  $\lambda_{ik}$  denotes the parameter of the Poisson distribution, and  $r, q_{ik}$  are the parameters of the NB distribution. Finally,  $\boldsymbol{\beta} = (\beta_1, \beta_2, \dots, \beta_k)^t$  are the regression coefficients of the predictors.

### 3.2.2 | Data transformations of the dependent variables

There are various reasons for applying a transformation to the dependent variable of a regression model. These may include (i) improving model fit in linear regression, for instance by normalizing the dependent variable, or (ii) correcting for the skewness of positive data. Typically, transformations of this type include the logarithmic transformation and the square root transformation.

In the former case, the  $\log(x)$  transformation is used (Box & Cox, 1964). Log transformations are often applied to count data due to the inherent high degree of variation in these types of data. We will also test the frequently used square root transformation  $\sqrt{x}$  and its effect on the results. Unlike the log transform, the square root transformation does not require special treatment of zero responses.

Hence, in addition to the previously described regression models, the following transformed regression models will be applied to the data:

Squared-root-transformed normal:

$$\sqrt{y_{ik}} \sim N(\mu_{ik}, \sigma^2); \quad e_{ik} \sim N(0, \sigma^2) \quad (4)$$

$$\mu_{ik} = \mathbf{X}^t \cdot \boldsymbol{\beta}$$

Log-transformed

$\log(y_{ik})$

Normal:

$$\log(y_{ik}) \sim N(\mu_{ik}, \sigma^2); \quad e_{ik} \sim N(0, \sigma^2) \quad (5)$$

$$\mu_{ik} = \mathbf{X}^t \cdot \boldsymbol{\beta}$$

### 3.2.3 | Bayesian variable selection

The variable selection problem in regression consists of finding the predictors that enter the regression equation of which their coefficients  $\boldsymbol{\beta}$  are non-zero. The variable selection problem arises when there is some unknown set of predictors with regression coefficients so small that it would be preferable to ignore them (George & McCulloch, 1993).

Typically, standard regression models assume independent covariates, and some type (either forwards or backwards) of stepwise elimination method for variable selection is performed. However, these approaches, although relatively cheap computationally, have been recognized as suffering from drawbacks (see Hurvich & Tsai, 1990; Roecker, 1991). In this paper, we illustrate the use of Bayesian covariate selection to adequately address the potential high collinearity issues present in the specific covariates.

Variable selection in Bayesian regression modeling typically involves the introduction of a vector of binary indicators  $\gamma \in \{0, 1\}^p$  that serves as an indicator of the  $p$  possible sets of covariates that should be included in the final model (i.e.,  $\gamma_j = 0$  or  $1$  if coefficient  $\beta_j$  is small or large, respectively) (George & McCulloch, 1993). Then, Markov chain Monte Carlo (MCMC) methodology is used to approximate the posterior distribution of  $\gamma$  given the data.

In this way, if for the  $j$ th covariate  $X_j$ ,  $\gamma_j = 1$  then  $X_j$  is included in the set of predictor variables, whereas if  $\gamma_j = 0$  then  $X_j$  is excluded. Many applications of this problem are high dimensional, namely, there exist a large number of candidate variables for selection.

In our study, driven by the results of previously conducted analysis, we hypothesize that only a few of the utilized variables of practices and performance dimensions will have an effect on the economic performance indicators. Hence, we will resort to Bayesian variable selection as defined previously in terms of assigning a probability to each covariate for inclusion/exclusion from the final best model.

Regarding the specification of a prior distribution for the  $\gamma$  values a Bernoulli distribution for the prior specification of indicators  $\gamma$  is used,

setting 50:50 odds for each explanatory variable to be selected, that is:  $\gamma \sim \text{Bernoulli}(0.5)$ . This is typically called the uniform prior specification. Subsequently, inference concerning the issue of whether to include each one of the covariates in the final model selection is based on the posterior probabilities given the prior model probabilities.

### 3.2.4 | Hyper g-prior specification

As discussed previously, a hyper g-prior approach could be used for assigning prior distributions to model parameters to improve on the variable selection problem. The most common family of prior distributions for variable selection is Zellner's g-prior (Zellner, 1986). In the current paper, the popular extension to the classical Zellner's g-prior, known as the hyper g-prior, is followed (Liang, Paulo, Molina, Clyde, & Berger, 2008; Sabanés Bové & Held, 2011), which assumes the regression coefficients of the candidate covariates follow a Gaussian distribution according to:

$$\beta \sim N\left(0, g e^{\beta_0} (\mathbf{X}^t \mathbf{X})^{-1}\right)$$

and the constant term follows a Gaussian distribution with zero mean and large variance, for example,

$$\beta_0 \sim N\left(0, 10^4\right)$$

Furthermore, the approach assigns a Beta prior to the shrinkage factor  $g/(1+g)$ , such that:

$$\frac{g}{1+g} \sim \text{Beta}\left(1, \frac{\alpha}{2} - 1\right).$$

The authors propose any choice of  $\alpha$  between  $2 < \alpha \leq 4$  for the specification of the latter prior distribution on  $g$ . For our analysis,  $\alpha = 4$  has been chosen.

### 3.2.5 | Prior specification

Upon selecting the most important covariates through the variable selection scheme described in previous sections, the models selected are fitted to derive the parameter estimates. In doing this, we assign suitable prior distributions to the parameters of chosen covariates. As regards the prior distributions of parameters  $\beta_i$  of interest, usually the prior mean is set to zero, and the corresponding variance is set large to express prior ignorance, that is, the dependents are assumed to follow a Gaussian distribution,  $N(\mu_i, \sigma^2)$  where  $\sigma^2$  follows an inverse Gamma distribution, with  $1/\sigma^2 \sim \text{Gamma}(10^{-3}, 10^{-3})$ .

## 3.3 | Inference

We have used McMC techniques to run the models. The posterior distributions have been obtained by using 10,000 iterations as the burn-in period and an additional sample of 10,000 iterations with thinning one out of 10 iterations. We have used the WinBUGS software for model estimation (Lunn, Thomas, Best, & Spiegelhalter, 2000). The model was selected through the use of the posterior mean deviance (see Spiegelhalter, Best, Carlin, & van der Linde, 2002). Models with smaller mean deviance value are better supported by the data.

## 4 | RESULTS

Bayesian variable selection and inference is performed, hypothesizing that only a small number of practices and performance aspects variables will be of importance to the response variables. To perform this, we rely on the already described Bayesian variable selection methodology.

The results of the variable selection approach for the various modeling considerations, (i.e., the Normal, log-transformed Normal, square root transformed Normal, Poisson and NB specifications) are presented below. Table 2 gives model selection criteria for the candidate models, on the response of turnover.

It can be seen that the log-transformed model presents the best fit, according to the posterior mean deviance results, followed by the squared root-transformed data. Among the remaining models, the Poisson specification seems to perform better than the Normal and NB modeling specifications. At this point, it should be noted that comparisons between the models with raw and transformed data are not meaningful, because the transformation of the initial data is expected to reduce the variance of the dependent variable, hence making the posterior mean deviance between the raw data and the transformed data model incomparable.

Table 3 presents the posterior inclusion probabilities  $\gamma$  for the variable selection on the response of turnover, using the uniform prior specification. Ideally, the posterior probabilities of inclusion should be close to 0 or 1, for a covariate being included or excluded in the model, respectively. However, covariates are usually selected using a threshold value on the inclusion probabilities. The standard value for this threshold is 0.5, and hence this approach is followed for the rest of the analysis.

As can be seen from the results in Table 3 that only a few of the candidate independent variables of sustainability practices and performances are included in all models using the threshold value of 0.5. Specifically, the items of standardized business process practices (OPER\_PR\_3), health and safety practices (SOC\_PR\_2), long-term relationship with customers performance (OPER\_PE\_1), waste reduction performance (ENV\_PE\_2) and health and safety performance (SOC\_PE\_2) are the ones selected for inclusion in all five models. The dummy variable for French SMEs is also included, with the exception of the normal model. Finally, the variables of customer relationship management (CRM) effectiveness practices (OPER\_PR\_1) and supplier relationship management (SRM) effectiveness performance (OPER\_PE\_5) are only marginally included in the log-transformed model.

**TABLE 2** Goodness-of-fit statistics for the candidate models (response variable: turnover)

Model	Turnover Mean deviance ( $\bar{D}$ )
Normal	484.3
Log-transformed	-11.05
Square root transformed	158.6
Poisson	462.1
NB	464.3

Table 4 shows the results for the second dependent variable of SME economic performance, that is, the variable of business growth. The goodness-of-fit results are partly similar to the results for turnover. As regards the log- and square root-transformed models, best fit is exhibited by the log-transformed normal model. For the raw data models, however, the best fit is provided by the normal model (posterior mean deviance: 362.4).

The posterior inclusion probabilities for the hyper g-prior approach for the business growth models are shown in Table 5. Here, the most important covariates for inclusion are CRM practices (OPER\_PR\_1), lean practices (OPER\_PR\_4), health and safety practices (SOC\_PR\_2) and the country effect of France. Furthermore, the energy consumption and emissions performance (ENV\_PE\_3) is selected for inclusion except for the Poisson and NB models. Other variables marginally included by some of the models are SRM practices

**TABLE 4** Goodness-of-fit statistics for the candidate models (response variable: business growth)

Model	Business growth Mean deviance ( $\bar{D}$ )
Normal	362.4
Log-transformed	-146.7
Square root-transformed	79.15
Poisson	387.6
NB	390.4

(OPER\_PR\_2), the adoption of standardized environmental system practice (ENV\_PR\_1), the long-term relationship with customer performance (OPER\_PE\_1) and the reduction of energy consumption and emissions performance (ENV\_PE\_3).

Next, we present the posterior medians, along with the corresponding 95% posterior credible intervals, for each selected coefficient in the turnover model (Table 6).

As revealed by the parameter estimates and the corresponding intervals, regarding the sustainability practices of SMEs, we find that standardized business process practices have a strong positive effect on the variable of turnover, according to the perceptions of the SME managers. Also, health and safety practices positively affect the dependent variable. Mixed results are observed however for the question of the importance of sustainability performance. The operational performance of the long-term relationship with customers is positively associated with turnover, whereas specific environmental and social dimensions of performance appear to negatively affect business turnover. Specifically, estimated coefficients of the performance on waste reduction (ENV\_PE\_2) have a negative sign on turnover in all five tested models. The same partly holds for health and safety performance. Finally, the French SMEs tend to have lower turnover levels when compared to the British SMEs, as found in four out of the five models.

The results of the second model are presented in Table 7, using the economic performance variable of business growth as the dependent economic variable.

CRM practices appear to be an important factor for the increase in business growth, a result that holds for all fitted regression models. Also, French SMEs, as was the case with turnover, exhibit lower levels of business growth when compared to British SMEs. Health and safety practices are also an important indicator for business growth, according to SME managers. This result is however marginal for three out of the five fitted models.

The results for the remaining covariates are not strongly conclusive however, as either there is no statistically significant outcome in terms of achieving the threshold of 0.5 for variable selection or covariates selected with a threshold near the borderline of 0.5 are marginally significant according to the parameter estimates results. For instance, although SRM practices (OPER\_PR\_2) are selected for inclusion with inclusion probability threshold values just above 0.5 in the normal and square root-transformed models, the corresponding credible intervals indicate a marginal significance on the dependent variable of business growth. The same holds for operational lean practices (OPER\_PR\_4) and the practice of adopting a standardized environmental system (ENV\_PR\_1).

The operational performance of long-term relationship with customers (OPER\_PER\_1), and the environmental performance of reduction of energy consumption and emissions (ENV\_PER\_3) negatively affect business growth to a marginal degree.

Figures 1 and 2 provide a visual presentation of the models' fit, plotting together the observed and estimated by the models' outcome variables of turnover and business growth. It is noteworthy that when

using the normal and log-transformed normal models, a few negative predictions are obtained, which for the latter model is expected due to the values of ones in the dependent variable.

## 5 | DISCUSSION

Sustainability is today highlighted as the key to long-range business planning to facilitate performance refinements and improvements for the common good. With this in mind, we assert that there is a tangible need to develop a better and clearer understanding of the moderating role sustainability has on SME economic performance.

In this paper, we sought to examine the effects of individual sustainability practices and performance dimensions on the economic performance of SMEs, using a carefully chosen sample of SMEs from three countries. Specifically, we examined which operational, environmental and social practices/performance aspects are the most accurate predictors of SME economic performance. The latter was estimated through business growth and turnover, according to the perceptions of the managers/owners of the selected SME sample, using regression-type methodology. The conceptual framework and proposed assessment methodology developed in this paper attempt to meet calls for more theory-building research on SME sustainability (Ates, Garengo, Cocca, & Bititci, 2013; Jansson et al., 2017) and offer several advantages.

Specifically, to derive valid and robust results, Bayesian regression models were employed based on various specifications of the

distribution of the dependent variables of economic performance measured on a Likert scale, as well as on typical transformations of the latter. More importantly, the results of a typical OLS regression based on assigning a normal distribution on the dependent variable have been compared with more suitable distributions for positive count data, such as the Poisson and the NB. Additionally, for selecting the most important covariates we opted for Bayesian variable selection based on the hyper g-prior specification.

By observing the outcomes, we have seen that only a few of the potential explanatory variables for inclusion were selected, having an inclusion probability that is above 0.5. Thus, despite the relatively large number of covariates (24), all the fitted models choose a very parsimonious specification, with only a few regressors being included in the model with a threshold probability exceeding 50%. Especially for the covariates near the borderline selection threshold of 0.5, the results in most cases were marginally statistically significant, suggesting that potentially a higher cut-off value could be used instead of the 0.5 threshold value for covariate selection.

As regards the model comparisons, although the various modeling specifications generally exhibited similar results for the significance of parameters, there were also many exceptions, especially concerning those covariates at the borderline of selection. Model fit results showed some contradictory results when using the raw data of the dependent variables, because both normal and Poisson distributional specifications provided the best fit, but on different occasions. Generally, OLS regression does not produce significantly

different results from the alternative specifications. However, the NB and Poisson models, at least for the first model, have been shown to yield better performance as regards model fit than the OLS regression model. Superiority of the fit of the normal model in the case of the growth dependent variable may be merely attributed to the fact that the latter variable appears to be slightly less skewed than the dependent variable of turnover ( $\alpha_3 = 0.497$  and  $0.441$  for the variables of turnover and economic growth, respectively). Hence, the asymmetry of the discrete variable should be taken into account when choosing a suitable distribution for the response in regression modeling. The logarithmic transformation, on the other hand, has shown superior performance in comparison with the square root transformation of the data.

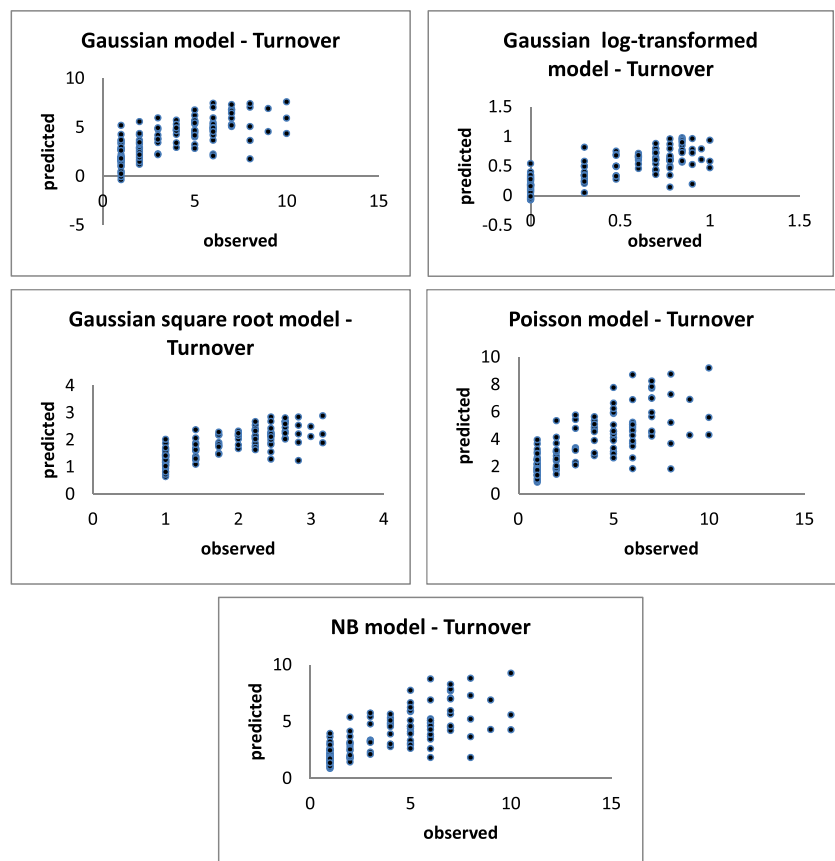

In relation to the association between economic indicators and sustainability practices and performances, turnover was found to be positively associated with standardized business processes and health and safety practices. A positive association with turnover was also verified for the long-term relationship with customers, whereas waste reduction and health and safety performance was found to negatively affect turnover.

The positive statistically significant association between health and safety practices and turnover can be attributed to the fact that usually this type of practice is publicized as part of a company's public relations initiatives, which in turn may result in a positive effect on its economic growth. Furthermore, health and safety performance is more directly connected to the actual results of the actions and spending on

these actions. Actual spending may have a direct negative result on the turnover that may overcome any indirect increase of business turnover due to the health and safety performance actions.

The results of this study are partly in line with previous research that has identified positive relationships between sustainability management practices and SME performance, although the exact items measuring sustainability practices vary from one study to another (e.g., Jayeola, 2015; Ong et al., 2014; Stewart & Gapp, 2014).

Our findings reveal more positive effects of certain practices on turnover whereas the corresponding aspects of performance were found to be negative or nonsignificant. We believe that this result is because practices in many instances lead to more positive impacts than their realizations through performance. Specifically, economic performance is reflected through business growth and turnover, which is directly connected to capital cost, operating cost and cash flow. Companies intending to enhance economic performance will identify most appropriate enablers that will first affect their practices, subsequently sustainable performances and, in the end, their economic performance. If there is no economic benefit to amending sustainability practices, companies will not undertake such a venture. Therefore, practices are expected to always be very positively connected to economic performance. By contrast, each practice is likely to produce a positive impact on the corresponding sustainable performance but it may not associate positively to others. However, the relationship between sustainable performance and economic performance will depend exclusively on the experience and perceptions of the interviewees from the organizations. Therefore, if specific sustainable performance does not contribute to economic performance but

corresponding practices do, we can interpret that the company did achieve the desired objective but still there is potential for further improvement.

The reduced association (positive or negative) between economic performance with the sustainability practices and performance of the SMEs found in the current study is in line with the inconclusive and contradictory results of the previous limited literature investigating this association (e.g., King & Lenox, 2001; Waddock & Graves, 1997; Wagner, Schaltegger, & Wehrmeyer, 2001). It should be noted, however, that our findings contradict previous research that argues in favor of the positive association of sustainability (environmental) performance with economic performance (Yang, Hong, & Modi, 2011). Yang et al. (2011) also report a negative association between the environmental practices and financial performance of companies; their study, however, was not restricted, as was ours, to SMEs.

SME business growth was associated with a reduced number of practices and even fewer performance indicators. Specifically, the analysis conducted on the results of all fitted models verified that CRM practices, lean practices, and health and safety practices are positive predictors of SME business growth. Here, as with the turnover model, the corresponding performances are shown to be less important factors for the business growth of SMEs.

Finally, results showed that French SMEs substantially differ from the British and Indian SMEs, with respect to their economic growth (we cannot confidently verify this difference for turnover because the significance is on the borderline of selection, with zero value being close to the 95% upper credible limit). This result might be an indication of reduced results and performance of the adopted sustainability

practices by the French SMEs, compared to the British and Indian SMEs, at least for the selected sample of our analysis.

These findings provide fruitful insights to SME owners/managers trying to identify and control critical sustainability aspects of business practice for their bottom-line performance. However, the study has limitations which highlight areas for further research. First, the sample size and generated dataset is relatively small; replicating the methodological approach to larger samples (and perhaps from other countries' business sectors) may provide additional insights and reinforce the results of our assessment. Secondly, our proposed proxies of SME sustainability practices and performance can be refined and/or extended to include additional or more rigorous scales, measures and key performance indicators (Chae, 2009). Moreover, qualitative data derived from multiple in-depth case studies with selected SME owners/managers could provide support to the study's findings and allow a more detailed investigation of interrelations between sustainability practices found to contribute to business growth and economic performance. A focus on particular industries and sectors is explicitly encouraged as it may allow specific features of sustainability performance growth to be identified in greater detail with regard to how they affect economic output and growth of SMEs. Lastly, ethnographic inquiry and action research via observation of an SME may allow researchers to gain experiential insights into sustainability implementation/management, and examine the deeper relationships and implications of the suggested impact of sustainability aspects on SME economic performance.

## 6 | CONCLUSIONS

The major contribution of this paper lies in the implementation and comparison of different modeling strategies concerning the distributional specification of the dependent variable, as well as the careful implementation of covariate selection, especially in datasets that include a large number of predictors. It is one of the very few methodological approaches that facilitates a better understanding and identification of key sustainability performance measures with direct influence on business growth.

Various distributions have been used for the most accurate modeling of SME economic performance in relation to sustainability practices and performance. These results have also been compared with those obtained by applying transformations on the dependent variable and investigating how the various transformations affect variable importance. The results indicated that only specific practices and performances focused on environmental, social and operational sustainability seem to benefit an SME's economic performance.

Overall, a few important differences between the various approaches were observed, especially for the covariates on the borderline of selection. However, these differences are not sufficient to suggest that any method performs significantly better than the others. A major finding is that the degree of skewness of the dependent variable should be considered for choosing the link distribution of the regression modeling.

## APPENDIX A

**TABLE A1** Analytical description of the 22 observed items from the SMEs' questionnaire (response: Turnover (ECO\_PER\_1) and business growth (ECO\_PER\_2))

Practice	Performance
<b>Operational:</b>	<b>Operational:</b>
1. Customer relationship management (CRM) practices (OPR_PR_1)	1. Long-term relationship with customers (OPR_PER_1)
2. Supplier relationship management (SRM) practices (OPR_PR_2)	2. CRM effectiveness (OPR_PER_2)
3. Standardised business process (OPR_PR_3)	3. Demand uncertainties (OPR_PER_3)
4. Lean practices (OPR_PR_4)	4. Long term relationship with supplier (OPR_PER_4)
	5. SRM effectiveness (OPR_PER_5)
	6. Supply uncertainty (OPR_PER_6)
	7. Business process effectiveness (OPR_PER_7)
	8. Lean effectiveness (OPR_PER_8)
<b>Environmental:</b>	<b>Environmental:</b>
1. Adopting standardized environmental system (ENV_PR_1)	1. Effectiveness of environmental system (ENV_PER_1)
2. Waste management practices (ENV_PR_2)	2. Waste reduction (ENV_PER_2)
3. Energy consumption and emission control (ENV_PR_3)	3. Reduction of energy consumption and emissions (ENV_PER_3)
<b>Social:</b>	<b>Social:</b>
1. Corporate social responsibility (CSR) practices (SOC_PR_1)	1. CSR performance (SOC_PER_1)
2. Health and safety practices (SOC_PR_2)	2. Health and safety performance (SOC_PER_2)
